Dr. ATTHILL: The Apothecaries' Hall had laid the blame of their grievous failure on the ill will and persistent hostility of the College of Physicians. He assured the Council that that hostility did not exist. He had known the governors of the Apothecaries' Hall for many years, and he and the other Fellows of the College respected and esteemed the great majority of them personally. But they did not think a body which was subordinated to the College of Physicians should be made in all respects their equal, and be made a qualifying body. When the College of Surgeons and the Apothecaries' Hall were first joined there was no difficulty in getting examiners; the examiners of the College of Surgeons and the College of Physicians and the Apothecaries' Hall were nearly identical to within a year or so, when they were all changed, and a Board of Examiners was got which were as lax as they could possibly be. Men rejected not only in Ireland, but in Scotland and by the Apothecaries' Society here—rejected in some cases three or four times—went over to Dublin, and although they had not complied with the curriculum, they were admitted within twenty-four hours as licensed practitioners. That brought the Conjoint Board into disrepute, and respectable men refused to act upon it. It was then, and not till then, that examiners could not be obtained. The Apothecaries' Hall, when constituted, was not left without any supervision; the College of Physicians was appointed their superior, with power to inspect the apothecaries' shops. That power was not a mere form, but was continued till very recently, when it had fallen into abeyance; but it only fell into abeyance when the Pharmaceutical Society of Dublin was established. There were several reasons for it, the chief one being that there were, and are, no apothecaries' shops in Dublin; the whole business had fallen into the hands of chemists. The College of Physicians had no jurisdiction over chemists and could not inspect their shops. The Apothecaries' Hall could make no by-law, statute, or ordinance for or concerning the composition of medicines which should be issued without the approbation of the College of Physicians in writing under the College seal. The only licence they could give was to carry on the art and mystery of an apothecary.

The PRESIDENT pointed out to Dr. Atthill that he was dealing with antiquated matters quite set aside by the Acts of 1858 and 1886. By those Acts the Apothecaries' Hall of Ireland was recognised as a medical authority. It was perfectly useless to go into what they were; it was what they are. If the Apothecaries' Hall of Ireland was on the same footing as the Apothecaries' Society of London, it was a very strong argument in their favour, but it was not so. The Apothecaries' Hall had had a full and a fair trial in conjunction with the College of Surgeons, and had failed because they did not maintain the standard of education, and allowed their examinations to degenerate into a mere form. He was sure the Council would do what was right and proper for the interest of the public first and of the medical profession second.

Sir PHILIP SMYLY said he had applied to the body he represented—the College of Surgeons of Ireland—as to what action he should take upon the question, and had been left an entirely free hand. He did not think that the time had come for the Council to interfere with the Apothecaries' Hall. He had opposed that body as a Conjoint Board, and his feeling was against their being put on a level with their ancient Universities and examining and licensing bodies; but he thought in simple fair play they ought to be given an opportunity of proving what they could do, and he should vote for the motion.

Dr. MACALISTER said that they had been repeatedly told that it was not on the surgical side that the conjoint

examination was defective, and yet they were asked to appoint surgical examiners. The defects associated with the Board were not only in the matter of laxity of the examination, but much deeper than that—in their curriculum. In their programmes and advertisements were matters the only object of which must have been to make the education easier to the country and so more attractive to less prepared candidates. He had a profound distrust of the machinery of the Hall, without any reference to the individuals composing it, to maintain the high standard which was required for admission to the Register. He declined to vote for that patch on the leak in a place where a leak did not exist.

Sir WALTER FOSTER said he considered the application of Apothecaries' Hall, Ireland, as on all fours with that of the Apothecaries' Society of London, which had been granted, except that the former body had been labouring since 1886 under very great difficulties in carrying on its work. It was said that the great difficulty in getting examiners in Medicine had arisen, not from any inherent qualities in itself, but from a disinclination on the part of other Corporations in Dublin to give the Hall that meed of honest and just assistance which it ought to receive. He considered that that position should appeal to the more generous side of their nature, and help the Council to come to the assistance of a body which, to his mind, had not been fairly treated. They had an application made according to precedent, but that application could be amended if necessary. If the Council amended the proposition, and said they would give the Hall examiners in medicine, surgery, and midwifery, the Apothecaries' Hall would gladly accept that in place of the present motion, and in that way the Council would make the examination a good one by having themselves control over the examiners. He should be glad to support any amendment of that kind, if he could not support the original resolution. From his knowledge of the history of the body during the last three years, and the difficulties it had had, he was disposed to support the application.

Dr. BATTY TUBE thought the discussion had been altogether upon too narrow grounds. For thirty-four years the Council had been trying to raise the standard of medical education in Great Britain. It had been done by sensible pressure slowly and gradually applied, and that standard must be protected. If the Council was so lax as to grant the application, and afterwards any body with which he was connected received from it any adverse criticism, he should put that criticism in the waste-paper basket. It would be of no value because it would be stultified by references to the action of the Council with regard to the Irish body. It was an imperial question affecting the medical practitioners of Great Britain. If from their action they lowered themselves in the estimation of the profession and the public, they showed that they were not able to maintain what they had done, and they must fall. The result would be that the public would take the matter into their own hands.

Dr. HENRY WATSON moved:

That the application of the Apothecaries' Hall, Ireland, and the motion of Dr. Moore founded upon it are not in accordance with the provisions of the Medical Act, 1886, Section 5. That the authorities of the Apothecaries' Hall be informed of this, with a view, should they think fit, to make a new application for the appointment of such examiners to assist at the examinations of that body in medicine, surgery, and midwifery as shall secure at the said examinations the maintenance of such standard of proficiency as is required under the provisions of the Act, 1886, from candidates at such qualifying examinations.

Dr. McVAIL seconded the amendment, which was put to the Council and lost. The numbers were: for, 9; against, 12; did not vote, 7; absent, 2.

Sir DYCE DUCKWORTH said he could hardly recall an occasion on which the Council had had a more important statutory duty laid upon it than at the present moment, because they were deliberately called upon to do nothing less than to disfranchise one of the qualifying bodies in the three kingdoms. As chairman of the Examination Committee it had been his duty to go through the report of the inspector of the Council and the examinations of all the qualifying bodies in the three kingdoms. Those reports had been most carefully discussed in the Committee, and had also been brought before the Council and considered with great care. The reports

relating to the Apothecaries' Hall of Ireland had given more trouble than any other body in the United Kingdom. They had been so unsatisfactory and inadequate that the Council had judged it necessary to visit and revisit on four occasions several of the examinations held by that body in conjunction with the Royal College of Surgeons of Ireland. The Examination Committee had reported the examinations as insufficient, and the Council had accepted that opinion and had reported the matter to the Privy Council. Now they were solemnly asked to put the body on its legs again and prop it up. They had first to determine whether they would do so, and if they decided that they would, it remained for them to determine what support should be given. But he hoped that the first part of the question would be answered in so decided a manner that there would be no occasion for them to consider the second. If the body was propped up it would stultify all the work of the Examination Committee and the opinion of the Council as expressed again and again during the last three years, and would render nugatory and impossible all further useful action on the part of the Council, which would become the laughing-stock of the whole profession. The Apothecaries' Hall had had many chances, and had not availed itself of them because it was not possible for it to do so. It was not a sentimental question. They had their duty to the public to perform. He recognised no higher body than the Council; if there was, there ought not to be; and if they were not fit to say what was best for the interests of the public and of the whole profession they were not fit to be there. Could they honestly say that they ought to keep open such a back door into the ranks of the profession? Most emphatically, No! He considered that the body was practically effete; it had had its day and ought to die gracefully.

Dr. GLOVER said that even in the serene atmosphere of London there had been a disposition on the part of certain Colleges to put down the Apothecaries. He admitted that the Apothecaries' Hall, Ireland, had given much greater reason to its opponents and to the Royal Colleges to be dissatisfied with its continued existence than the Apothecaries Society of London; but he thought they all now felt that it would have been a great mistake on the part of the Council to have obliterated the Apothecaries Society of London. They were asked to do a similar thing now with regard to the Apothecaries' Hall, Ireland; but, although there was a good deal of reason to be alleged for their taking that course, he did not think the reason was sufficiently strong to justify them in taking that exceedingly strong measure. He admitted that the examinations of the body had been exceedingly unsatisfactory, but they had not been so absolutely unsatisfactory as the Chairman of the Examination Committee would have them believe.

Sir DYCE DUCKWORTH said that they had not had any examination at all comparable in inferiority and in weakness with that of the Apothecaries' Hall.

Dr. GLOVER said that the fact remained that the supreme reason for reporting that body to the Privy Council was in the facts of one case. There the words: "For these reasons, although we have no fault to find with the actual examination itself, the fact that a candidate passed who exhibited gross ignorance of medicine compels us to report that in medicine the examination is insufficient." Of the examinations in the last report it was said: "The examination itself was in every respect a most satisfactory one, and the marks awarded were strictly equitable."

Sir DYCE DUCKWORTH submitted that they must not have little extracts without the context; that was not fair.

Dr. GLOVER said that he did not feel sufficiently justified in being a party to the obliteration of that body upon that basis. Sir John Banks had told them that in the economy of Ireland the body was wanted. He considered that the examinations were unsatisfactory; he had no controversy with Sir Dyce Duckworth upon that, and if they were not amended and improved the body must cease to be. But his opinion was that they should give the body a chance under better conditions. It was not denied that the Apothecaries' Hall had great difficulties to contend with. He would propose the following amendment:

That the petition of the Apothecaries' Hall, Ireland, be granted on the condition that the Council appoint in addition to two examiners in

surgery, one in medicine, and also one in midwifery; to act as assistant examiners under Section 5 of the Medical Act of 1858.

He hoped that that amendment would bring the Council to a unanimous vote, because it would have the admirable effect of putting the body on its metel, and the examiners, being their nominees, appointed by the Council, would virtually be inspectors. "It shall be the duty of the said examiners to secure at the said examination the maintenance of such a standard of perfection in medical surgery and midwifery as is required." If that were not secured it would be their duty, and he had no doubt it would be their action, to report to the Council as to the unsatisfactoriness of the examinations.

Dr. BAUX seconded the amendment.

Dr. THOMAS THORNTON asked if the amendment were really in order. They were asked by written document to appoint two examiners in surgery, and the amendment said, "We will do so, but we will do something more; we are going to appoint examiners in midwifery and in medicine also." They had never been asked to do anything of the sort, and the Apothecaries' Hall might not only resent it but disclaim it.

Dr. CHARLES MOORE said he had a special letter from the Governor and Council of the Apothecaries' Hall, Ireland, authorising him to use his discretion in anything and in everything that came before the Council, and he therefore had power to withdraw the proposition which he had made to the Council.

The President said that Mr. Muir Mackenzie had informed him that the amendment was quite in order.

Dr. LEXON thought it would be a very dangerous thing for them to pass the amendment, which was quite sprung upon them, and it ought not to be voted upon in a hurry.

Dr. MACALISTER said that the Apothecaries' Hall would be quite in a position to accept the appointment of the two examiners and decline the condition.

Dr. McVAIL suggested to Dr. Moore to withdraw his resolution completely and allow the Apothecaries' Hall to make an application under the Act. It was perfectly certain that the motion would have a disastrous result, and many would vote against it in its present form who might be disposed to assist the Hall if the resolution asking for examiners in all three subjects were before the Council. He did not think the Council would be wise in accepting the mere statement of a plenary power on the part of Dr. Moore; there ought to be a definite written application for examiners under the terms of the Act. The Hall would lose little by the postponement of the matter until next May.

Mr. BRUCE-CLARKE said that if they were to pass the amendment where were they to find the examiners, seeing that the Hall desired to hold an examination next January? They could not find them and settle their remuneration during the present session of the Council, and therefore it might just as well stand over until next May, for any good which the resolution would do. If Dr. Moore was of opinion that the proposal to appoint examiners in all branches would be acceptable to the body which he represented, Dr. Moore would be able in May to come prepared with the names of gentlemen who were willing to act as examiners, and for some remuneration which the Council would authorise them to receive. At present the resolution would be little more than an expression of an inclination of good will on the part of the Council, and would not carry the matter forward one single step. It would be very judicious if both the amendment and the resolution were withdrawn and the whole matter allowed to stand over till next May.

Dr. HENRY WATSON thought they would be occupying a singularly undignified position if they passed the amendment, because they would be passing away from the application which had been made to them, and would give the Hall something for which they had not asked.

Mr. BRYANT said he hoped they would stick to the point, and keep before them the request made by the Hall. The Council was asked to help them. Were they ready to do so? The mode of helping them might come afterwards, but it was for the Council to consider whether they were disposed to give that rickety body a prop up. They were literally asked now to make that rickety body one which would be officered by nominees of the Council, and which would be looked upon in Ireland and all over the world as a remarkably

good Board to go to because it had the stamp of the Council, and because the Council had elected all the examiners. Up till 1858 the Apothecaries' Hall was not a medical body; it had powers for preparing a conjoint examination, but it never held the position of the Apothecaries' Society of London. Up to 1858 it simply had some examiners in materia medica and in some elementary things connected with dispensing medicine, and nothing more. It was proved to have been a failure; it was a failure when they nominated two surgical examiners; it had been a failure since it had been in combination with the College of Surgeons, and the College of Surgeons had quietly left them in the lurch. He must fix the responsibility as much upon the Royal College as upon the Apothecaries' Hall. It had a Committee of Management comprised of the representatives of the Royal College of Surgeons and the Apothecaries' Hall, and the Committee of Management was to blame.

Mr. PHILIP EARLY said that the College of Surgeons had maintained that they had a good surgical examination, and he called the attention of the Council to the fact that the Committee of Management had no voice whatever in the election of medical examiners. He had been asked why the College of Surgeons had separated from the Hall. It was because they had no control over the medical examination, and also because they had been recommended by the Council to separate. Those were the reasons, and not because the Apothecaries were conformed.

The amendment was then put to the Council and negatively.

Sir WILLIAM TURNER said that as Mr. Muir Mackenzie was present he should like to ask him a question upon Section 5 of the Act: "It shall be lawful for the General Medical Council from time to time, if they think fit on the application of such corporation," etc. What latitude was expressed in the words, "If they think fit"?

Mr. MUIR MACKENZIE said, as a matter of law, absolute latitude. That was held in the Bishop of Oxford's case. Perhaps the Council would forgive him for saying one thing which was perhaps a matter of law. It was that Section 4 prescribed the procedure by which the statutory privilege of granting a diploma was to be taken away—namely, by a representation to Privy Council; and if the Privy Council had not taken that statutory privilege away, it seemed to him that the body might remain as a statutory body entitled to grant a diploma; and although the power in Section 5 to refuse assistant examiners was no doubt absolute, he could not think that the Act of Parliament intended that the General Medical Council should, by refusing examiners, be able to deprive a college of its statutory position. The Council, in exercising its jurisdiction to refuse examiners, must have regard to the fact that the body possessed at this moment the statutory right to grant diplomas and to have assistant examiners appointed unless the Council saw some reason which made it obligatory upon them to refuse. Undoubtedly it could refuse. In answer to Sir Walter Foster, he said that Section 5 of the Act was passed with a view rather of allowing a body to go on than to destroy one.

The President said that after what Mr. Muir Mackenzie had stated, he thought that they should go under the 4th Section if they wished to be an extinguisher on the Apothecaries' Hall. To refuse the examiners was an indirect way of attempting the same thing, in which they might fail. Let them have the courage of their convictions and go upon the 4th Clause, but do not let them go in the indirect way of refusing to appoint examiners in surgery.

The motion

That the petition of the Apothecaries' Hall be granted was then put to the Council and lost, the voting being as follows—against, 15; for, 8; did not vote, 4; absent, 3.

Moved by Dr. MACALISTER, seconded by Sir WALTER FOSTER, and agreed to:

That the Executive Committee be instructed to prepare for the consideration of the Council a suitable form of standing order for the procedure to be followed in cases in which, under the last paragraph of Standing Orders XIV. 16, a decision has been postponed.

TRAINING OF STUDENTS IN MIDWIFERY.

Dr. LEXON moved and Mr. WHEELHOUSE seconded:

That the Education Committee be requested to consider whether the

recommendation of the Council of May 20th, 1892, and reaffirmed May 20th, 1895, that, with regard to the above cases of university, under the supervision of a registered practitioner, required of candidates for medical qualifications, is carried out by the regulations of the different licensing authorities, and to report at the May session on this point, and on any modification of the recommendation which they may think to be desirable.

This was agreed to.

EXAMINATIONS IN SANITARY SCIENCE.

Moved by Dr. THOMAS THORNTON, seconded by Mr. TALKER, and agreed to:

That the report of the Public Health Committee on the Inspection of Examinations in Sanitary Science be received and entered on the Minutes, as also the reports of the Inspector of Public Health Examinations on the bodies inspected, and the answers of the bodies thereto.

DIPLOMAS IN DENTISTRY.

A letter was read from the British Dental Association, stating that the Faculty of Physicians and Surgeons, Glasgow, accepted the dental curriculum of Michigan, a curriculum no longer recognised as satisfactory by the General Medical Council in lieu of their own, and had admitted a gentleman holding the D.D.S. diploma of Michigan University, U.S.A., to examination. The Secretary submitted that the action of the Glasgow Faculty was *ultra vires*, and begged the Council to take steps to prevent a recurrence of such action.

It was moved by Dr. CAMERON, seconded by Dr. McVAIL, and agreed to:

That the Committee be referred to the Dental Education and Registration Committee.

The Council then adjourned.

Saturday, November 30th.

Sir RICHARD CLAIN, Bart., President, in the Chair.

THE APPLICATION OF THE APOTHECARIES' HALL, IRELAND.

Sir WILLIAM TURNER said a question had been sent to the Privy Council as to whether there should not be a communication made by the Council to the Lord President of the Privy Council, intimating what had taken place with regard to the petition of the Apothecaries' Hall, Ireland.

Sir WILLIAM TURNER said the only object was the Apothecaries' Hall, Ireland, might not make any application to the Privy Council. The better way would be to authorise the Executive Committee to reply to such application if it were made.

Sir WILLIAM TURNER proposed that a motion would be drawn up and placed on the programme for the next sitting.

TRAINING OF STUDENTS IN MIDWIFERY.

Sir WALTER FOSTER presented the following petition from the Council of the British Medical Association:

TO THE GENERAL MEDICAL COUNCIL.

THE PETITION OF THE COUNCIL OF THE BRITISH MEDICAL ASSOCIATION.

RESPECTFULLY SHewETH

That the members of the British Medical Association view with deep concern and regret the recommendation of the General Medical Council to the Licensing Bodies that they should admit students to their Final Examination who present a certificate stating that they have "conducted personally" only three, and "been present at" only nine confinements, and also that the General Medical Council has refused in November, 1895, to alter this recommendation. We, the Council of the British Medical Association, therefore respectfully petition the General Medical Council to recommend that no student be admitted to his Final Medical Examination, until he presents a certificate showing that he has personally conducted at least thirty confinements under the direct supervision of a registered medical practitioner.

J. WARD COCHRAN,

President of the Council of the

British Medical Association.

FRANK FOSTER,

General Secretary.

On the motion of Dr. GIBSON, seconded by Dr. MACALISTER, the petition was received and entered in the Minutes, and referred to the Education Committee for consideration and report.

EXAMINATIONS IN SANITARY SCIENCE.

The Council then went into committee to consider the report of the Public Health Committee on the Inspection of

the examinations in sanitary science, and the recommendations contained in it.

Dr. THOMAS THORNTON stated that the Public Health Committee, instead of drawing up a report on each individual examination held by the different bodies, had dealt with the examination as a whole.

Dr. PHILLIPS called attention to some discrepancies in the report of the Inspector on the examination for the degree of Bachelor in Hygiene and the Diploma in Public Health of the University of Durham. He also expressed his surprise that the Committee in preparing their report had omitted a commendatory sentence, in which the Inspector had described the examination as being "conducted with commendable care and precision." He stated that the recommendations of the Inspector, as contained in the report, had been strictly attended to by the University.

Dr. THOMAS THORNTON thought that Durham had nothing to complain of, seeing that the Durham University was singled out by the Committee as one of the bodies that had reached the necessary standard.

Some remarks having been offered by the representatives of the University of London, the Victoria University, and the University of Aberdeen on the reports of the Inspector at their examinations for the Public Health diplomas, the Council resumed, and it was moved by Dr. THOMAS THORNTON:

That the Council approve of the report of the Public Health Committee and of the conclusions and recommendations therein contained. That the report be transmitted to the medical authorities who conduct examinations in diplomas in Public Health.

Sir WILLIAM TURNER seconded the motion, which was agreed to.

In the report the Committee stated that there were fifteen bodies in the United Kingdom who conferred registration or registered diplomas in Sanitary Science, Public Health, or Hygiene Medicine. Eleven of these bodies had been visited by Dr. G. F. Bailey, the Inspector appointed by the Council, who reported that a number of the examinations were generally reached the necessary standard. The examination of the English Joint Board was stated to have been "excellent and painstaking," that of the University of Cambridge as "excellent and conducted with care and efficiency," of the University of London it was stated that only those candidates who possessed a high standard of proficiency received the degree; and at the University of Edinburgh it was found that there was evidence of "high proficiency, extensive and general." The examination of the Durham University was "on the whole satisfactory." The Committee expressed their opinion that the standards should be maintained at a distinctly high standard, but that the standard should be progressive, taking cognisance of the advance made from time to time in the knowledge which it was essential that a competent and skilled medical officer of health should possess. Those who sought the diplomas in question were not mere students, they were a body of qualified men, who, if successful, would be before the public and the medical profession to the possession of special and expert knowledge in one important branch of medicine, and would require a satisfactory mastery of nearly all the best parts of medical science and of health in the country. After dealing at length with the various matters the Committee arrive at the following conclusions:

"1. We are of opinion that it is necessary to call the attention of some of the licensing bodies to the instruction of the Council (Minutes, vol. xix, p. 145, Session II) in the effect that every candidate who takes a diploma or certificate is considered should give evidence of a sufficiently high proficiency, scientific and practical, in each and all the branches of study which concern public health, and we are of opinion that this instruction should consist of no exceptions, whether on account of the seniority of the candidate or by way of lowering standards is not subject to compromise for failure in another." 2. We are of opinion that it is a matter of primary importance that each candidate should, in addition to giving indication of competency in the written and practical examination, display similar competency in the oral examination. The oral examination is especially called for in such matters as general practical epidemiology and the duties of a medical officer of health. 3. Whilst we are not prepared to advocate a uniform standard for the general examinations, we are of opinion that they should all be regarded as of the character of an honours examination. 4. We are of opinion that no body conferring a registrable diploma or certificate in Public Health should adopt different standards for different classes of candidates. 5. We are of opinion that where the examination is conducted in two parts no candidate should be allowed to present himself in Part II until he has passed in Part I. And we are further of opinion that failure in any one subject in either part ought to entail re-examination in the whole of that part. 6. We are of opinion that practical examinations should form a distinct part of every examination for a diploma or certificate in public health. 7. We are of opinion that practical examinations in the medical work of a medical officer of health, including a knowledge of sanitary inspection, should form part of every examination for a diploma or certificate in public health. 8. Whilst we attach great importance to the possession by every successful candidate of diploma or certificate competency in relation to the clinical aspects of the subjects in question, we are not prepared to say that practical examinations in this matter should in every case be necessarily taken part of the examination. 9. We are of opinion that a practical knowledge as to the various causes of infectious diseases, including food in the form of vegetables, should be regarded as properly entering within the scope of an examination which aims at preparing competent medical officers of health. 10. In conclusion, your Committee desire to

express their regret that so many of the licensing bodies should have thought fit to institute examinations, and to grant diplomas and certificates, in public health. The multiplication of such examinations, quite irrespective of the number of candidates, is, in our opinion, not conducive to the maintenance of the standard of efficiency which should be aimed at."

It was moved by Dr. THORNE THORNE, seconded by Mr. TRALE, and agreed to:

That the Rule 1 (3) adopted by the Council on December 1st, 1893, for Diplomas in State Medicine be amended, and that the rule be as follows: Every candidate shall have produced evidence that, during a period of six months after obtaining a registrable qualification, he has either practically studied the duties of outdoor sanitary work, under the medical officer of health of a county or of an urban district having at the date of the last census a population of not less than 50,000, or of a combination of two or more sanitary districts having collectively at the date of the last census a population of not less than 35,000, or else has himself held an appointment as medical officer of health under conditions not requiring the possession of a special sanitary diploma. The certificate of an assistant officer of health of a county or a large urban district may be accepted, provided the medical officer of health of the county or district consents to the assistant officer giving such instruction.

REPORT OF EXAMINATION COMMITTEE.

Sir DYCE DUCKWORTH moved:

That the resolutions passed by the Council in committee on the recommendations of the Examination Committee be adopted by the Council in the following form:—(i) That fixed intervals of time between the several examinations should be maintained, and that at least two academic years should intervene between the date of passing the last examination in anatomy and physiology and that of admission to the Final Examination in medicine, surgery, and midwifery. (ii) That the extreme subdivision of any subject of examinations, and particularly of the Final, as now permitted by some Boards, should not be sanctioned. (iii) That in all the written examinations of the different bodies the questions in each subject shall be submitted to the whole of the examiners in that subject before they can be set at any examination. (iv) That candidates in all their examination work should be carefully supervised. (v) That an average of at least half an hour should be allowed for a candidate to answer each question in the papers on medicine, surgery, and midwifery. (vi) That no candidate should be orally examined in any subject, or part of a subject, except in the presence of two examiners. (vii) That the Clinical Examinations in medicine in surgery should be conducted under the personal surveillance of two examiners. (viii) That the Final Examination should include the examination of secretions, the testing of urine, clinical microscopy, and prescription writing, and that there should always be an oral examination in both medicine and surgery, which should include the recognition of pathological specimens. (ix) That at every Final Examination there should be a practical examination in pathology, macroscopic and microscopic, unless this has been included in the examination immediately preceding the Final Examination. (x) That the examination in midwifery and forensic medicine should be made as practical as possible. (xi) That whatever may be the system of marking, the percentage for a pass (50 per cent. in each division of a subject) should be uniform in all the Boards, and in accordance with previous recommendations of the Council. (xii) That the marks obtainable on the written examination ought not to have greater weight than those given at the oral or clinical examinations. (xiii) That marks given in any part of an examination should be given on the merits of that part alone, and not be subject to future revision, unless for the correction of a manifest error. (xiv) That the former recommendation of the Council that knowledge of one subject should not be allowed to compensate for ignorance in others should be more carefully regarded by some of the examining bodies. (xv) That as the art of examining is only to be acquired by practice, it is desirable that an examiner should be re-elected, where practicable, for at least five consecutive years, particularly for the Final Examinations. (xvi) That the clinical examinations in medicine and surgery should be held in hospitals wherever that may be possible.

Dr. BATTY TUXE pointed out that Resolution II as it stood practically repealed the existing standing recommendation of the Council and involved a very important principle. The Council had held the opinion all through that it was undesirable to break up the subjects for examination, whereas this resolution spoke of "extreme subdivision."

Mr. BRYANT said it was a change of principle, but not a change of practice, for it had been the practice in most examining bodies to allow men to come up for medicine, surgery, and midwifery separately. Although he agreed that in the case of very good men it was possible to pass these three important subjects at one examination, yet taking the

body of men he held that such a requirement was impossible, and even if they were to pass such a rule he did not think they would induce examining bodies to compel a man who had done a thoroughly good examination in either subject to reappear at the Board and be re-examined on those subjects. The theory might be good, but practically he thought it would be inadvisable to compel men to do it. Under the circumstances he did not see how the Council could go further than the resolution they were now asked to pass.

Dr. BATTY TUXE said he was not advocating any principle but was only pointing out that this resolution changed the principle which had ruled in the Council for many years.

Dr. McVAIL hoped the Council would not sanction the idea that a man might pass into the profession who after a five-year curriculum could not pass an examination in one of the subjects. He was surprised to hear the statement by the representative of the College of Surgeons of England that the candidates whom they dealt with could not at the end of the five-year curriculum pass an examination in any of the three subjects; that they came up to the College and passed in surgery, and went away and forgot that. The suggestion was that a man might come up to the College of Surgeons of England and pass in surgery alone, and might come back at some future time and be examined in medicine alone, and then come back again and having passed in midwifery alone could then enter the profession, the double Colleges believing that if at the last examination they had examined him again in medicine and surgery he would have failed. He held most emphatically that the Final Examination to admit to the Register should be in medicine and surgery and midwifery, and that unless a man knew his subject sufficiently to pass at the time of Final Examination he should not be passed. This resolution was no ordinary one, but was to go out as the outcome of four or five years of inspection of the Final Examinations. This was the first inspection of Final Examinations that the Council had undertaken since the new Act of 1886 was passed, and it was to be supposed that in adopting those recommendations they would get finality for half a generation. Were the Scotch Triple Board and the University of Glasgow to be at liberty to cut up the Final Examination, and to allow students to take the three subjects separately? He protested against the resolution telling the profession and the public, as it did, that a man was not able to pass in medicine, surgery, and midwifery at the same time.

Mr. TRALE said Dr. McVail's remarks were all very well, but he had failed to distinguish between passing an examination and having knowledge. He hoped it would not be laid down absolutely in this country that it was absolutely necessary for a man to take up the three great groups together, but that he could not take them all together did not mean that he had forgotten everything that was past.

Mr. BRUDENELL CARTER asked Dr. McVail what had been the practice of his body with regard to the subdivision of examinations since the Council's recommendation was issued, whether they had insisted upon combining all the subjects in one examination.

Dr. McVAIL said his body had been unduly dragged by the double Board in England to have the subjects examined into separately; but it had been unwillingly done, certainly so far as the Glasgow Faculty was concerned.

Dr. CAMERON said as an examiner and a member of the Council of the Faculty he had resisted as far as he could this subdivision of the Final Examination, but he had always been met with the objection Dr. McVail had just stated, that they could not do otherwise than to allow candidates to come up for one department at a time as long as that method was followed by the Conjoint Board in London. He would say as an examiner in surgery for a long period of years that he never examined a student who came up in surgery alone and found him a thoroughly good man. Whatever it might be with the Conjoint Board in London it was the weak men who came up and passed the examination in compartments, and they appeared to do that on the same principle as shipbuilders built ships in compartments, because they found it made the voyage much more easy. It was the strong desire of the Faculty of Physicians and Surgeons in Glasgow, and of the two Royal Colleges in Edinburgh that that practice should be discontinued.

Dr. McVAIL moved as an amendment that:

The Final Examination should include the subjects of medicine, surgery, and midwifery, and a failure in more than one of these subjects should involve the re-examination in all of them.

Dr. CAMERON seconded.

Dr. GLOVER hoped the amendment would not be carried. They all knew there were giants amongst candidates who did everything well, but there were men equally entitled to respect, and who would make equally good practitioners, who could not pass all three at once. Probably the man who passed three good examinations would come out a better practitioner than the man who passed all at once. He hoped the Council would not listen to Dr. McVail in this matter.

Sir DYCE DUCKWORTH said the Council had recognised the present system by a resolution passed in May, 1893, which suggested that a percentage of not less than 60 marks on each of any two subjects, supposing that the pass requirement was 50 percent., should exempt from re-examination.

Sir Wm. TURNER suggested that the Council should reaffirm the recommendation of the Council referred to by Sir Dyce Duckworth.

Dr. McVAIL said he would withdraw his amendment if that was done.

Sir DYCE DUCKWORTH said the "extreme subdivision" was intended to refer to the division of subjects, not of groups. For instance, a man might pass in his surgical paper and fail in his clinical, and it had been the practice in some instances to let him come up afterwards for his clinical alone. That was the "extreme subdivision" objected to.

Sir WALTER FOSTER: I condemn that as much as you do.

Mr. BRYANT: That is an example of what we mean; we mean minute subdivision of subjects.

Mr. BRUDENELL CARTER moved:

That the recommendation (ii) he adopted in the following amended form:—(ii) That the subdivision of any one subject of examination, and particularly in the Final, now permitted by some Boards, should not be sanctioned.

This was seconded by Dr. PHILIPSON, and agreed to.

It was then moved by Mr. BRUDENELL CARTER, seconded by Dr. McVAIL, and agreed to:

That the following resolution, passed by the Council on June 8th, 1890, and reaffirmed on May 29th, 1893, be now reaffirmed and adopted as recommendation (iii):—Seeing that the practice of different authorities varies on the question whether a student who fails to satisfy the examiners in each of the several subjects of medicine, surgery, and midwifery should be referred on all of them, or only on those in which he fails, the Council recommends that some general principle should be adopted with reference to this question; and suggests that a percentage of not less than 60 marks on each of the two subjects—supposing that the pass requirement be 50 per cent.—should exempt from re-examination in those two subjects.

It was moved by Dr. McVAIL, and seconded by Dr. GAIRDNER:

That the following recommendation be adopted in place of the present Recommendation xi (a): That when a candidate has, in clinical medicine or in clinical surgery, had a mark awarded that is below the pass mark, the mark shall not be raised because of any excess of marks in the oral or written parts of the examination.

The amendment was lost.

The Council then adjourned.

Monday, December 1st.

Sir RICHARD QUAIN, Bart., President, in the Chair.

REPORT OF EXAMINATION COMMITTEE.

The first business at the final meeting of the session on Monday was the adjourned consideration of the recommendations of the Examination Committee.

Sir DYCE DUCKWORTH moved that the following additional recommendation be adopted by the Council:

That in whatever subject, or part of a subject, a candidate may be rejected, satisfactory evidence shall be produced from his teachers that he has carried on his study during the interval of his remission; such a candidate shall not otherwise be eligible for readmission to examination.

He pointed out that whilst many Examining Boards carried out the recommendation, yet there were some who permitted the student to do whatever he liked during the interval of remission. It was a very proper thing that the student should be required to continue his study.

Mr. BRYANT seconded the resolution. He said that no doubt many Examining Boards would welcome the recommendation.

Dr. MACALISTER pointed out that many of the candidates were already qualified and in practice, and therefore could not produce evidence from their teachers.

Sir DYCE DUCKWORTH said he was quite willing that the words "from his teachers" should be omitted, and the resolution was agreed to with that amendment.

Dr. MACALISTER moved the following resolution:

That the resolutions on professional examinations, with the amendments now adopted by the Council, be remitted to the Examination Committee, with instructions to reconsider them in relation to the existing recommendations on the subject, and to draw up in a consolidated form a series of definitive recommendations suitable for transmission to the licensing bodies.

He said that many of the existing recommendations were of extreme value, and it would not do to omit them from the new recommendations. Then, again, many of the recommendations were somewhat ambiguous, and it was necessary before the rules were finally issued by the Council that they should go out in a complete form.

Dr. BATTY TUBE seconded the resolution.

Sir WALTER FOSTER moved the addition of the following words to Dr. Macalister's motion:

And that reference be made to the reports of the inspectors on which each recommendation is based.

He said that many of the examining Boards already observed the recommendations, and it would therefore be a work of supererogation to the Council to send them the recommendations unless they contained a reference to the inspector's report on which each recommendation was based. In that way when the rules were sent out those bodies with whom no fault was found would see that there were other bodies who had not observed the rules, and those bodies who did not observe the rules would have their attention specially called to their own defects.

Dr. BRUCE seconded the amendment of Sir Walter Foster. He said that the Council could not be too precise in fixing on the particular bodies that had not carried out the recommendations.

Dr. MACALISTER said he would accept Sir Walter Foster's suggestion; and the resolution was carried with that addition.

APPLICATION FOR REGISTRATION.

The REGISTRAR read a report from the Branch Council for Scotland stating that they had considered the applications for the names and diplomas of Mr. R. B. Taylor, Lic. of Faculty of Physicians and Surgeons of Glasgow, November 8th, 1894, and Lic. of the Royal College of Physicians of Edin., April 5th, 1895; and of Mr. Arthur Worsley Powell, Lic. of the Faculty of Physicians and Surgeons, Glasgow, 1890, to be registered in the *Medical Register*, as well as the documentary evidence in support of the applications, and had found them to be in conformity with the Council's directions. The Council recommended, therefore, that the General Medical Council should direct the Branch Registrar for Scotland to register the names and diplomas accordingly.

Dr. HERON WATSON moved:

That the General Medical Council should give directions to the Branch Registrar for Scotland to register the names of Mr. Taylor and Mr. Powell.

Dr. PRITCHARD seconded the motion, which was agreed to.

PROSECUTIONS TO BE CONDUCTED BY THE COUNCIL, UNDER PENAL CLAUSES.

The Council considered in camera a communication from the Royal College of Physicians to the President. On the readmission of strangers, the President stated that a communication had been made to the Council regarding the case of a person who had no qualification whatever in this country, calling himself an "M.D." and practicing medicine and sending out indecent pamphlets, and that the following resolution had been passed:

That the Council instruct its Penal Committee to inquire into the cases of persons offending under Section 59 of the Medical Act of 1886, and, when the Committee see fit, to instruct the legal advisers to proceed against such persons.

THE APOTHECARIES' HALL, IRELAND.

SIR WILLIAM TURNER moved the following resolution:

That if the Privy Council should notify to the General Medical Council their opinion, and issue any directions on the points submitted to the General Council regarding the examinations of the Conjoint Board of the Royal College of Surgeons and Apothecaries' Hall, Ireland; also on the decision of the General Council not to grant the petition of the Apothecaries' Hall, that the Council should appoint Assistant Examiners under the Medical Act (1886); the General Council empowers the Executive Committee to explain to the Privy Council the grounds on which the General Medical Council have arrived at their conclusion, and to take any further steps that may be necessary.

He said that the resolution had been framed in accordance with the views of the Business Committee and the President. It was also in accordance with Section 19 of the Medical Act of 1886, which gave power to the Privy Council under certain circumstances to do any Act authorised to be done by the General Medical Council. There were two modes which the Privy Council might adopt. They might notify their opinion to the General Medical Council; that was, they could notify their opinion of what the Council had just done, and might give directions concerning it, and if the Council failed to comply, the Privy Council itself might give effect to such directions. It was felt by the Business Committee that in case the Privy Council expressed any opinion on the point under discussion, or gave directions relating to them, it would be as well, if the communication came out of session, that the Council should have some means of receiving it, and, if necessary, making a report upon it.

Mr. WHEELHOUSE seconded the motion.

Dr. MACALISTER: Shall we notify the Privy Council?

Sir Wm. TURNER said it was thought that the Apothecaries' Hall would notify the Privy Council. It was for the body that was refused to make a representation to that body to issue directions to the Medical Council.

Dr. MACALISTER said he should be of that opinion but for the fact that it was not an isolated thing. He thought it would be more respectful to the Privy Council that the General Medical Council should give them all the facts without any remarks.

Sir WILLIAM TURNER said that the Privy Council had not, as in the other case, asked the General Medical Council for any opinion on the appointment of assistant examiners to the Apothecaries' Hall. If the Apothecaries' Hall was not satisfied with the decision of the General Medical Council, it was its business to raise the question with the Privy Council. On the whole he thought that the General Medical Council ought not to take the initiative.

Dr. CHARLES MOORE said the Apothecaries' Hall would take whatever legal steps were necessary to maintain its status. He thought that due notice should be given to any bodies interested in order that their representatives and legal advisers might be enabled to attend at all the conferences between the General Medical Council and the Privy Council.

The President thought that Sir William Turner's motion should be adopted by the Council.

Dr. BRUCE wished to know whether the Council was to be involved in a legal plea.

Sir WILLIAM TURNER said that the future steps to be taken would depend entirely on the nature of the communication received from the Privy Council.

Dr. BRUCE inquired if authority was to be given to employ counsel.

The President: Certainly.

Dr. GLOVER thought it would be unfair to give the Executive Committee power to deal with the question, and that the proper and most courteous course would be to send the minutes to the Lord President, and to await his further wishes and instructions.

The motion of Sir William Turner was then put to the Council, and carried, with three dissentients.

STUDENTS' REGISTRATION COMMITTEE.

The report of the Students' Registration Committee was adopted and entered on the minutes. The report contained applications that had been made to the Committee either for exceptional registration as students, or for the antedating of the commencement of professional study, with the Committee's decisions thereon.

Sir DYCE DUCKWORTH moved the following resolution:

That on and after January 1st, 1897, the registration of students under Resolution XI of June 2nd, 1891, shall be discontinued, so far as concerns the preliminary examinations of the Pharmacologist Society.

He said that it had been the custom previously to allow students who had passed the preliminary examination of the Pharmaceutical Society to register as medical students on taking the previously omitted subjects, but the Council wished to discourage that in future.

Dr. MACALISTER seconded the resolution, which was agreed to.

VOTES OF THANKS.

Mr. WHEELHOUSE moved the following resolution:

That the thanks of this Council be conveyed, through its President, to the President and Fellows of the Royal College of Physicians for their courtesy in granting the use of their library and other rooms for the session of this Council, and for their generous and kindly hospitality to the Council.

Sir WILLIAM TURNER seconded the motion, which was carried with acclamation.

Dr. GLOVER moved the following resolution:

That the best thanks of the Council be given to the President for his able services in the chair during the present session.

Sir PHILIP C. SMYLY seconded the motion, which was carried with acclamation.

The session then terminated.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION IN 1896.

At a meeting of the Border Counties Branch of the British Medical Association, held in Carlisle, it was unanimously resolved to invite the Association to hold its annual conference in Carlisle next year, and Dr. Henry Barnes was nominated for the office of President for the year. The invitation and nomination of President will come before the Council of the Association in due course, and if the invitation should be accepted the meeting will be held at the end of July or beginning of August next year.

THE ASSOCIATION OF FELLOWS OF THE ROYAL COLLEGE OF SURGEONS, ENGLAND.

A MEETING of the Committee of the Association of Fellows of the Royal College of Surgeons, England, was held on December 4th, 1895, Mr. GEORGE POLLOCK, President, in the chair.

A reply from the Council of the Royal College of Surgeons acknowledging the receipt of the resolutions which the Committee had passed at their last meeting was read. After some discussion, a resolution was adopted unanimously expressing regret that the Council of the Royal College of Surgeons had not discussed the important suggestions made by the Committee for the more satisfactory conduct of the half-yearly meetings of the Fellows of the College; but in view of the important questions set down for discussion at the half-yearly meeting of Fellows in January, it was resolved to postpone further action for the present.

The Committee then received a deputation from the Civil Rights Defence Committee, headed by Lord Stamford, in reference to the case of Mr. R. B. Anderson.

The agenda for the annual general meeting of the Association on December 11th were then determined.

At the instance of Mr. T. HOLMES, the question of the attitude of the Association in regard to the claims of the Members of the College was again brought under the notice of the Committee. It was decided that the advocacy of the Members' claims could not be undertaken by the Association, but it was pointed out that the adoption of this policy was not intended to fetter individual action or expression of opinion.

We regret to hear of the serious illness of Dr. G. H. Kidd of Dublin.

A NEW ERA IN INDIAN SANITATION.

UNDER this heading the Exchange Telegraph Company has issued the subjoined paragraph, which accords in the main with our own despatches just received from India :

'We understand that the Government of India have adopted a highly important resolution for practically carrying into effect the reforms destined to meet the sanitary needs of India, which were so strongly advocated at the Indian Medical Congress held at Calcutta in December last by Mr. Ernest Hart in his published Address to the Congress, and by Dr. Simpson, the medical officer of health of Calcutta, and subsequently insisted on by Mr. Hart in his address in August last to the British Medical Association in London. These recommendations were endorsed and presented to the Indian Government by resolution, and although they created at the time and since no small opposition, it is satisfactory to see that the resolutions of the Congress have met with the approval of the Government. This resolution is destined to create a new era in sanitation in India. The broad outlines of the scheme, as suggested in Mr. Hart's address and Dr. Simpson's paper were :

1. The complete separation of the sanitation of the Army and of the military cantonments from that of the civil population.
2. The special sanitary training of students in the medical and veterinary colleges and schools of India, and the affording to other classes of students facilities for obtaining, when desired, special training in sanitary engineering and architecture in the engineering colleges and technical schools.
3. The compelling of each municipality, or combination, or group of municipalities or local authorities to appoint a health officer after a certain date. Such officer's appointment, pay, leave, dismissal, etc., being subject to the approval of the sanitary commissioner.
4. The formation on every municipal board of a small but special sanitary committee with a medical man, and, when possible, the civil surgeon as president, and the compulsory setting aside annually of a certain sum of money to be placed at the committee's disposal for sanitary work only.
5. The appointment of the civil surgeon on a proper remuneration with defined powers as chief consultant health officer of the district, and in those places in which he is not available, either owing to overwork or other cause, the appointment of a special district officer.
6. The placing of the local and district health officers in close relationship with the sanitary commissioner of the province.
7. The placing of the provincial sanitary commissioner in touch with the Imperial sanitary commissioner.
8. The representation of health matters on the Imperial Council.
9. The establishment of a scientific institute for India.

With the exception of the representation of health matters on the Imperial Council, all the other suggestions have been most sympathetically dealt with, and more or less adopted, and the Congress is to be congratulated on being the means of bringing forward a reform which is destined to create a new era in sanitation in India.

The Government of India are to be heartily congratulated on the broad views they have taken in the question,

and the excellent manner in which they have handled it. An Imperial bacteriological laboratory is to be established at Agra under the directorship of Mr. Hankin, and an Imperial chemical laboratory in Calcutta. Health officers are to have a six months' training in bacteriology ; special diplomas, after careful training in hygiene, are to be granted by the colleges, and 1,900 municipalities will be expected to appoint trained men for sanitary work. The scheme, when completed in details and in course of time, will give to India a sanitary organisation and service second to none in any other country.'

The following are the paragraphs in Mr. Ernest Hart's address on The Medical Profession in India, its Position and its Work ; an address delivered before the Indian Medical Congress held at Calcutta in January, 1895,* in which the outlines were laid down for the reorganisation of the sanitary services in India :

"The Indian sanitary services should be reorganised on the following basis :

"(a) An Imperial sanitary department attached to the Government of India.

"(b) A provincial sanitary department attached to each of the provincial governments, such as Bengal, North West Provinces, Punjab, Madras, Bombay, Central Provinces, etc.

"(c) A local sanitary department attached to each municipality, district board, etc.

"(a) The Imperial sanitary department should be administrative and scientific, and quite distinct from the sanitary department of the army. It should consist of (1) the Sanitary Commissioner with the Government of India ; (2) a deputy sanitary commissioner ; (3) a medical statistic ; (4) a veterinary commissioner ; (5) a sanitary engineer ; (6) a Minister of Health, having a seat in the Viceroy's Council, as president. Scientific agents : Laboratory with trained experts. Duties : The advising of the Viceroy and Council on important health matters, either initiated by the Imperial sanitary department, or referred to it by the local governments ; the collection and publication of information as to epidemic diseases existing in India and in other countries ; the right of asking from provincial governments what they propose to do, or have done, in checking or inquiring into diseases affecting man, animals, or agriculture in their provinces ; the arranging that all administration reports shall be drawn up on a uniform plan for ready reference ; the acquiring of all information regarding the movements of pilgrims, coolies, and emigrants, and the advising the provincial governments, and requiring the latter to take proper precautions ; the consideration of new sanitary laws, etc.

"(b) The provincial sanitary department should consist of the following sanitary officers appointed by the local government : (1) sanitary commissioner ; (2) assistant sanitary commissioner ; (3) sanitary engineer ; (4) a president, who should be a high officer in the Civil Service. Travelling agents : deputy sanitary commissioners or inspectors, veterinary surgeons, deputy sanitary engineers, as may be required ; scientific agents : trained professors and assist-

* Calcutta : Thacker, Spink, and Co., 1895. (Note also Mr. Ernest Hart's address delivered at the Congress of the British Association of Public Health at Edinburgh, and the annual meeting of the British Medical Association held at Newcastle in 1891. *BRITISH MEDICAL JOURNAL*, August 1st, 1891, February 10th and 20th, and December 20th, 1894, and *AMERICAN JOURNAL*, October, 1895.)

ants in government laboratory for bacteriological, chemical, agricultural work, etc., and general sanitary investigations requiring to be done in laboratory. Duties: to control local authorities; to institute special investigations at any particular spot on any particular subject; to make by-laws and amend sanitary laws; to investigate diseases of men and animals, and study agricultural pests, etc.; to analyse water, etc.

"(c) Local sanitary departments to consist of municipal commissioners or district magistrates, with civil surgeon when obtainable. Executive agents: A health officer, attached to one or more towns; an engineer in a similar position, and a sanitary staff for each place as required. Duties: Conservancy, water supply, building regulations, drainage; registration of births and deaths, vaccination, stamping out of infectious disease, and informing provincial authority by weekly reports as to prevalence of cholera, small-pox, or other dangerous disease."

These may be compared with the above scheme now proposed by the Indian Government, and it will be seen that they closely correspond, although, as might have been expected, the proposals of the Government fall short in some respects of the original proposals. These proposals were strongly reinforced by the able paper of Dr. Simpson read at the Congress on the same subject, and a resolution in their favour, which was suggested and drafted by Mr. Hart, was unanimously passed at the last general meeting of the Congress and presented to the notice of Sir Antony MacDonnell, the Secretary for Home Affairs of the Indian Government, by a deputation of which Mr. Hart was requested to act as spokesman, and of which Surgeon-Colonel Harvey, President of the Congress; the Hon. Dr. Lethbridge, member of the Indian Council; Surgeon-Colonel Joubert, and Dr. Simpson were members, and spoke in support of the propositions brought forward.

Mr. Hart's open letter to the Secretary for Home Affairs of the Indian Government urging that Mr. Hankin's laboratory at Agra should be transformed into an imperial bacteriological laboratory for the training of medical officers was published in the *BRITISH MEDICAL JOURNAL* of May 11th, 1895, p. 1057, and was forwarded to the Indian Government in March, 1895, and it is satisfactory to learn that this proposal also has been adopted.

To make the scheme complete further laboratories need to be, and we understand are likely to be, organised on a smaller scale in each of the great Indian presidencies, and arrangements will be made for giving six months' training of medical officers in the service.

We have received further congratulatory despatches and communications from officials and others in India on this subject too late for publication this week. Full credit should be given in the matter to Dr. Simpson, the able Medical Health Officer of Calcutta, to whom—and also, we hear, to Sir A. MacDonnell—much is due for the good and rapid result thus accruing from Mr. Hart's recent visit and labours in India during his last winter holiday and the work done at the Calcutta Congress.

In memory of the late Dr. Andrew Miller, of Hampstead, who was killed by a fall from his horse at Henley-on-Thames in July, 1891, a stained-glass window has been placed in Holy Trinity Church in that town. The window has two lights containing the figures of St. Andrew and St. Luke, and a quatrefoil with the geometrical emblem of the Trinity.

CANON WILBERFORCE ON THE TREATMENT OF HOSPITAL PATIENTS.

A few days ago the *Times* published a letter from Mr. Burford Rawlings, exposing the attack made on our hospitals by the antivivisectionist societies. Among the letters that followed it was one from Canon Wilberforce. He says: "If vivisection be only one half what its assailants aver, it is impossible but that a vague feeling of uneasiness should exist as to the bare possibility of the extension of experiments in some measure to hospital patients. Some authoritative assurance would counteract the vague impression which is undeniably perceptible amongst the classes for whose benefit the hospitals exist."

It is to be noted that Canon Wilberforce writes in a quiet and temperate style, rather as if he were understating his case. But we are not now concerned—bad as it is—with his style, but with some of the examples which he brings forward to support his assertion that hospital patients are in danger of being made subjects of experiment:

1. "Poor woman, admitted to a hospital in a dying condition, made the subject of constant observation and examination with tuning forks, etc. These examinations were continued till her death, which occurred twenty-four hours after her admission." This was a case of tumour of the medulla. "A watch was heard one inch and a-half from the right and eight inches from the left ear, and the tuning fork was heard best on the left side. The symptoms noted subsequently were increasing dysphagia, and rapid shallow respiration without dyspnoea. More complete notes could not be taken, as she was only under observation for twenty-four hours, when she died of asthenia" (*BRITISH MEDICAL JOURNAL*, October 27th, 1883).

2. "Patients admitted to hospital in dying condition made the subject of minute and tedious examinations, merely to furnish reports to the medical journals." Reference is made to the *BRITISH MEDICAL JOURNAL* of June 7th, 1879, but a careful search has failed to find any account of anything of the kind.

3. "Experiment of injecting milk into the veins of a dying patient" (*BRITISH MEDICAL JOURNAL*, June 6th, 1885). This case is cited in a long paper on the use of milk for transfusion, with an account of several earlier cases where the patient's life was thus saved.

4. "Experiments on varnishing the skin—so frequently tried on animals—tried on men" (*BRITISH MEDICAL JOURNAL*, May 11th, 1878). This statement, as made, is perfectly untrue. The reference is to a clinical lecture on myxœdema by Dr. Ord, who hazards a conjecture that the action of the disease is analogous to the effect of varnishing the skin in animals.

So much for the truthfulness of Canon Wilberforce's letter. Now let us see how much harm he may have done.

Perhaps it is not our business to consider what harm he may have done to himself. But this much must be said—that we demand of a priest that at least he should not bear false witness against his neighbour. He has disgraced himself by a reckless statement of things that are not true: he could easily have assured himself that they were not true; he has published his false statement to the world. And we hope that those who are put in authority over him will take notice of his offence, and tell him plainly that he has played fast and loose with common honesty, and has brought no small discredit on the English Church.

The harm that he may have done to our hospitals is probably not great. It is not likely that his letter will be taken very seriously by those who know either him or the hospitals. We have the poor always with us, and whenever we will we can do them service: he has with him the antivivisectionists. Some of these will doubtless leave to animals the money that ought to go to men, women, and children; others will make their opposition to all experiments on animals an excuse for giving nothing to hospitals, and will spend the money on themselves. But we doubt whether the sums thus lost to our hospitals are so large that by losing them we lose our power of helping the poor. Moreover, the antivivisection societies have lost ground of late years; their exposure at the Church Congress at Folkestone weakened them; and they are disheartened by the discovery of the treatment of myxœdema with thyroid extract; the antitoxins have also been a great blow to them. Therefore their rallying cry is that the

patients in our hospitals are made subjects of experiment. And the harm done by this agitation is done not to the hospitals, but to the patients themselves. It is impossible to doubt this: Canon Wilberforce's letter has done most harm to those whom he least thought to injure.

Every hospital surgeon is familiar with those most unhappy cases where the patient refuses some operation that may prolong or save his life. It may be some simple thing—the opening of an abscess, the withdrawal of an effusion. Argument, appeal, assurance, encouragement are all in vain; one has the headache all for nothing, the miserable presentiment of failure. The patient only answers, "I'm not going to be cut about," or "I'm sure you are very kind, but I won't have anything done." Probably every year, in the London hospitals alone, 400 or 500 patients thus refuse treatment, and are discharged at their own request. Lives that might be saved are lost by the score. At whose door are these deaths to be laid? Some of them lie at the doors of the quack doctors of London. Others lie at the doors of those who make money out of Mallet's fluids, Mother Siegel's Syrup, and the like. For others, those who are to blame are the poor against our hospitals—the editors of certain papers or their correspondents. Ignorant, credulous, incredulous, self-willed, and proud of their own judgment are many hospital patients; and some of them pay a heavy price for it. We implore Canon Wilberforce, not for our profession nor for our hospitals, but for the sake of our patients, to write or speak not a single word against the hospitals. But if speak and write he must, at least we hope he will accept our "authoritative assurance" that his letter to the *Times* is not the way to do it.

PRESENTATION TO SIR HENRY ACLAND.

On December 4th, in the hall of All Souls College, Oxford, Sir Henry Acland was presented with the testimonial which has been raised to commemorate his long and faithful services to the University, the City, and the County of Oxford, and the part which he has borne in the advancement of medical science, more particularly in the direction of sanitary reform during the 40 years for which he held the office of Regius Professor of Medicine.

The presentation was made by the Vice-Chancellor, who, in the course of his speech, said that the allocation of the fund in part to defray the cost of a bust to be placed in the University Museum, and in part to increase, by over £3,000, the funds of the Sarah Acland Home for Nurses, had been so arranged in order that Sir Henry Acland's name might continue to be connected with two institutions, the one designed to foster the study of scientific medicine, the other to carry benefits into the homes of all classes.

Sir Henry Acland, in the course of a feeling reply, expressed his satisfaction at the manner in which the fund had been expended.

ASSOCIATION INTELLIGENCE.

NOTICE OF QUARTERLY MEETINGS FOR 1896.

ELECTION OF MEMBERS.

MEETINGS of the Council will be held on January 15th, April 15th, July 8th, and October 21st, 1896. Candidates for election by the Council of the Association must send in their forms of application to the General Secretary not later than twenty-one days before each meeting—namely, December 26th, 1895, March 26th, June 15th, and October 1st, 1896.

Any qualified medical practitioner, not disqualified by any by-law of the Association, who shall be recommended as eligible by any three members, may be elected a member by the Council or by any recognised Branch Council.

Candidates seeking election by a Branch Council should apply to the Secretary of the Branch. No members can be elected by a Branch Council unless their names have been inserted in the circular summoning the meeting at which they seek election.

FRANCIS FOWKE, General Secretary.

LIBRARY OF THE BRITISH MEDICAL ASSOCIATION.

MEMBERS are reminded that the Library and Writing Rooms

of the Association are fitted up for the accommodation of the members in commodious apartments, at the offices of the Association, 429, Strand. The rooms are open from 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 2 P.M. Members can have their letters addressed to them at the Office.

BRANCH MEETINGS TO BE HELD.

METROPOLITAN COUNTIES BRANCH: NORTH LONDON DISTRICT.—A meeting of this District will be held on Tuesday, December 17th, at 4 P.M., at Highgate Infirmary, Northgate Park Hill, Highgate. Dr. Cleveland will preside. Mr. D'Arny Power will read a paper upon the Differential Diagnosis and the Treatment of Cystic Lymphangioma in Children, accompanied and a case will be shown. Interesting clinical cases will be shown by Dr. Bennett, Medical Superintendent of the Infirmary.—RICHARD WOODS, Honorary Secretary.

METROPOLITAN COUNTIES BRANCH: SOUTH LONDON DISTRICT.—The next meeting will be held on Tuesday, December 10th, at 3.30 P.M. at the Lambeth Infirmary, Kennington. Clinical cases will be demonstrated on by Dr. Quarry, Medical Superintendent. All practitioners, whether members of the Association or not, will be heartily welcomed.—H. BRITHAM ROBINSON, Honorary Secretary, 1, Upper Wimpole Street, W.

ABERDEEN, BANFF, AND KINCARDINE BRANCH.—An ordinary general meeting will be held in Aberdeen on Wednesday, December 10th, at 4 P.M.—C. THIRLTON URQUHART, J. SCOTT RIDDLE, Joint Honorary Secretaries.

SOUTHERN BRANCH: SOUTH WILTS DISTRICT.—A meeting of this District will be held at the County Hotel, Salisbury, on Wednesday, December 18th, at 2 P.M. The business will be as follows: 1. Statement of Accounts. 2. Election of Officers. 3. Consider the report of the Committee of the British Medical Association on Medical Charities. 4. Mr. Hosking: (1) Notes of a Case of Sarcoma of the Scapula; (2) Mesothelioma of Lower Eyelid, with specimen. 5. Mr. Straton: The Use of the Tintometer in Water Analysis. 6. Mr. Manning: A Case of Orchitis for the Relief of Enlarged Prostate. 7. Specimens. Luncheon will be provided at 1 o'clock, at 2s. 6d. a head, not to include wine or ale.—H. J. MANNING, Honorary Secretary.

STAFFORDSHIRE BRANCH.

The first general meeting of this Branch was held at Stoke-on-Trent on November 28th; Dr. GEORGE REID (the President) in the chair.

Cases and Specimens.—Mr. W. D. SPANTON showed: (1) A large Myoma of Uterus, weighing about 13 lbs., removed by abdominal hysterectomy from a married woman aged 38. The operation was performed on August 25th by long median incision, the uterus, both ovaries and tubes being removed and the pedicle clamped in the wound. The patient made a good recovery. (2) A very large Ovarian Tumour, removed from a married woman aged 43, densely and universally adherent, followed by good recovery. (3) A Malignant Right Ovary, removed from a married lady aged 40, from whose right breast a recurrent cancerous tumour was also removed after what seemed a simple growth had existed for about ten years; also a small tumour previously excised from the left breast some months before. It was brought forward as an illustration of the obscurity of the origin of malignancy. (4) A married woman, aged 48, whose Spleen, weighing 6½ lbs., had been removed in March. The patient had a good colour, and appeared in perfect health. (5) Mr. Spanton also described some Expanding Bougies he had had made for treatment of stricture of the oesophagus, and related a case in which they had been successfully employed.—Dr. McALDOWIE showed a Piece of Steel from a corset, which had sprung in a bent position into a boy's mouth, and become fixed in the naso-pharynx, one arm passing above the soft palate, the other down the oesophagus.—Mr. H. R. FOLKEN showed: (1) A child, 3 years of age, with Congenital Absence of both Irids, complete Coloboma of Choroids, and Anterior Polar Cataract in both Lenses, both Corneas hazy, marked Nyctalopia. The child had very fair vision. (2) A specimen showing Ossification of Choroid in the right eye of a miner, who was operated upon twenty years ago for staphylocoma of the cornea of the same eye, due to injury.—Dr. G. S. HAYTON showed Stones removed by nephrotomy from a patient in whom one of the ureters had suddenly become blocked. The patient recovered well from the operation, but died two months afterwards from suppression. On post-mortem examination the other kidney was found to contain numerous calculi.

Papers.—Dr. McALDOWIE read a paper on Pseudo-Bulbar

Paralysis, referring to this disease two cases which had come under his care in the North Stafford Infirmary, and whose symptoms he analysed.—Mr. A. W. GRIFFITHS read notes of a case of Inversion of the Uterus in a primipara. The condition was brought about apparently by kneading the uterus to expel the placenta. Hemorrhage was profuse, but was checked on the organ being returned. The patient made a good recovery.

ABERDEEN, BANFF, AND KINCARDINE BRANCH.

The annual general meeting of this Branch was held in Marischal College, Aberdeen, on November 16th; Professor STEPHENSON, the retiring President, in the chair.

Confirmation of Minutes.—The minutes were read and approved.

Installation of New President.—Professor STEPHENSON introduced Dr. McHARDY (Banchory), the President for the year 1896, who then took the chair.

Report of Council.—The Council's annual report was read, and was a very satisfactory one. The members now numbered 152, as compared with 146 last year. Thirteen new members were admitted; one resigned, and two died, namely, Dr. Jenkyns (Gladstone Place, Aberdeen), and Dr. Samuel Davidson (Wartle, Aberdeenshire), who had been twice President of the Branch.

Treasurer's Report.—The Treasurer's balance sheet showed the funds of the Branch to be in a very satisfactory state.

Election of Officers.—The following were elected:—*President:* Dr. McHardy (Banchory). *President-Elect:* Dr. Trail (Strichen). *Vice-Presidents:* Dr. Paterson (Inverurie), Professor Stephenson. *Representatives on Parliamentary Bills Committee:* Professor Ogston. *Representative on Council of the Association:* Professor Finlay. *Hon. Treasurer:* Dr. J. Y. Dalgarno. *Hon. Secretaries:* U. Thielton Urquhart; J. Scott Riddell. *Council:* County: Dr. Fergusson (Banff), Dr. Taylor (Keith), Dr. Wilson (Old Deer); Town: Dr. Rose, Dr. Blaikie Smith, Dr. Mackenzie Booth.

June Meeting.—The next June meeting was arranged to be held at Auchinblae.

Postponement of Motion.—A motion by Dr. Mackenzie Booth was in his absence postponed.

Hospital Visit.—A hospital visit took place at 11 A.M., and the members of the staff kindly attended in their wards, and demonstrated the cases, of which due notice had been given to the members by circular.

Annual Dinner.—The annual dinner was held in the Imperial Hotel; Dr. McHARDY, the President, was in the chair, while Professor STEPHENSON acted as croupier.

SOUTH-EASTERN BRANCH: EAST KENT DISTRICT.

The 187th meeting of this District was held at the Kent and Canterbury Hospital on November 21st, Mr. ROBERT HICKS, of Ramsgate, in the chair. There were twenty-five members and visitors present.

Confirmation of Minutes.—The minutes of the last meeting were read and confirmed.

Chairmanship of the March Meeting.—On the proposal of Dr. TYSON, seconded by Mr. F. WACHEE, it was resolved that Dr. Robinson, of Dover, should take the chair at the meeting to be held at Dover next March.

Rare Sequela of Pleuritic Effusion after Aspiration.—Dr. GOGARTY (Canterbury) read a paper on this subject. The case was related of a man, aged 28, who was admitted into the Canterbury Hospital suffering from rheumatism, endocarditis, and double pleural effusion following influenza. To relieve distress of breathing he was aspirated, and 18 ounces of serum were drawn off from the left pleura. Eleven hours after the operation, profuse albuminous expectoration, amounting to between 1 and 2 pints, set in, and the man died three hours afterwards. *Post-mortem examination* showed endocarditis, vegetations on the mitral valve, double pleural effusion, and enlarged heart and liver. The expectorated fluid was like serum—coagulable with heat and nitric acid. Dr. GOGARTY pointed out that but little was to be found on this subject in English medical literature, and that most of the information he had gained came from a paper by a French physician,¹ together with a discussion on the sub-

ject among the members of a French medical society. After enumerating the various theories which had been advanced to account for this albuminous expectoration, he said that pulmonary engorgement, leading to oedema and exudation of serous fluid into the bronchi, was the hypothesis which met with most approval. Some abnormal distribution of the vasomotor nerves to the lungs was the most probable explanation.

Boric Acid Poisoning in Milk.—Dr. ROBINSON (Dover) read a paper on this subject. Of a household of seven adults five were attacked with severe colic and vomiting, lasting from two to four days, and accompanied, in the worst cases, by suppression of urine. Much prostration and irritability of the stomach persisted for some days. On the day of seizure it was found that some milk which was partaken of by the five victims had been treated with "glacialene" as a preservative. This glacialene was found to contain boric acid. In addition to this, boric acid had been added to the milk, with the same object, before delivery. The milk in question, mixed with some blanc-mange, was given to some fowls, and, out of nine, five died; the others showed signs of poisoning, though in a less degree. There were no other circumstances to account for the outbreak. Dr. Robinson dwelt on the necessity of precautions in prescribing this drug, and of greater restrictions in its use as a food preservative.

Appendicitis.—Dr. TYSON (Folkestone) read a paper on appendicitis. Clinically the disease was met with in three conditions: (1) A local adhesive peritonitis, capable of resolution; (2) a localised inflammation, resulting in the formation of pus; (3) an acute general peritonitis. The symptoms, pathological conditions, and treatment of each of the three classes were described. The first division contains the greater number of cases met with. They generally get well under proper medical care. The cases under the second head, when pus forms, are to be treated as ordinary abscesses. In such instances the appendix is usually destroyed in the suppurative process, so that relapsing appendicitis need not be apprehended. The extreme fatality of the cases coming under the third head was then alluded to. Idiopathic peritonitis was so rare that Dr. Tyson deprecated the use of the term without some qualifying adjective. Peritonitis in a child, excluding enteric fever and tuberculosis, was almost invariably due to appendicitis. Other causes—intussusception, strangulation by Meckel's diverticulum or from trauma—should not be forgotten but they were very rare. As to the use of opium in appendicitis and peritonitis, Dr. Tyson was of opinion that it should be restricted to the early cases, when the patient was in the hands of the physician, and before the surgeon has been called in, and to those desperate cases where perforation had taken place and no operation was intended.

Refreshments.—After the meeting tea and coffee were served in the board room of the hospital.

BATH AND BRISTOL BRANCH.

The second ordinary meeting of the Branch was held at Bath on November 27th, 1895, CAREY COOMES, M.D., President, in the chair. Thirty-seven members and four visitors were present.

New Members.—The following were elected: C. E. Wigan, M.B., C.M.Aberd., Clevedon; A. L. Fuller, M.R.C.S., L.R.C.P., Bath; H. A. Beaver, M.B., B.Ch.Vict., Clifton; H. W. Kendall, M.R.C.S., L.R.C.P., Clifton; E. B. Garland, M.B., C.M.Edin., Bristol.

Communications.—Dr. GEO. PARKER read notes of (a) Case of Perforation of Appendix in Enteric Fever, and (b) Perityphlitis: Portal Pyæmia. In the discussion which ensued the following members took part: The PRESIDENT, Dr. MICHELL CLARKE, and Dr. GOODRIDGE.—Dr. MICHELL CLARKE gave particulars of the Sequel to a case of Trephining to relieve symptoms of Cerebral Tumour, and also described a case of Birth Palsy, in which an operation was performed. The PRESIDENT, Dr. GEORGE PARKER, and Mr. WOODS commented on these cases.—Mr. CHARLES GATNE read a paper on Some Forms of Cachexia arising from the Retention of Diseased Teeth and Stumps which are not amenable to conservative treatment, upon which Dr. J. G. SWAYNE, Dr. MARKHAM SKERRITT, and Dr. SHINGLETON SMITH made some remarks.—Mr. S. E. RIGG described for Mr. T. G. STOCKWELL,

¹ BRITISH MEDICAL JOURNAL, 1872.

and showed the specimen of, a Sarcoma of the Scapula. Comments were made by Drs. GOODRIDGE and HARRISON.—Mr. BASIL TREVELYAN gave a brief Clinical Comparison of Young and Old Primiparae, which was discussed by the President, Dr. J. G. SWAYNE, Dr. WIGMORE, and Mr. WOODS.

JAMAICA BRANCH.

A GENERAL meeting of this Branch was held on July 31st, 1896, at the Institute of Jamaica, Kingston, the President in the chair.

Confirmation of Minutes.—The minutes of the last meeting (May 29th, 1896) were read and confirmed, and signed by the President.

Communications, Notes.—The following cases were read by Mr. G. COOK: 1. Gangrene of Leg from Embolism of Femoral Artery in a Patient of Advanced Age, Amputation, Recovery; 2. Rupture of Femoral Artery from Muscular Action, Large Diffused Aneurysm, Recovery; 3. Abdominal Pregnancy lasting Eighteen Months, Death. The reading of the papers was followed by discussion. In the case of amputation for dry gangrene of the leg the operator and patient were alike congratulated on the fact that so grave an operation as amputation in the lower third of the thigh at so advanced an age was successful. The case of aneurysm especially interested the meeting, the cause being so obviously traumatic.

CAPE OF GOOD HOPE BRANCH.

General Report, 1894-95.—Since the last annual general meeting the Association has met nine times; thrice at members' houses in summer, and six times in the English Church House, Burg Street. At the various meetings a large number of interesting papers were read and discussed, among others on the following subjects: Abnormal cases of Typhoid, Diphtheria, and Antitoxin (three papers), Hydatid Disease (two papers), Spontaneous Cretinism, Ectopic Fœtation, Life Assurance in South African Races, Hepatic Abscess, Intraocular Ophthalmia, and Iritis in Young Children. Numerous pathological specimens were exhibited, both macroscopic and microscopic, and some living patients were shown. A committee was appointed to investigate the prevalence of hydatid disease with a view to disseminating information as to its dangers and the means of its prevention. The Health Bill and certain desired amendments to the Medical and Pharmacy Act were discussed, and a committee was appointed to impress on the medical members of Assembly, and on the Government through the Colonial Secretary, the necessity for legislation on these subjects. Although favourably received on both occasions, these measures had again been shelved to make way for less important matters. The Association having still no permanent home, was indebted to Drs. Anderson and Kitching for housing the library at 47, Burg Street. Surgeon-Colonel Hamilton and Dr. Dyer kindly represented the Branch at the general meeting in London. The report further stated that three members had resigned, one had died, and one new member had been elected.

Electors of Office-bearers.—The following were elected office-bearers for 1896: President: G. E. C. Anderson, M.D., Lond., Sea Point. Vice-President: Surgeon-Colonel Hamilton, F.M.O., Newlands. Honorary Secretary: D. J. Wood, M.B., Cape Town. Honorary Treasurer: L. A. W. Beek, M.B., Claremont. Council: W. J. Dodds, M.D., Valkenberg Asylum, Mowbray; J. H. M. Beek, M.D., Rondebosch; C. F. K. Murray, M.D., Kenilworth; C. L. Herman, M.B., Cape Town.

SYDNEY AND NEW SOUTH WALES BRANCH.

THE usual monthly meeting of the Branch was held on September 27th, 1896, Dr. E. J. JENKINS, President, in the chair. There were thirty-one members present.

Confirmation of Minutes.—The minutes of previous meeting were read and confirmed.

New Members.—The President announced the election of Dr. Richards, of Vacy, as a member.

Communications.—Dr. BENNET exhibited a patient suffering from Urticaria Pigmentosa, and read notes of the case. Dr. FIASCHI read notes of a case of Partial Excision of the Elbow Joint for Ankylosis following Fracture. Drs. CLARKE, SYDNEY JONES, and THIRING discussed the case.—Dr. W. C. WILKINSON read notes of two cases of Papilloma

of the Larynx. Drs. W. F. QUAYNE, CLUBBER, and SPENCER discussed the case.—Dr. SPENCER read a paper on Morbid Alvine Secretions. Drs. WILKINSON and WORRALL discussed the paper.

SPECIAL CORRESPONDENCE.

PARIS.

The Organisation of Medical Charity.—Closure of the International Sanitary Exhibition.—Law and Medicine.—Criminal Anthropology in the Law Courts.—The Association des Dames Françaises.—An Infant Asylum.—General News.

THE *Journal Officiel* publishes the decree, which sets forth how the Paris District Public Assistance is to be organised. The twenty district charity offices will henceforth be composed of the Mayor, the deputies, district municipal councillors, and four administrators to each district, nominated by the prefect; another member performing the double duties of secretary and treasurer. Women may be elected to fill the post of administrators in district benevolent offices. The members of the office elect a controlling administrator, whose duty it is to put in force the decisions arrived at by the officials, to verify the accounts and examine the documents connected with legacies and donations; likewise those relating to expenditure. The revenue of each office is drawn from gifts, subscriptions, and legacies; from the general fund under the direction of the Public Assistance, which apportions to each office its share of this fund according to the number of the poor living in the district; from the sum voted by the Municipal Council for poor relief and paid to the Public Assistance; from the poor-boxes; from the sums collected by ladies at the doors of public exhibitions, church collections, and charity festivals; the sum collected by mayors, deputies, administrators, commissaries, and lady patronesses. Only those poor who are inscribed on a list drawn up each year by the office of their district, and approved of by the Director of the Assistance Publique can receive help; none can be placed on the list but French citizens who have lived three years in Paris. In exceptional cases temporary help is granted persons in temporary distress. The district charity offices give money to those who apply bringing a card issued by the office, and signed by the applicant. Household articles are also lent to the poor on application; and they are sent back to their homes in the country by the district charity offices when unable to earn their living; when behindhand with their rent the office advances it as a loan. The indigent poor who are not inscribed on the list of their district charity office cannot receive gratuitous medical help except in cases of sudden severe illness. The medical help provided by the district poor relief offices is distinct from that of hospital medical help. The poor are treated in their homes or in dispensaries by medical officers appointed to take charge of the sick poor. These medical officers have to live in the district to which they are appointed by ministerial decree. After having passed a competitive examination they hold their appointment for three years. The patients can be treated by any one of the doctors they prefer appointed in their district; medicine is provided free.

The International Sanitary Exhibition is closed, and the last honours have been paid to its memory in the form of a public dinner at the Grand Hotel. M. Bourgeois, President of the Cabinet Council, was in the chair, supported by many notabilities. The Dean of the Paris Medical Faculty proposed the health of the President of the Republic, who had inaugurated the exhibition. Dr. Brouardel went on to say that faulty sanitation is a public danger. At the exhibition of 1889 nearly all the articles of sanitation were of foreign manufacture, principally English. At the present time Dr. Brouardel declares it is France that triumphs; at the exhibition of 1889 French articles of sanitation carried off the palm. The Dean concluded by asking M. Bourgeois to further the passing of a public health law. The Minister, in his speech, said it was the duty of the State to say to sanitarians, "Show us what to do, and we will do it." He further promised that the Chamber of Deputies would, as soon as possible, urge

the Senate to pass the public health law which the Chamber had voted two years ago.

Law and medicine frequently have disagreements, and law, rightly or wrongly, has the upper hand. Not long ago a medical man sued a client to recover fees which had been left unpaid. He recovered the £12 sued for, but was condemned to pay exactly the same sum to his client as indemnity for the injury he had done him by violation of professional secrecy. In proceeding against his debtor and stating the services for which he claimed payment the wife of the defendant became aware of circumstances her husband had hidden from her, and thus his domestic happiness was threatened.

A curious case of another nature has just been tried at the first civil chamber. Dr. Aubry some time ago published a book, entitled *La Contagion du Meurtre*. In this volume there is a chapter treating of *la contagion par la famille* (family contagion). The author maintains that heredity and example are important factors in criminality. In order to prove the truth of his views he relates in the chapter on contagion by family influence the history of a family of criminals in a good position in the social scale. The brother and sister in this family both committed murder. Dr. Aubry explains this criminal mania by tracing their genealogy; they were the descendants of the illegitimate children of a woman who was accused of attempting to poison her husband; the father was well born and honourable, acknowledged the children, and gave them his name; the mother of the children was the wife of a hairdresser, and had legitimate children. Dr. Aubry closely studies the generations descending from the legitimate and illegitimate children of the hairdresser's wife in order to establish the different degree of criminality manifested in these two branches possessing the same mother. It is thus that Dr. Aubry is led to conclude that the legitimate children, in consequence of the marriages they made, manifest much feebler tendencies to criminal acts. One of the descendants is living, and has proceeded against Dr. Aubry on the ground that she is mentioned in his book and her dishonourable means of gaining her living used as proof that the legitimate branch is guilty of offences but not crime. M. Selegman has given judgment in favour of the plaintiff, who is 81 years of age. Max Nordau, in his criticism on Emile Zola, accused this author of having plagiarised Dr. Aubry; the attention of the person libelled was thus drawn to the fact.

The Association des Dames Françaises have held their annual general meeting. In the report read by Dr. Duchaussoy it was stated that thirty new committees have been founded; the Auteuil Hospital has been built; hospitals organised for war time are in the possession of the Association; instruction has been organised for the benefit of the lycée pupils; and a large supply of medical comforts, clothing, etc., sent to Madagascar. The military authorities authorised the Association to distribute among the soldiers returning from Madagascar non-military clothing, and to provide them with means to return to their families. In Paris the Association distributes clothing, food, medicine, and money in sums from 4 francs to 40, three times a week, among the soldiers and their families left in distress. The Association has spent this year £8,200. The Press Festival Committee has placed £2,000 at the disposal of the Association des Dames de France.

The Pouponnière de Porchefontaine, an asylum for infants at Versailles, has been visited by Mme. Félix Faure, the wife of the President, and the baby inmates rendered happy by a shower of cakes and toys. This building is situated in beautiful grounds measuring 15,000 square centimetres. Quite recently fresh pavilions have been added, and they were inaugurated by the visit of Madame la Présidente. There is in addition to the pavilions an infirmary and a lazaretto. Every wet nurse and every nursing admitted to the Pouponnière is kept in quarantine during eight days in the lazaretto; all doubtful cases are immediately removed from contact with the other inmates and placed in the infirmary. Linen is disinfected in a stove, and every article after use is disinfected. Children brought up at the breast are paid for; 40 francs are charged, and given to the wet nurse; when the child is not entirely nourished by human milk 30 francs are charged. Money grants called *bourses* and *dembourses* are given under circumstances meriting help.

In 1890 the Michelet Asylum for Pregnant Women was constructed by the Municipal Council. During the last ten months the applications for admittance has been so numerous that 157 women a month have been refused. The Municipal Council in consequence asks a further grant of £12,000.

Professor Lannelongue, member of the Chamber of Deputies, has been elected member of the Academy of Sciences, in the place of the late Professor Verneuil.

BERLIN.

Centenary of the Pépinière.—The Brandenburg Medical Association and the Reform of Lunacy Administration.—Puffs and Professors.

THE Pépinière of Berlin—the State training college for army surgeons—looks back on a hundred years of existence, and its jubilee, which has just been celebrated by a banquet and other festivities, has been graced by a congratulatory letter from the Emperor, and by quite a shower of “decorations” for its chief officials. And certainly the Pépinière may turn with proud satisfaction to its record of a century; modern military surgery owes to it a great part of its development, nor must it be forgotten that here for the first time surgery and medicine were united in one course of instruction. The Pépinière is a residential college; its director-in-chief at present is General-Army-Surgeon von Coler, who is assisted by twenty-eight staff-surgeons, but the principal lecturers are university professors. The entire cost is defrayed by the State; the students on their side bind themselves to serve as army surgeons for a certain number of years. Among the men who have gone forth from it are Helmholtz, Virchow, Nothnagel, Leyden, Nachtigal, von Lauer, von Coler, Leuthold, Gaffky, Loeffler, Hueppe, Behring, etc.

The autumn meeting of the Medical Association (*Aerztekammer*) for the province of Brandenburg, which includes the city of Berlin, was chiefly occupied by a discussion on the reform of the lunacy laws. Several Government representatives attended the meeting and took part in the debates. Professor Mendel and Dr. Lepmann were the chief speakers. Among the resolutions passed by the meeting were the following:

1. A request that no asylums or institutes for mental cases of whatsoever description be permitted except under the directorship and responsible guidance of properly qualified medical men.
 2. A demand for more thorough psychiatric training of medical students, with the proposal that a course of at least six months in a mental clinic be made obligatory for obtaining a doctor's degree.
 3. A request for the creation of a separate department for matters connected with lunacy, with an experienced alienist as chief and alienists as assistants in the Ministry of Education (*Cultusministerium*).
- Since its last meeting the *Aerztekammer* has suffered two severe losses through the death of its founder and president, Dr. Graf, and of Professor von Bardeleben.

Among the testimonials appended to the advertisements of a new soap in the Berlin papers were four signed by members of the medical teaching body of the Berlin University (one professor and three *privat-docenten*). These four gentlemen were requested by the Prussian Minister of Education to explain how their names came to be used as an advertisement for soap. It appears that three of them gave answers that were considered satisfactory. The fourth, the *privat-docent* Professor Krause (one of the laryngologists who attended the Emperor Frederick in his last illness), declined to give any explanation whatever. Thereupon the Minister passed the matter on to the Medical Faculty of the University, with the demand that this body should use its “disciplinary power,” and call Herr Krause to account. Thus the matter now stands, and it is not yet known what steps the Faculty propose to take. The principle involved in this matter is twofold: (1) Should a member of the teaching body of the University allow his name to appear in a manufacturer's advertisement? and (2) Has the “*Facultät*” of the University disciplinary power over the *Privat-docenten*, as it certainly has over the professors?

At a special meeting of the Tyne Port Sanitary Authority held on November 25th, Dr. Harker, of Tynemouth, was appointed medical officer of health in succession to Dr. H. E. Armstrong.

EDINBURGH.

*Alarming Outbreak of Waterborne Typhoid Fever in East Lothian.
—The Water Supply of Dunbar.—The Stirling County
Ball Poisoning.*

A serious outbreak of enteric fever has occurred in the county of East Lothian, something like fifty cases being now under treatment. Most of the cases have occurred in and about Dunbar, a town with a population of 3,645. The local authorities look on the matter as of such gravity as to warrant them in ordering the compulsory removal to hospital of those cases that cannot be effectively isolated. The first case occurred at a hamlet called Pathhead, some four or five miles from Dunbar, in the end of October. This case was at once removed to the caravan hospital. A second case from the same house and family was also removed to this travelling hospital about November 16th. The Pathhead water supply is drawn from wells sunk in the vicinity of the Spott burn. This water has been examined, and declared to be satisfactory. On or about November 20th it was found that there were eight or ten cases in Dunbar. On December 2nd the number was upwards of fifty. An analysis of the water was ordered, and this analysis was discussed at a private meeting of the local authority the other day. Why such a matter should be private we are unable to say. Sir Henry Littlejohn, who has been at Dunbar, has been asked for a further report.

The water supply of Dunbar comes from the Spott burn, and this burn, or a tributary of it, flows past the place where the Pathhead Caravan Hospital has been located. Whether this has any causal connection with the Dunbar outbreak has yet to be determined. There is another possible source of evil. Presmennan Loch, situated five miles from Dunbar, and about one mile from Pathhead, has an overflow outlet into the Spott burn. It is stated that no overflow has taken place for several weeks. It appears, however, to be the fact that during last summer the trout in Presmennan Loch were dying in hundreds. Actually some 500 dead trout were removed, and the water was considered so impure that cattle were fenced off to prevent their drinking it. The cause of the impurity is not so clear. There is a large and rapid growth of weeds in the lake, and whereas formerly these weeds were cut yearly, or from time to time, they have not now been cut for several years. It is supposed that the intense frost of the early part of this year, followed by the sub-tropical heat of August and September, has so acted on these weeds as to give rise to the state of affairs we have indicated. But it does seem incredible that water in which fish were unable to live, in which they were dying in hundreds, water that was deemed unfit for cattle, should yet be allowed even several weeks ago, to overflow into the water supply of Dunbar. But so it is. Into all the facts the most stringent inquiry will have to be made, and responsibility laid in the proper quarter.

The official inquiry into the Stirling County Ball poisoning is proceeding but owing to the extended area is necessarily slow. It will be remembered that a large number of persons who had been present at the ball, and who had partaken of oysters at supper, suffered afterwards from enteric fever caused, it was believed and alleged, by these oysters. There was a case in the town of Stirling (undoubtedly virulent typhoid), one in the county of Stirling, one in Linlithgowshire, one in Dumbartonshire, three or four in Glasgow, one in London, one in Venice, one in Bombay, and probably cases in Edinburgh, Kent, and Oxford. There were at least three fatal cases. The oysters came from the island of Tholen, Holland. The consignment consisted of sixteen barrels, four of which, containing 2,000 oysters, were sent by rail from Tholen to Rotterdam, from Rotterdam to Grangemouth by steamship, from Grangemouth to Stirling by rail. They were not opened till they reached Stirling. It appears that certain other persons in Stirling and Glasgow received oysters from the same consignment, and that no evil results are known to have followed their ingestion. It is stated that the bacteriologist to the Glasgow Western Infirmary has examined samples of the oysters, and pronounced them to be healthy. It is not asserted that he actually examined any of the particular lot that produced the cases of enteric fever.

CORRESPONDENCE.

DR. CALMETTE AND PROFESSOR FRASER ON SNAKE POISON.

SIR.—I desire, without offering any comments on the facts, to bring under the notice of your readers the following simple statement:

In the *Annales de l'Institut Pasteur*, May, 1894, Dr. Calmette described in full detail his researches on snake poison, and demonstrated that not only can animals be rendered resistant to cobra (and other snake) poison by the injection into them of graduated doses of the poison (so that rabbits were rendered tolerant of sixty times the lethal dose), but that the serum of such immunised rabbits is found to contain a powerful antitoxin, which can be used successfully as an antidote to snake poison. In April, 1895, in the same *Annales*, Dr. Calmette described the result of a year's further work on this subject, giving the most important facts as to the antidotal action of snake antitoxin in regard to poisons allied to snake poison, and of other antitoxins in regard to snake poison. On both occasions Dr. Calmette formulated his discoveries in such a way as to render them applicable to the treatment of snake bite in man.

On June 3rd, 1895, Professor Thomas R. Fraser, of the University of Edinburgh, read to the Royal Society of Edinburgh a paper (subsequently printed in the *Proceedings* of that Society). On the rendering of Animals Immune against the Venom of the Cobra and other Serpents; and on the Antidotal Properties of the Blood Serum of the Immunised Animals. In this paper, read more than a year after Calmette's first paper above cited was published, Professor Fraser has refrained from any textual reference to Calmette's published work. His only citation of Calmette is as follows: "Within the last few months Phisalix and Bertrand have obtained experimental indications of the antidotal power of the blood serum of animals immunised, but only to a low degree, against the venom of vipers; whilst Calmette, working in the Pasteur Institute of Paris, after several unsuccessful endeavours had led him to express the opinion that immunity against snake venom could not be produced, afterwards succeeded in obtaining evidence of its production and of the power of the blood serum to counteract the effects of venom."

The medical journals of Great Britain have represented Professor Fraser as the discoverer of the antitoxin of snake poison. Two distinguished Edinburgh biologists—Professor Geddes and Dr. Arthur Thomson—writing on Pasteur in the *Contemporary Review*, have put forward Professor Fraser as one who has made an important life-saving discovery, which is the latest fruit of Pasteur's fertile conceptions. As a matter of fact, anyone who will take the trouble to read Dr. Calmette's papers and Professor Fraser's will find that the sole credit of discovery in this matter rests with Dr. Calmette, who worked under the direction and with the suggestions of Dr. Roux.

It would be interesting to know whether the *Annales de l'Institut Pasteur* are accessible to Professor Fraser, and whether he thinks that his vague reference to Calmette's detailed researches, and his designation of the interval between May, 1894, and June, 1895, as "a few months," are calculated to give to the British public a fair notion of the merit in this matter of his French colleague.—I am, etc.,

Oxford, Nov. 28th.

E. RAY LANKESTER.

* * The results of Dr. Calmette's investigations were stated in a leading article published in the same number of the *JOURNAL* (June 16th, 1895) as Professor Fraser's paper.

THE BATTLE OF THE CLUBS.

SIR.—In April last the Inverness Medical Society unanimously adopted several resolutions relating to medical attendance on members of the clubs and friendly societies in this town; these resolutions were noticed in your columns at the time, and are briefly as follows:

1. An examination fee of 2s. 6d. to be charged all candidates for admission to clubs or friendly societies.
2. That 2s. 6d. a head a year be the minimum sum paid to the medical officer for attendance on members of these societies; this sum not to include medicines; if medicines are supplied, the charge a head to be 2s. 9d.
3. No family branch to be countenanced on any terms, and juveniles to be charged the same as adults.

All the medical men in actual practice in Inverness have signed a pledge agreeing not to accept any appointment unless the club conforms to the terms of the above resolutions. Furthermore, the medical men have also unanimously resolved, in the event of any of the present holders of club appointments being discharged, or their vacating their appointments on account of the society of which they may act as medical officer refusing to adopt the conditions laid down by the Inverness Medical Society, that no medical practitioner in Inverness will accept any such appointments rendered vacant by the discharge of the present holder for at least one year from January 1st, 1896, and after that date these appointments will only be accepted if the societies comply with the conditions above referred to.

The foregoing resolutions were rendered necessary on account of the inadequate remuneration paid to the medical officers of several of the clubs in proportion to the amount of work performed, and also by the rapid growth of the family branch of the friendly societies; this branch of the club system is taken advantage of very largely by members, who are by no means in a position to require medical attendance at reduced rates, and who for a small annual payment get medical attendance for themselves and their families.

The clubs in Inverness were notified of the foregoing resolutions some weeks ago, and evidently consider we are asking too much for our services, as in to day's *Scotman* an advertisement appears asking for a medical officer for several benefit societies. They have combined, and hope to get someone to carry on club work here for a salary which will be totally inadequate and unremunerative in proportion to the amount of work which will be expected from anyone who unfortunately may be got to accept the appointment. The combined salaries of the different medical clubs will not amount to more than £100.

In addition to the stand the Inverness medical men have taken in connection with club abuses, they have also unanimously resolved not to have anything to do with medical aid associations. It is to be hoped, now that the members of the medical profession are becoming alive to the fact that club work at the salaries paid the medical officers is unremunerative, and also that in the majority of clubs a large number of their members are in receipt of incomes which place them quite beyond the necessity of getting medical attendance at reduced rates, a stand will be taken by the profession in different parts of the country, and an effort made to have the salaries of club medical officers raised to a more remunerative rate. What Cork, Eastbourne, Portsmouth, and Inverness have done can be done in other parts of the kingdom, but this is only to be gained by organisation and unanimity amongst the members of our profession.

I do not anticipate that any medical man will be found to accept the appointment of medical officer to the combined friendly societies in Inverness, as the salary attached to the office will probably not be more than £100 a year. Should there be any such, I think it is only right to warn him that besides occupying an unenviable position in the eyes of his professional brethren, he will at the same time find that the work expected to be performed by him will be "sweating" of the hardest description.—I am, etc.,

J. MUNRO MOIR,

Inverness, Dec. 2nd. Hon. Secretary Inverness Medical Society.

SIR,—We are having at Woolwich a contest on the subject of women's clubs. A newly-formed female lodge of the I.O.O.F. was taken on by the local Branch of the Metropolitan Provident Dispensary on the same terms as the rules provided for men's lodges, namely, 4s. a year. After a short time the ladies (who belonged to the superior artisan class, and included several publicans' families) not finding themselves treated with the consideration they had expected, invited the local practitioners to apply for the post of sole medical officer to the club at 4s. a year. Upon this a meeting of medical practitioners was held, at which a resolution was drawn up in the following terms:

The undersigned members of the medical profession residing in the Woolwich district are agreed that it is incompatible with the interests of the profession, as also of the public, to accept any appointment of medical officer to a female club at a lower annual remuneration than 5s. per member; and pledge themselves to abide by this agreement, and to refuse any such appointment at a lower rate.

Every general practitioner in the district gave in his adherence to this resolution, and all but two have signed it. The resolution was not intended to be retrospective, and only to apply to new appointments; but, in consequence of it, the medical officers of the Provident Dispensary gave notice that they could not continue to attend the members of the female lodge of the I.O.O.F. unless they paid 8s. a year.

The matter is still under discussion by the Dispensary Committee, but in all probability the dispensary will agree to the terms of the medical officers, even though it should mean the loss of the club. We are told, however, that we, the doctors, have made a mistake, and are fixing too high a figure for female clubs. We maintain that women who are not in regular work will probably give twice as much trouble as men, and therefore, unless there is a wage limit, they ought to pay at least twice as much. I shall be glad to know from those who have had experience of female clubs whether they find this contention to be correct.

There is no doubt that the club referred to can well afford the payment proposed, but there is some question whether as much can be expected from all female clubs. I should be very glad to learn whether there are any clubs paying as much as 8s.—I am, etc.,

Plumstead, S.E., Nov. 30th.

SIDNEY DAVIES, M.D.

SIR,—The successful issue of the contest at Portsmouth will do much to convince the medical profession that by shaking off their fatal apathy which renders them an easy prey to their enemies, and by honourably standing by one another, many of the evils of which we complain can be overcome. It is a scandal that clubs should have the upper hand of their medical officers—it is a disgrace that the medical profession should have lost control over these and similar associations. But seeing that the medical officer is the essential element of the club system, we can regain control over those bodies that now sweat the profession by organising ourselves against them in a business-like manner. Any extended movement can only be carried through successfully by adopting the more reasonable tactics of "trades unionism." In the British Medical Association we have ready all the organisation we require—what we want to do now is to make use of it. It is essential that we have a central organising body as well as local branches; without the former local exertions will as often meet with failure as with success, for there will be no bond of union. This is the one cardinal fact that is recognised by all associations organised for any common aim. It is so obvious that it may be reckoned a truism.

In July last a resolution was passed at the annual meeting, urging upon the Council the necessity of including among the active labours of the Association those duties which are comprehensively included under the title of "Medical Defence." Previous to this a large number of Branches passed similar resolutions. If members who realise how grave the condition of the medical profession is becoming, and who are anxious to do something to advance the interests of their profession, will propose the resolution at the next meeting of the Branch to which they belong, much good will result. Grumbling and invective are interesting and instructive, but not productive of much good unless accompanied by action. Dissatisfaction is the first step to progress, but to win the prize the second step of exertion must be taken. As a profession we are excellent hands at grumbling, but very difficult to move to do anything for ourselves.—I am, etc.,

Dover, Dec. 1st.

A. G. WELSFORD.

THE GENERAL MEDICAL COUNCIL AND PENAL CASES.

SIR,—In your report of Sir R. Quain's presidential address to the General Medical Council the following passage occurs: "In reference to the subject of the penal cases, which happily are on this occasion but few.....I may mention that there has been, in the opinion of the Penal Cases Committee and the solicitor no well-established case of covering." I am directed to inform you that the Council of the Medical Defence Union reported two extremely grave cases of covering, and that I have written in accordance with my instructions to Sir R. Quain, as President of the General Medical Council, to learn what has become of the cases in question. I may further mention that during the past week I was informed by an

official connected with the Council that the penal cases were to be adjourned until the next session so as to enable the Council to complete its work quickly.—I am, etc.,

A. G. RATHMAN.

General Secretary, Medical Defence Union.
King William Street, Strand, W.C., Dec. 4th.

PROPOSED HOSPITAL FOR CAMBERWELL.

SIR.—We presume that Mr. H. Jephson, who has replied to our letter regarding the South London Hospital, is the promoter of this scheme. He has accused us of misstatements without mentioning what they are, and has not attempted to refute any of our reasons for opposing the project.

On inquiry to-day we find that there are 120 vacant beds at St. Thomas's, and over 100 at Guy's, from want of funds.

We, the "nine medical gentlemen" so frequently and satirically alluded to, beg to subscribe ourselves,

NORMAN B. ELLIOT.	C. PINEL GALLIE.
HENRY B. SHILLINGFORD.	CAMPBELL BOYD.
W. BRAMLEY TAYLOR.	A. BRENCHLEY.
WALTER A. ATKINSON.	FREDK NORMAN.
F. HORTON VILLANUEVA.	

CONVOCATION AND THE NEW UNIVERSITY OF LONDON SCHEME.

SIR.—I am afraid that the notice in the *BRITISH MEDICAL JOURNAL* of November 30th, p. 1374, headed as above, is very likely to mislead those who are not themselves members of Convocation. It states that a meeting of members of Convocation was held on November 25th; and though it is not very clearly stated what the wishes of the meeting were and the place of meeting, and the chairmen are not mentioned, it may be gathered that the feeling of members present was opposed to Lord Playfair's Bill, and that they thought the scheme when arranged should be submitted to Convocation for approval in the manner prescribed for senatorial elections.

It is important to note that this was not a meeting of Convocation duly summoned, but only a meeting of some members of Convocation. Convocation of the University of London was not summoned for, and did not meet on, November 25th. Convocation has not met since May of this year; but the delegates of the Annual Committee of Convocation joined with others of the deputation to the Duke of Devonshire on November 26th, in the view that it was neither necessary nor desirable that the scheme should be referred back to Convocation at all.—I am, etc.,

FREDERICK TAYLOR,

Member of the Annual Committee of Convocation.

Wimpole Street, Dec. 4th.

JOHN HUNTER'S FAMILY.

SIR.—The following extract from a contemporary notebook belonging to one of the members of the Hunter family is, I think, worthy of publication. It was shown me this evening by Miss Hunter-Beillie whilst we were looking over a series of manuscripts belonging to the Hunter, Jenner, and Baron families. She has kindly allowed me to copy the note, which runs in the following words:

John Hunter and Agnes Paul marry'd Dec. 20, 1767. He died Oct. 30, 1793. She dy'd Sunday, Nov. 3; bury'd Wedn., Nov. 6, 1793.
1. Their son John. Born Oct. 5, 1768. Dy'd Feb. 27, 1792.
2. Their daughter Elizabeth. Born Feb. 8, 1770. Dy'd Sept. 12, 1791.
3. Their son Andrew. Born Oct. 4, 1771. Dy'd May 18, 1774.
4. Their daughter James. Born March 10, 1773. She dy'd Saturday, May 27, 1793: was buried Tuesday, May 30.
5. Their son James. Born Thursday, Jan. 1, 1775. Dy'd in Glasgow, Thursday, April 11, and was buried there Saturday, April 14, 1793.
6. Their daughter Agnes. Born July 17, 1776. Dy'd Friday, March 13, 1794: buried March 15, being Tuesday.
7. Their son William. Born May 1, 1778.
8. Their daughter Dorothy. Born Jan. 26, 1780.
9. Their daughter Isabella. Born Dec. 1, 1780. Dy'd Friday, July 20; buried Monday, Aug. 2, 1782.
10. Their son James. Born Feb. 25, 1782.

The note is of very great interest, for it is written by one who apparently obtained his information at first hand. It gives the names and dates of the births and deaths of Hunter's brothers and sisters, some of whom are vaguely alluded to in the various biographies as "having died young." It gives, too, yet another clue for the disputed birthday of John Hunter.—I am, etc.,

Bloomsbury Square, Nov. 17th.

D'ARCY POWER.

INDEX MEDICUS.

SIR.—In the *BRITISH MEDICAL JOURNAL* of November 30th you refer to Messrs. Davis's list of subscribers to the *Index Medicus* which contains only four British subscribers. I fancy this list must be of the old subscribers, for I have sent to Dr. Billings a list of new subscribers which includes a round dozen of orders from British institutions and private persons. Even this result is rather disappointing, but it is much better than Messrs. Davis's list.—I am, etc.,

J. Y. W. MACALISTER,

Resident Librarian

20, Hanover Square, W.

Royal Medical and Chirurgical Society.

A MEDICAL HERO.

SIR.—It will be within the memory of most of your readers that in July last Dr. J. T. Reese of Ystradgynlais, near Swansea, met his death by lightning whilst crossing a mountain during a thunderstorm to attend a burnt child. Such cases do our profession infinite credit, and show that Ian MacLaren's picture of the doctor in *Beside the Bonny River Bank* is not overdrawn. Application is being made to secure the election of one of the sons, Oscar Reese, to Epsom Medical College, and I trust a favourable response will be widely made. My own vote is unfortunately engaged elsewhere.—I am, etc.,

Kington-on-Thames, Nov. 27th.

D. PROBLE.

OBITUARY.

GEORGE R. MATHER, M.D. GLASG., F.F.P.S.G.

THE annual dinner of the Glasgow Faculty of Physicians and Surgeons, held in the Faculty Hall on Friday, November 23rd, was brought to an abrupt and sadly tragic termination by the sudden death of one of the Fellows, Dr. G. R. Mather. He had just resumed his seat, after replying to the toast of the "Army, Navy, and Reserve Forces" and one of the guests, the President of the Art Club, Mr. Tom McKean, had begun a song, when Dr. Mather was observed to be breathing stertorously. He was immediately attended to, but had hardly been removed from the hall when he expired.

Dr. Mather was one of the best known and most popular of the practitioners in the East End of Glasgow. Under any circumstances his death would have evoked evidence of the esteem and affection in which he was held by the people among whom he practised for over thirty years, but the suddenness of his death has made the expression all the more deep and impressive. He was 55 years of age, and had been all his life associated with the East End of Glasgow, where he succeeded his father in a large practice. What leisure he had was devoted to literature and art. He loved art, and gave free play to his passion for the possession of pictures, and his collection was more than once drawn on for illustrations of the Scottish school for exhibition purposes. Two years ago he published a volume on Dr. William and John Hunter entitled *Two Great Scotmen*. He was one of the promoters of the Burns exhibition proposed to be held in Glasgow next year, and he was one of the original members of the Sir Walter Scott Club. Dr. Mather's funeral took place on Tuesday, and, in view of the circumstances attending his death and the fact that he was a member of the Council of the Faculty, it took place from the Faculty Hall, which at the hour of service was thronged by his medical brethren. A representative of the corps of which he was Surgeon-Lieutenant-Colonel was present, and there were also representatives of the other professions, of literature, of art, and of commerce.

THE death, at the age of 77, from typhoid fever, of Dr. VAN DYCK, the Arabic scholar, is announced. He was born in 1818 at Kinderhook, a small town in the town of New York. His father and mother were Dutch, and Dutch was the first language which he spoke. He received his early education at the Kinderhook Academy, from which he proceeded to the Jefferson Medical College, Philadelphia, where he took the degree of M.D. At the age of 20 he was accepted as a missionary by the American Board of Foreign Missions. In 1848 there was an outbreak between the Druses and the Maronites of the Lebanon, and Dr. Van Dyck, who had assumed the native dress, was attending the wounded on both sides.

the subject to show that this was intended. In the absence of fraud or illegality, it may be taken as a clear general rule of law here that where a contract is reduced into writing it is presumed that the writing contains all the terms of it, and evidence will not be admitted of any previous or contemporaneous oral agreement which would have the effect of adding to or varying it in any way. (2) We are doubtful if proceedings would be successful here unless on the clearest evidence of a willful and false assumption of the title. (3) There is nothing to suggest the invalidity of the agreement as a whole. (4) In this country, according to the case of *Davies v. Mann*, L. R. 2 Ch. Div. 504, it is not improbable that proceedings to enforce the bond would be unsuccessful so far as relates to the practice of a "physician." In our opinion it would be undesirable to litigate the matter in any way, and certainly this should be done only on the advice of a solicitor.

CLUBS AND MEDICAL ETIQUETTE.

ASTENISK.—Were a brother practitioner to become an honorary member of a club to which another is the surgeon, and should he then agitate to alter the rules of the society in order to deprive the latter of a portion of the emoluments arising from the office for his own advancement, it would be a serious breach of professional etiquette. Such conduct would be severely condemned as very unworthy of a professional man.

CONSULTING SURGEONS AND GENERAL PRACTITIONERS.

M. P. L. writes: An old patient of mine, Mrs. G., whose medical attendant I have been for nearly fifty years, and on all occasions, discovered that she had a glandular swelling. At the wish of her son, who is practising in a colony, she consulted Mr. X., one of the assistant surgeons at a leading London hospital. He recommended its immediate removal, stating at the same time he would not undertake the operation unless the after-treatment was conducted by some one with whom he had previously worked, and recommending Mr. A., a practitioner in this neighbourhood, living about a mile from the patient's residence, thus altogether ignoring me. Mr. C. called on me, and assured me that this procedure was entirely contrary to the wishes of both himself and his wife, and asking me to call and see the latter occasionally. I did so this morning, and found to my great surprise that the operation was performed yesterday.

"Assuming, as we do, that the above statement justly represents the facts, we may note that, although it was within the right of the surgeon referred to to decline undertaking the operation in question, otherwise than conditionally, he was, in our opinion, unquestionably ethically wrong, and exceptionally discourteous, moreover, in ignoring the patient's old medical attendant.

REFUSING CALL TO OLD PATIENT

A. B. was attending a patient with heart disease, when, without his knowledge, another practitioner, C., was called in and prescribed for the patient. A. B. was asked to attend the patient. A few days later he was rung up early in the morning and asked to go to the patient again. A. B. objected at first, as the care of the patient had been taken out of his hands and had passed into those of C. On being told that C.'s further attendance was declined, A. B. asks whether when rung up he might have declined to go, and what C.'s conduct should have been when he found that A. B. was already in attendance.

"In reply to A. B.'s first question we may note that, although under the circumstances related he would have been justified in declining further attendance on the case, we are distinctly of opinion that in visiting the patient he acted wisely and in the true spirit of the profession. The answer to his second query will be found in the following rule: "When a practitioner is called in to, or consulted by a patient who has recently been, or still may be, under the care of another for the same illness, he should on no account interfere in the case, except in an emergency—having provided for which, he should request a consultation with the gentleman in previous attendance, and decline further attention of the case except in consultation with him."—*M. E. C. C.*, chap. II, sect. 5, rule 2.

B. It would obviously be unethical.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF OXFORD.

The Oxford University Calendar just issued shows that between Michaelmas Term, 1891, and Trinity, 1894, six members of the University proceeded to the degree of M.D. and nine to that of M.B. The honorary degree of M.D. was conferred on Professor Burdon Sanderson on his election to the Regius Professorship of Medicine in succession to Sir Henry Acland. During the same period the honorary degree of D.C.L. was conferred on two members of the medical profession, Sir William Power and Professor Michael Foster. The only change in the professorial staff in the Faculty of Medicine is the transference of Professor Burdon Sanderson and the election of Professor Gotch to the Waynflete Professorship of Physiology.

UNIVERSITY OF CAMBRIDGE.

APPOINTMENTS.—Professor Bradbury, M.D., and Dr. I. E. Shore, of St. John's College, are appointed members of the State Medicine Committee. Dr. A. H. H. M. of Downing College, a member of the Agricultural Science Committee; Dr. D. MacLennan, of St. John's College, a member of the Special Board for Medicine; and Dr. Gaskell, F.R.S., a member of the Special Board for Biology and Zoology.

UNIVERSITY COLLEGE, CARDIFF.

PROPOSED PUBLIC HEALTH DEPARTMENT.—A meeting of representatives of the county councils of Glamorgan and Monmouthshire and the University College, Cardiff, was held recently in the college buildings for the purpose of considering the expediency of instituting a department of public health, in connection with the University College, for the purpose of teaching the higher branches of sanitary science, and also, to sanitary inspectors and medical officers of health. Professor J. H. Jenkins, Chairman of the Glamorgan County Council, presided. Several speakers urged the expediency of instituting a public health department established, Professor H. Jenkins explaining that the department would be about £2,000, that the annual charge would be about £1,000, and that the following resolution was carried: "That in the opinion of this conference it is desirable that a public health department should be established in connection with the University College, but that any further consideration of the scheme should be deferred for the present." It was also decided to call another similar conference representative of the South Wales counties as early as would be deemed expedient.

PUBLIC HEALTH

AND

POOR-LAW MEDICAL SERVICES.

THE AERIAL CONVECTION OF SMALL-POX.

WHAT IS PROOF? Such is the question that must have occurred to many on reading the judgment given by Mr. Justice Kekewich in the case in which the Guildford, Godalming, and Woking Joint Hospital Board were arraigned in respect of their desire to erect a hospital for the treatment of small-pox patients. The question arises because of this desire having been held to be one that has in it no element of danger to the neighbourhood around the hospital such as to lead the law courts to restrain the defendant Joint Board from carrying out their design. The proof that is needed is one that shall satisfy the courts of justice that there is a distinct danger to a locality from a small-pox hospital by reason of atmospheric spread of small-pox therefrom. That there is danger from maladministration of such an institution was held, and the defendants are not to be allowed to use a cottage standing on their hospital site for small-pox patients, lest infection might be communicated to the outside world by personal means. It is true that during the hearing of the case there was evidence given that ought to have had weight with the court as to the inability of medical men of good standing to accept the hypothesis of aerial convection of small-pox. But it must not be overlooked that such evidence was of necessity of a negative rather than of a positive character. It is one thing to say that in some instances there has been no known spread of small-pox around a hospital in use for the treatment of cases of that disease, but it is another to show that the circumstances in which this exemption was found were on all fours with others in which mischief has been held to have accrued.

Whatever may have been the strength of the arguments put forward by those who have little or no faith in the hypothesis of aerial convection, the evidence of others to the contrary was of such character as to have carried the day in favour of the danger of small-pox hospitals to their surroundings being of appreciable quantity. The masterly and detailed reports of Mr. W. H. Power to the Local Government Board on the behaviour of small-pox in the neighbourhood of the Western Hospital of the Metropolitan Asylums Board at Fulham, with the convincing arguments which were backed by circumstantial evidence in abundance, showed that the hospital had been disseminating small-pox around it by means of the atmosphere only. Other instances were those of the Leicester Hospital in the small-pox epidemic of 1892-93, and of the Halifax Hospital at Cuddysfield in a recent small-pox epidemic principally around that building. Then, again, Birmingham furnished another example of the tendency of small-pox to centre round hospitals where cases were being isolated. Only a year or so ago Dr. Bruce Low found the same thing going on near Hastings, and there are but samples of occurrences which go far to show the positive side of the case which was danger in the aggregation of small-pox patients in the vicinity of inhabited dwellings. Among those who gave evidence were Dr. Thorne Thorne and Dr. Bruce Low of the Local Government Board, and their statements should have carried conviction as to the potency for harm of small-pox hospitals. When small populations in the

immediate neighbourhood of a small-pox hospital are concerned, they can be warned of their danger, and the law as to vaccination enforced. But there is no compulsion as to revaccination, and none as to primary vaccination in respect of persons aged over 14 years.

It can never be held that primary vaccination in infancy will avail with absolute certainty to protect against small-pox attacks in persons over 10 years of age. Beside which, the matter would be entirely different where hundreds or thousands of persons were exposed to infection by means of the hospital. According to the decision given, there would seem to be nothing to hinder the erection in populous London districts of small-pox hospitals, and thus save the expense and trouble of the long ambulance and steamer transits of patients down river to the ships. The London small-pox hospitals were only given up after mature consideration and after repeated experience of their dangers. To revert to the old order of things would, we venture to assert, be a retrograde step of great magnitude. True that an absolute enforcement of our vaccination laws, and of revaccination into the bargain, would do something, nay much, to reduce the amount of danger to be apprehended from small-pox hospitals wherever set up; but then these measures would at the same time render small-pox hospitals but little needed at all. Hence, we would wish to see the two combined—namely, vaccination and revaccination universally enforced, and small-pox hospitals removed as far as possible from centres of population. Unless these things be done, we fail to see how danger is to be avoided pending the destruction of all air leaving the hospital wards prior to its mixing with the general atmosphere, and we seem as far as ever from the accomplishment of this destruction.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns, including London, 5,690 births and 3,690 deaths were registered during the week ending Saturday November 30th. The annual rate of mortality in these towns, which had declined from 23.1 and 19.0 per 1,000 in the three preceding weeks, further fell to 17.9 last week. The rates in the several towns ranged from 11.5 in Croydon, 12.2 in Brighton, and 12.5 in Portsmouth to 22.7 in Preston, 23.3 in Liverpool, Salford, and Oldham, and 29.0 in Blackburn. In the thirty-two provincial towns the mean death-rate was 23.4 per 1,000, and exceeded by 1.1 the rate recorded in London, which was 17.3 per 1,000. The zymotic death-rate in the thirty-three towns averaged 2.6 per 1,000; in London the rate was equal to 2.8 per 1,000, while it averaged 2.9 in the thirty-two provincial towns, and was highest in Salford, Wolverhampton, and Blackburn. Measles showed a death-rate of 2.2 in London, 2.4 in Wolverhampton, 2.5 in Salford, and 2.0 in Blackburn; whooping-cough of 1.2 in Wolverhampton, and 1.3 in Leeds; and "fever" of 1.1 in Sunderland, and 1.2 in Wolverhampton. The 93 deaths from diphtheria in the thirty-three towns included 63 in London, 6 in Birmingham, 3 in West Ham, and 3 in Sheffield. Two fatal cases of small-pox were registered in West Ham, and 1 in London, but not one in any other of the thirty-three large towns. The number of small-pox patients in the Metropolitan Asylums Hospitals and in the Highgate Small-pox Hospital, which had been 78, 53, and 59 at the end of the three preceding weeks, had declined to 70 on Saturday last, November 30th; 9 new cases were admitted during the week, against 14, 23, and 26 in the three preceding weeks. There were 2,395 scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and in the Locksley Fever Hospital on Saturday last, against 2,507, 2,583, and 2,577 at the end of the three preceding weeks; 325 new cases were admitted during the week, against 349, 293, and 286 in the three preceding weeks.

HEALTH OF SCOTCH TOWNS.

DURING the week ending Saturday last, November 30th, 618 births and 593 deaths were registered in eight of the principal Scotch towns. The annual rate of mortality in these towns, which had declined from 21.4 to 18.1 per 1,000 in the three preceding weeks, further fell to 17.4 last week, and was 0.5 per 1,000 below the mean rate during the same period in the thirty-three large English towns. Among these Scotch towns the death-rates ranged from 11.4 in Leith to 21.0 in Perth. The zymotic death-rates in these towns averaged 1.7 per 1,000, the highest rates being recorded in Aberdeen and Greenock. The 219 deaths registered in Glasgow included 9 from whooping-cough, 3 from scarlet fever, and 2 from "fever." Four fatal cases of scarlet fever were recorded in Edinburgh, and 2 of diphtheria in Dundee.

THE WATER SUPPLY OF CHESTERFIELD.

AT a recent meeting of the Chesterfield Town Council, the subject of the apprehended scarcity of water for the supply of the borough was under consideration. Some correspondence between the Town Clerk and the officers of the water company was read, and ordered to be entered on the minutes. In a letter dated October 19th from the Town Clerk, it was stated that the medical officer had reported to the Health Committee that portions of the borough had been without a supply of water from the company's service for upwards of two months, and that the health of the inhabitants had suffered in consequence. "If it should become necessary," the letter continued, "to obtain water from the old wells of the borough in order to meet the needs of the people, I am directed to

ask whether the water company will join with the council in the cost to be incurred." To this the company replied that it was doubtful whether they had power to join with the council in the cost suggested, and that it was hoped the usual autumn rains would gradually remove all grounds for anxiety. It was resolved by the council that the borough medical officer of health should be authorised to take all necessary steps to ensure the best practicable supply of water to the inhabitants of the borough.

CONDENSED SKIM MILK.

WE are glad to see that, following up our recent reports on condensed milk, the quarterly report of Mr. Stokes, analyst to the Paddington Vestry, draws special attention to some of the brands of condensed skim milk which find their way to the homes of the people. His analysis showed that nine-tenths of the cream had been abstracted from some of his samples, that 800 parts were boiled down to 100 parts, and 40 parts of sugar were added. The labels on the tins described the contents as "condensed skim milk and sugar." There can be no doubt that much of this mixture is used to feed infants, for which it is wholly unfitted. It has, however, a sweet flavour, and, having also the appearance of milk, it is much in demand among inexperienced mothers. Those who buy such an article are, perhaps, not aware that infants would starve if fed upon it exclusively. Several recent inquests have shown that this so-called condensed milk has contributed to the deaths of children. Condensed "whole milk," which has been successfully used as food for infants, is one thing, and condensed skim milk and sugar another.

THE ANTITOXIN TREATMENT OF DIPHTHERIA AND THE NEW YORK DEATH-RATE.

THE President of the New York Health Department has presented a report to the Mayor, in which it was stated that the use of antitoxin had reduced the death-rate from diphtheria and croup in the city of New York nearly 44 per cent. The antitoxin employed is produced in the bacteriological laboratory of the Board of Health, under the direction of Dr. Herman M. Biggs. The following table shows the cases of diphtheria and croup, and the mortality therefrom, for the first three-quarters of the years 1891, 1892, 1893, and 1894, as compared with the first three-quarters of the present year:

	Cases.	Deaths.	Per Cent.
1891	3,686	1,349	36.59
1892	4,155	1,840	37.04
1893	4,721	1,769	37.34
1894	7,446	2,284	30.67
1895	20,011	6,986	34.66
	7,591	1,643	19.43

The report proceeds: "The reduction in the mortality rate for the first, second, and third quarters of 1895, as compared with the average death-rate for corresponding periods of the previous four years, has been 43.94 per cent. If the death-rate from diphtheria and croup during the first, second, and third quarters of 1891-94 had been the same as in 1895, there would have been 3,045 fewer deaths in that period. The large reduction in the mortality rate from diphtheria and croup for the first three quarters of 1895 is attributed mainly by the medical officers of this department to the introduction and use of diphtheria antitoxin, and if this remedy had been generally or universally employed the reduction in the mortality-rate would doubtless have been larger."

THE BACTERIOLOGICAL DETECTION OF DIPHTHERIA.

SOME time ago Professor Wynter Blyth, Medical Officer of Health for St. Marylebone, reported to his vestry in favour of putting at the disposal of the practitioners in the district the means for arriving at a complete bacteriological diagnosis in cases of suspected diphtheria. We understood that this recommendation has now been adopted by the vestry, and that each medical man in the parish will shortly receive a "diphtheria outfit," consisting of a sterilised test tube fitted with a cork carrying a wire holding a little sterilised cotton wool. This wool is to be gently applied to the affected part, and then replaced in the test tube, which is then to be forwarded to the bacteriological laboratory for examination. It will be observed that this arrangement is a simplification of the New York plan in so far that the inoculation of the culture is done at the laboratory and the medical man has only to infect the swab and forward it. The bacteriological diagnosis of diphtheria ought to have been long ago undertaken in London as it has in some provincial towns. This is a step in the right direction, but the fact must not be overlooked that, as has been well shown in Bristol, while the demonstration of the presence of the diphtheria bacillus is to be taken as proof of the diphtherial nature of the malady, its absence is by no means to be accepted as showing the innocence of the disease. There are, however, so many cases of true diphtheria in which the clinical evidences of the nature of the case are but vague that it will be of great advantage to the community that a certain means of diagnosis of such cases should be placed at the disposal of the profession.

COUNTY COUNCILS AND COMPULSORY NOTIFICATION.

THE Wiltshire County Council have once again had before them the question of the non-adoption of the Infectious Disease (Notification) Act by some of the district councils in the county. We are glad to see that they maintain their attitude towards the matter, deeming those councils who have persisted in their refusal to adopt the Act as "standing in the way of a general system of public health for the whole county." The county authority are desirous of getting into workable order a scheme whereby the health officers of the several sanitary areas shall communicate with the clerk of the county council whenever infectious disease breaks out, so that information can then be sent to all the constituent districts apprising them of the facts. And in this again the adoption of notification would materially assist the health officers in their endeavours to send complete and reliable information. But here the county council fails in one very important particular, inasmuch as it has not yet appointed a county health officer. It has, it is true, em-

played a medical man for the purpose of "codifying" the reports of the district officers. But a county wants something more than a medical précis writer. Not until the county authority have made good this deficiency will they be in a strong position to influence backward constituent health bodies for good.

SALARY OF POOR LAW MEDICAL OFFICER.

PUZZLE.—It would certainly seem that the amount paid by the Board is very inadequate; four guineas a year for the medical charge of a district with a population of between three and four hundred, mostly paupers, can scarcely be regarded as remuneration at all. It is sad to think that such a scale of payment is possible in the Poor Law Medical service. Our correspondent should investigate the salaries paid to their medical officers by other unions throughout the county, and claim at least to be paid on the same scale as they are, and if unsuccessful in this, should appeal to the Local Government Board.

MEDICAL APPOINTMENT TO A PAUPER FEVER HOSPITAL.

A. asks whether he has committed any breach of professional etiquette in claiming to be appointed medical officer to a fever hospital under the following circumstances:

A. is a district medical officer, in whose district there is a town of 6,000 inhabitants. The sanitary authority of this town has erected a fever hospital in B's medical district, two miles from A's residence and three miles from B's. A considers that, as at present arranged all the patients in the hospital will be from his district, he has the first claim for the appointment as medical officer of the hospital. B also claims this on the ground that the hospital is in his district.

Q. We are of opinion that as long as the hospital is for patients from A's district only, he has the first claim for the appointment, but should any arrangements be made (and this appears likely) for other patients to be admitted, A's claim for attendance on such might not be equitable or reasonable.

HOSPITAL AND DISPENSARY MANAGEMENT.

THE NEW ASYLUM FOR THE COUNTY OF LONDON.

The building of the new asylum for London at Bexley to house 2,000 patients is just about to be commenced. The main building is designed on the continuous principle combined with villas. The main building is to provide for 1,845 patients, and there are provided one villa for 35 farm workers on the male side, two villas each for 35 women, and a special hospital villa for 50 women, making a total of 1,100 women and 900 men. The patients' blocks are all two storeys high, and are divided into wards for the (1) infirm, (2) acute, (3) epileptic, and (4) chronics and working. An isolation hospital is also provided for, and a mortuary. The whole of the east, south, and west sides of the building are confined entirely to the patients. The building is to be completed with the least possible delay, as the asylum is urgently needed.

THE GREAT NORTHERN CENTRAL HOSPITAL.

According to the *Edinburgh Gazette*, a question was asked at the last meeting of the Islington Board of Guardians in reference to a circular letter sent out by Robert H. Bax, of 57, Finsbury Park Road, in which it was alleged that in the preparation of the balance sheet of the Great Northern Central Hospital a sum of £209 9s. 11d., described as for sundries, alterations, and repairs, included a sum of £119 9s. 9d. paid to the late secretary as commission in addition to his other salary. £275 having been deducted as commission from the legacy of the late Mr. R. A. Newbon. As to the facts we can give no opinion, but there need be no hesitation in saying that any hospital committee which entered into such a lax agreement with its secretary as to make such a payment possible was guilty of culpable want of foresight.

INDIA AND THE COLONIES.

INDIA.

SANITARY APPOINTMENTS IN BENGAL.—The *Indian Medical Gazette* writes: The reduction in the number of the deputy sanitary commissioners and the transference of vaccination duties to civil surgeons, who are overburdened already with State duties, have been distinctly retrogressive measures, and not conducive to the best interests of the inhabitants over which the Government rules; and now that these changes have been followed by the appointment of a surgeon-captain as sanitary commissioner, which is calculated to lower the status and curtail the powers of the sanitary commissioner, the retrogression has been accentuated. If this is the policy which the Bengal Government intends to carry out, it must have been decided on without a due consideration of the great health interests at stake; and it can only be characterized as extremely ill advised, and one which it will be the duty of all interested in preventive medicine to use their influence to reverse.

THE PROPOSED SANITARY REFORMS.—The proposal of the Government to abolish a considerable number of deputy sanitary commissionerships in order to raise funds for the establishment of a bacteriological institute at Agra is, says the *Times of India*, one which, if it has really been seriously entertained, is certain to come in for no small amount of severe criticism. Sanitation is still so backward in this country that even a bacteriological institute, valuable as it would undoubtedly be, would be too dearly bought at the price proposed. Even so it is the existing sanitary staff and it is impossible to accomplish more than a tithe of the work which lies at their hands, and in some instances the removal of the deputy sanitary commissioner would mean the practical cessation of detailed sanitary work, and all the good which might be achieved by the

bacteriology and would be counteracted by the evil involved in depriving the country of the already sufficiently meagre protection it may derive from sanitary work.

HOSPITALS IN NATIVE STATES.—Sir Dennis Fitzpatrick, during a recent visit to the native State of Nabha, opened a hospital, which has been erected by the Rajah at a cost of Rs. 10,000 to commemorate the visit of Lord Lansdowne to Nabha. The Nabha has already constructed seven hospitals for out-patients, and this new hospital will be mainly for in-patients. In declaring the hospital open Sir Dennis Fitzpatrick said that he would inform Lord Lansdowne of the fact that the hospital had been erected in his honour.

THE MOHAMMADAN AND THE PILGRIM BILL.—The Viceroy of India, in replying to an address presented to him on November 22nd by a delegation of the Mohammedans of Mysore, expressing the desires of that community for the Pilgrim Bill, said he hoped that all doubts had now been removed from the minds of the Mohammedans of India that they need expect anything from the Imperial Government but sympathy and honest endeavour to serve their best interests.

NEW SOUTH WALES.

LEPROSY.—The last report of the Board of Health for New South Wales states that all known cases of leprosy in the Colony are now segregated in the Lazarat. Five new patients were admitted to the Lazarat during last year—a smaller number than in any year since the Leprosy Act came into force. This fall in the number of admissions supports the view taken by the Board that the comparatively large increases during the years 1891 and 1892 were not an indication of the spread of the disease, but were due to the fact that the Act rendered the reporting of all cases compulsory. Altogether 55 lepers have been treated in the Lazarat since 1885; of this number, 29 were natives of China, 15 of New South Wales, 2 of India, and 1 of New Zealand. Of Java, of New Caledonia, of Fiji, of the Solomon Islands, of the West Indies, of England, and of Germany respectively. Clinical notes of the five cases admitted in 1894 are given in a separate report drawn up by the Chief Medical Inspector, Dr. Ashburton Thompson. Two of the patients were born in Australia, one in Sarony (resided in Australia since 1859), one was a New Caledonian aboriginal (in the Colony about one year), and one a native of London, who had been in Australia since 1892. As to one of the cases in a patient born in Australia Dr. Ashburton Thompson adduces evidence, collected with great industry, which renders it highly probable that the patient's elder brother suffered from leprosy, and some further facts which appear to bring the cases into some relation with another case, that of the son of a German immigrant, who died of the disease.

MEDICAL NEWS.

DR. HAFKIN, who has been carrying out the preventive inoculations against cholera on an extensive scale in India, will arrive in London on December 10th, and will be the guest of Mr. Ernest Hart, 38, Wimpole Street, W., where communications may be addressed to him.

A MUNIFICENT OFFER.—At a meeting of the directors of the Newport Infirmary, held on Tuesday, November 26th, the question of enlarging the present building was discussed. Dr. Garrod Thomas, J.P., offered, on behalf of himself and his wife, to contribute £5,000 towards the erection of another building in a different part of the town, the present one being unsuitable on sanitary and other grounds. This offer, it is stated, is conditional upon £15,000 being provided by public subscriptions.

UNDERFEED CHILDREN.—An appeal is being made on behalf of the funds of the National Food Supply Association, which lays itself out to provide wholesome food to poor children attending elementary schools. The Association has three large centres, where 12,000 meals a day can be turned out. The food—soup, pudding, and the like—conveyed in asbestos tin carriers, arrives hot at its destination, mostly schools and poor homes. A charge of one penny is made, except in the most desperate cases, and thus the independence of both parents and children is preserved.

"DRUNK AND INCAPABLE."—A farm servant, aged 60, died in the Peterhead Police-office on December 2nd. He had come in from a neighbouring village on November 30th or December 1st, and on the latter day he was seen going about. On December 2nd he fell, and struck his head heavily on the edge of the pavement. He was taken to the police-office and placed in a cell as incapable. Truly he was. The necropsy, however, revealed that he was incapable because his fall had caused fracture of the cranium and hemorrhage in and about the membranes.

SUICIDE AT THE EDINBURGH ROYAL INFIRMARY.—A most unfortunate case of suicide occurred at the Edinburgh Royal Infirmary on November 30th. A young married woman, who had been confined three months before, was under treatment for myxodema in a top flat ward. She was observed to be a

little strange in her manner, but there was nothing to suggest suicide. At 8 A.M. she suddenly pulled up the lower part of the window beside her, and threw herself out. The fall was not less than 43 feet. Several fractures and internal injuries caused her death six or eight hours after the accident. No blame can be attached to anyone in connection with what was evidently a sudden suicidal impulse.

LIFE ASSURANCE MEDICAL OFFICERS' ASSOCIATION.—The following officers and council have been elected:—*President*: Dr. Douglas Powell. *Vice-Presidents*: Drs. Boon, Crosby, and Symes Thompson. *Treasurer*: Dr. Theodore Williams. *Council*: Drs. C. Y. Bliss, R. W. Burnet, H. Fox, C. E. Hoar, G. A. Heron, F. de H. Hall, M. Murray, J. E. Pollock, G. V. Peore, N. West. *Secretaries*: Drs. T. G. Lyon and H. G. Mackenzie.

OPENING OF A CREMATORIUM AT GLASGOW.—The new crematorium at Glasgow, to which brief reference was made last week, is of red stone in the Gothic style of architecture, and stands in the western necropolis of Glasgow at Maryhill. The chapel is cruciform, and contains in the centre a catafalque, on which the coffin is placed during the service. Afterwards it is lowered into the vaults below, in which are placed the incinerating chambers. The work has been carried out under the direction of Mr. James Chalmers, I.A., and is the property of the Scottish Burial Reform and Cremation Society, Limited. The building was formally opened by Sir Charles Cameron, Bart., who was supported by Sir Henry Watson, Sir Henry Littlejohn, Medical Officer of Health, Edinburgh; the Right Rev. Dr. Donald Macleod, Rev. Dr. John Hunter, Ballie Bilsland, and other well-known gentlemen, in the presence of about 500 to 600 persons. The Cremation Society of England was also well represented. Sir Charles Cameron, in performing the opening ceremony, said the erection of the crematorium marked the entrance of the cremation movement in Scotland into a practical stage. It was a duty to inculcate by precept and example the necessity of reform in the matter of the prevalent method of disposing of the dead—a method to the dangers and drawbacks of which only long custom could reconcile an educated community; a method which abstracted hundreds of fertile acres from the land of the country available for the support of the living, and changed them into pestiferous storehouses for the germs of deadly diseases, which every dictate of reason and humanity should prompt to exterminate and destroy.

THE LIVINGSTONE COLLEGE.—The annual meeting of this institution was held recently at Stratford, where the new premises, which were opened on the same occasion, are situated. The work of the College has for some time been carried on at Bow, but owing to the extension of its work it has been found necessary to remove to Hamfrith Road, where a large house has been secured which will, it is hoped, prove sufficient for its purpose for some time to come. On the occasion of the opening a *conversazione* took place at the new College, the principal, Dr. Charles Harford-Battersby, receiving a numerous company, who had been invited to meet Captain Lugard and the Rev. Horace Waller. The object of the College is to provide those who definitely intend to become foreign missionaries with some elementary training in medical subjects. It is not intended for the training of "medical missionaries," but for giving enough knowledge of medicine and surgery to enable missionaries to look after their own health, and to render help to others when they are in isolated stations far from any qualified medical aid. The major part of the work of tuition is done by the Principal and Mr. McAdam Eccles, but in the third term lectures are also given by Dr. Patrick Manson and others. Clinical work is done at the West Ham and Poplar Hospitals, and visits are also made to the Shadwell Medical Mission and other institutions. The College appears to be doing a useful work in a quiet and unobtrusive fashion, and it guards against abuse by requiring those who enter "to sign a declaration that they will not take to themselves the title, or otherwise assume the position, of a qualified doctor."

The annual dinner of the Harveian Society of London took place at the Café Monico on November 28th. Sir J. Williams, Bart., President, in the chair. Sir J. Orichton Browne proposed the toast of the evening, "Success to the Harveian

Society," which, he said, was most ably fulfilling its educational purpose for the medical practitioner. Mr. Edmund Owen proposed the "Visitors," and Mr. Charters Symonds (President of the Harveian Society) responded. Mr. G. Eastes gave the "Sister Societies," the value of which to medical science, the profession, and the public was beyond all computation. Mr. Jonathan Hutchinson replied, and strongly urged all his hearers, especially the younger ones, to cultivate the societies. Mr. Howard Marsh proposed the "Health of the President," who made a suitable reply. Dr. Gee proposed the "Treasurer" and Mr. Cripps Lawrence, in reply, stated that the Society was now for the first time in many years free from debt. He proposed the last toast, the "Honorary Secretaries," to which Mr. Peyton Beale and Dr. Cagney replied.

SMALL-POX AT RIO JANEIRO.—The captain of the steamship *Haukhurst* arrived on November 29th at Galveston from Rio Janeiro, and reports a terrible epidemic of small-pox at Rio. He states that the deaths number 150 daily, and the disease is spreading to such an extent that the inhabitants are in a condition bordering on panic.

MEDICAL VACANCIES.

The following vacancies are announced:

- BATH ROYAL UNITED HOSPITAL.**—Resident Medical Officer. Appointment for three years. Salary, £100 per annum, with board, lodging, and washing. Applications to the Secretary-Superintendent by December 17th.
- CENTRAL LONDON OPHTHALMIC HOSPITAL, 28A, Gray's Inn Road, W.C.**—House-Surgeon. Rooms, coal, and light. Applications to the Secretary by December 10th.
- CITY ASYLUM, Birmingham.**—Resident Clinical Assistant; must be qualified. Board and residence provided. No salary. Applications to the Medical Superintendent.
- CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, Victoria Park, E.**—House-Physician. Appointment for six months. Board and Residence provided and salary at the rate of £80 per annum. Applications to the Secretary by December 12th.
- DENTAL HOSPITAL FOR LONDON, Leicester Square, W.C.**—Assistant Dental Surgeon; must be L.D.S. Applications to J. Francis Pluk, Secretary, by January 6th.
- DENTAL HOSPITAL FOR LONDON AND LONDON SCHOOL OF DENTAL SURGERY, Leicester Square, W.C.**—Demonstrator. Honorarium, £20 per annum. Applications to J. Francis Pluk, Secretary, by January 6th.
- DERBYSHIRE ROYAL INFIRMARY.**—Resident House-Surgeon and Resident House-Physician; doubly qualified. Appointments tenable for twelve months, with a possibility of extension. Salaries, £100 and £80 per annum respectively, with apartments and board. Applications, endorsed "House-Surgeon" or "House-Physician," to Walter G. Carni, Secretary, by December 21st.
- ENNIS DISTRICT LUNATIC ASYLUM.**—Assistant Medical Officer, doubly qualified, unmarried, and not more than 30 years of age. Salary, £100 per annum, with furnished apartments, rations, washing, fuel, light, and attendance. Applications to Dr. Geleston, Resident Medical Superintendent, by December 12th.
- EVELINA HOSPITAL FOR SICK CHILDREN, Southwark, S.E.**—Four qualified Clinical Assistants and eight unqualified Clinical Clerks in the Out-patient Department. Applications to the Secretary by December 17th.
- GLASGOW EYE INFIRMARY.**—Resident Assistant House-Surgeon. Salary £20 per annum, with apartments and board. Applications to William George Black, Secretary, 55, West Regent Street, Glasgow, by December 10th.
- HARTLEPOOL HOSPITAL.**—House-Surgeon. Salary, £20 per annum, with board, lodging, and washing. Applications to Robert Edger, Honorary Secretary, 15, Town Wall, West Hartlepool.
- NORTH-EASTERN HOSPITAL FOR CHILDREN, Hackney Road, Shoreditch, N.E.**—House-Physician; doubly qualified. Appointment for six months; at the expiration of this term he will be required, if eligible, to serve as House-Surgeon for a further period of six months. Salary as House-Physician at the rate of £20, and as House-Surgeon at the rate of £20 per annum. Junior House-Physician for six months; doubly qualified. No salary, but board and lodging, including washing, provided. Also Ophthalmic Surgeon; must possess surgical qualification. Applications to the Secretary, 27, Clement's Lane, E.C., by December 9th.
- NORFOLK AND NORWICH HOSPITAL.**—House-Physician and House-Surgeon; doubly qualified; unmarried, and under 30 years of age. Salary for each office, £20 per annum, with board, lodging, and washing. Applications to Poole Gabbett, Secretary, by December 10th.
- ROYAL BERKS HOSPITAL, Reading.**—House-Surgeon and House-Physician. Salary in each case £20 per annum, with board, lodging, and washing. Also Assistant Medical Officer, with board, lodging, and washing provided, but not salary. Appointments for six months. Applications to the Secretary before December 9th.

ST. MARK'S HOSPITAL, City Road, E.C.—House-Surgeon; must possess a surgical qualification. Salary, £50 per annum, with board and lodging. Applications to the Secretary by December 9th.

SWANSEA GENERAL HOSPITAL—House-Surgeon. Salary, £50 per annum, with board, residence, washing, and attendance. Applications to Jno. W. Morris, Secretary, 9, Castle Street, Swansea, by December 14th.

WARNEFORD HOSPITAL, Leamington.—House-Surgeon. Salary, £100, with board, lodging, and washing. Appointment for six months subject to re-election. Applications to the Secretary before December 14th.

WEST LONDON HOSPITAL, Hammermith Road, W.—House-Physician and House-Surgeon. Appointments for six months. Board and lodging provided. Applications to R. J. Gilbert, Secretary-Superintendent, by December 14th.

YORK LUNATIC ASYLUM, Bootham, York.—Assistant Resident Medical Officer. Salary, £100 per annum, with board, washing, and attendance. Applications, addressed to the Committee, to be sent under cover to E. D. Horne, Secretary, by December 14th.

MEDICAL APPOINTMENTS.

BADCOCK, Mr. E. R., appointed Assistant Medical Superintendent for the Infirmary of the Lewisham Union.

BRYAN, Richard, I., R.C.P. Lond., M.R.C.S., reappointed Medical Officer of Health to the Lydd Town Council.

BROWN, Robert C., M.B., B.Sc., B.A. Camb., appointed Senior House-Surgeon of the Blackburn and East Lancashire Infirmary.

BROWNING, Benjamin, I.R.C.P. Lond., M.R.C.S. Eng., D.P.H.R.C.P. Edin., reappointed Medical Officer for the Melcombe District of the Weymouth Union.

BRIDGMAN, P. Stedman, M.B., C.M. Glasg., appointed Additional Assistant Medical Officer to the Town's Hospital, Glasgow.

COLE, T. W., B.A. Dub., M.B., B.Ch., appointed Medical Officer of Health to the Hanover District Council.

DARR, Frederick, M.D. Cantab., F.R.C.S. Eng., appointed Honorary Consulting Surgeon to the Starborough Hospital and Dispensary.

DICKIN, E. P., M.B., C.M. Edin., M.R.C.S. Eng., I.R.C.P. Lond., appointed House-Surgeon to the General Infirmary, Northampton.

ELLIOTT, T. W., appointed Medical Officer for the Tonbridge Union, *vice* Peters, resigned.

FENNER, Dr. R. N., reappointed Medical Officer for the Northrepps District of the Beckham Union.

FULTON, Dr., appointed Medical Officer of Health to the Stevenston Parish (Glasgow).

GREGG, John W., M.B., C.M. Edin., appointed Junior Assistant Medical Officer to the Durham County Asylum, Winterton, Ferryhill.

HAMILTON, W. Crosbie, M.B., C.M. Edin., appointed Senior House-Surgeon of the South Devon and East Cornwall Hospital, Plymouth.

HARPER, W. E., M.D. McGill, I.R.C.P.I., appointed Medical Officer of Health to the Tyne Port Sanitary Authority, *vice* H. E. Armstrong.

HAWKES, J. E., M.B., C.M. Edin., appointed Junior House-Surgeon of the Blackburn and East Lancashire Infirmary.

JARDINE, Robert, M.D. Edin., M.R.C.S. Eng., F.F.P.S. Glasg., appointed Assistant Physician to the Glasgow Maternity Hospital.

LYONS, Edward, B.A., M.B., B.Ch., B.A.O.T.C.D., L.M. (Rotunda), appointed Junior Assistant Surgeon to the Jervis Street Hospital, Dublin.

MACRAY, Fred, W., appointed Ophthalmic Surgeon to the Western Dispensary, Edinburgh.

PATTERSON, G. H., I.R.C.P. Lond., M.R.C.S. Eng., reappointed Medical Officer of Health for the Dalmeny-Furness Urban District.

PERKINS, C. J., I.R.C.P., L.R.C.S.I., appointed Certifying Factory Surgeon for Kingwood, St. George, *etc.*, *vice* Henry Grace, L.R.C.P. Lond., M.R.C.S. Eng., deceased.

PITCHAM, John W., I.R.C.P. Lond., M.R.C.S., reappointed Medical Officer for the Upway and Chelmsford District of the Weymouth Union.

PITCHAM, Dr., appointed Medical Officer for the Weymouth District of the Weymouth Union, *vice* A. K. Prury, L.R.C.P., L.R.C.S. Edin., resigned.

PITCHAM, Dr., appointed Medical Officer of Health for the No. 3 District of the Bridgwater Union.

PITCHAM, Dr., appointed Medical Officer for the Marchard Bishop District of the Crediton Union.

RIMMON, E. P., M.D. Dub., M.R.C.S. Eng., reappointed Medical Officer for the Workhouse and Wyke District of the Weymouth Union.

SMITH, J. A., M.R.C.S. Eng., F.S.A., appointed Medical Officer for the Foston District of the Wakefield Union.

TAY, James Scott, M.D. Durh., M.B., M.R.C.S., appointed Medical Officer of Health for the Barncliffe and Southborough, Teesdale, and Tonbridge Urban Sanitary Districts and the Barncliffe (Teesside) Municipal Sanitary District, Teesdale, and Tonbridge Rural Sanitary District.

TAYLOR, Louis, M.D., M.B., C.M., appointed Physician for Diseases of the Ear and Throat, Western Dispensary, Edinburgh.

WATTS, H. Randall, M.R.C.S. Eng., I.R.C.P. Lond., reappointed Resident House Physician to the Great Northern Hospital, N.

WATTS, David, M.B., C.M. Edin., appointed Assistant Physician, Western Shin Hospital, London, W., appointed Physician.

WHITFIELD, George, Cecil, M.D. Lond., M.R.C.S., I.R.C.P., appointed Honorary Medical Officer to the Kiburn, Naida Vale, and St. John's Wood Dispensary.

WILLIAMS, W. T., M.R.C.S. Eng., appointed Medical Officer for the Second District of the Township of Manchester.

DIARY FOR NEXT WEEK.

MONDAY.

MEDICAL SOCIETY OF LONDON, 5.30 P.M.—Mr. Thomas Bryant: On the Diagnosis and Treatment of Early Cancer and Cysts of the Breast.

TUESDAY.

THE CLINICAL MUSEUM, 211, Great Portland Street—Open at 3 P.M. Lecture at 4.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, 20, Hanover Square, W., 8.30 P.M.—Adjourned discussion on the treatment of the Latency of Parasitic Germs of Special Pathogenic Animal Tissues, as the Hydatid, the Trypanosome, the Leprosy, Ringworm, Tuberculosis, etc.

WEDNESDAY.

LARYNGOLOGICAL SOCIETY OF LONDON, 20, Hanover Square, W., 5 P.M.—Cases, specimens, etc., by Mr. Crosswell Baber, Dr. J. B. Ball, Dr. Clifford Beale, Dr. Dundas Grant, Mr. De Santis, Dr. de Villand Hall, Mr. Walter G. Spencer, Mr. Charles Symonds, Dr. E. B. Waggett, and Dr. W. A. Willis.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen Square, W.C., 3 P.M.—Lecture by Dr. Gowers.

HOSPITAL FOR CONSUMPTION, Brompton, S.W., 4 P.M.—Dr. Sidney Martin on Tuberculous Disease.

WEST LONDON HOSPITAL, Hammermith, W., 5 P.M.—Mr. Bidwell: Intestinal Anastomoses (Post-Graduate Course).

THURSDAY.

HARVEIAN SOCIETY OF LONDON, 8.30 P.M.—Dr. M. Handfield-Jones: Second Harveian Lecture on the Heart in its Relation to Pregnancy, Parturition, and the Puerperal State.

BRITISH GYNÆCOLOGICAL SOCIETY, 20, Hanover Square, W., 8.30 P.M.—Specimens by Dr. Smyly (Dublin). Mr. William Armstrong (Buxton): On Utero-Ovarian Irritation as a Factor in the Causation of Rheumatoid Arthritis and the special Treatment necessitated thereby.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM, 11, Chandos Street, W., 8 P.M.—Clinical evening: Mr. Hartridge: Case of Retinitis Circinata. Mr. Ernest Clarke: Rare Form of Nystagmus. Mr. Grimsdale: Rare Form of Nystagmus. Dr. R. D. Batton: (1) Unusual Form of Choroiditis; (2) Paralysis of the Third Nerve, with Spasm of Accommodation. Mr. Marcus Gunn: Case of Embolism of the Central Artery of the Retina. Mr. Holmes Spicer: Case of Retrobulbar Neuritis. Dr. Ormerod and Mr. Holmes Spicer: Recurrent Paralysis of the Third Nerve, with Myopia. Dr. Donald Gunn: Peripapillary Choroiditis. Messrs. Silcock and Marshall: (1) Greenish Lenticular Opacities; (2) Exophthalmic Goitre in a man; (3) Coloboma of Iris with Localized Bulging of the Lens. Mr. Spencer Watson: Specimen of Eyeball lost after Penetrating Wound. Mr. Shell: Alveolar Carcinoma of Upper Eyelid.

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY, Great Northern Central Hospital, Holloway Road, N., 8 P.M.—Dr. C. E. Beavor: On Arsenical Neuritis. Dr. Thomas Hamilton: On Abdominal Suppuration.

FRIDAY.

CLINICAL SOCIETY OF LONDON, 20, Hanover Square, W., 8.30 P.M.—Dr. Hale White and Mr. Golding-Bird: A Case of Membranous Collitis treated by Night's Anodyne and Sulphate Course of the Wound. Dr. Lee Jackson: Two Cases of Spontaneous Thrombosis of the Cerebral Veins and Sinuses in Children. Mr. R. Barwell: A Case of Congenital Median Cervical Fistula; operation, recovery. Mr. R. Einger and Dr. A. G. Fisher: A Case of Addison's Disease treated with Suprarenal Extract (with an abstract of previously recorded cases).

EPIDEMIOLOGICAL SOCIETY OF LONDON, 11, Chandos Street, W., 5 P.M.—Dr. Walter Dowson: On Diphtheria in Older and Newer Bristol (notified cases for the five years 1890-94).

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 2s. 6d., which sum should be forwarded in post office order or cheque with the notice not later than Wednesday morning, in order to ensure insertion in the current issue.

MARRIAGES.

GORDON—GILLIVER—At Gordon's College, Aberdeen, on November 22th, by the Rev. Professor Gordon, D.D., assisted by the Rev. James Stark, B.D., John Gordon, M.D. Aberdeen, to Maria, M. Gilliver, B.Sc. Dundee, elder daughter of the Rev. Alexander Gilliver, B.A., B.Sc., Lecturer, Gordon's College.

MCCORMICK—MAYN—November 22nd, 1895, at St. Joseph's Catholic Church, Dublin, Maurice Gerald McCormick, I.R.C.P.I., I.R.C.S.I., of The Lanes, Helyer, fourth son of Gerald McCormick, Esq., of Mount Rivers, Lifford, County Kerry, to Eleanor Maynard, youngest daughter of the late Rev. J. Maynard, of Ballyvaughan and Dublin, and of Mrs. Maynard, Glasnevin Lodge, Glasnevin, County Dublin.

DEATHS.

SHAW—On November 26th, at Millington College, Southport, Mersey, wife of Edmund Shaw, M.D., aged 65 years.

LETTERS, NOTES, AND ANSWERS TO CORRESPONDENTS.

COMMUNICATIONS FOR THE CURRENT WEEK'S JOURNAL SHOULD REACH THE OFFICE NOT LATER THAN MIDDAY POST ON WEDNESDAY. TELEGRAMS CAN BE RECEIVED ON THURSDAY MORNING.

COMMUNICATIONS RESPECTING EDITORIAL MATTERS SHOULD BE ADDRESSED TO THE EDITOR, 42, STRAND, W.C. LONDON; those concerning business matters, non-delivery of the JOURNAL, etc., should be addressed to the Manager, at the Office, 42, STRAND, W.C. LONDON.

PERSONS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate beforehand with the Manager, 42, STRAND, W.C.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look to the Notices to Correspondents of the following week.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

IN order to avoid delay, it is particularly requested that all letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL, and not to his private house.

PUBLIC HEALTH DEPARTMENT.—We shall be much obliged to Medical Officers of Health if they will, on forwarding their Annual and other Reports, favour us with duplicate copies.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUESTIONS.

B. A. G. wishes to hear of a baker in Paris from whom a patient suffering from diabetes could obtain gluten bread while resident there.

A. M. desires to hear of a suitable home or institution for a young girl, aged 16 years, who is subject to epilepsy, followed by fits of temper. Her parents are middle-class people who could afford to pay from 14s. to 21 weekly.

H. M. H. writes: Will you kindly inform me if it is necessary to abstain from seeing patients for a fortnight, after the symptoms of mumps have disappeared, and also if there is any danger of conveying the contagion by letter.

A MEMBER would be very glad of suggestions for the relief of pain and spasm (tonic and clonic) in the arm and leg, in a case of amyotrophic lateral sclerosis of about two and a-half years' standing. Morphine is the only thing that has done any good, but that is losing its effect.

RHEUM asks what locality or localities in England will probably be best suited as residence for a patient suffering from rheumatism, of a muscular and fibrous nature, who is much worse in damp foggy weather. What is the best small work published which might be consulted on this subject?

MEMBER writes: It is desired to place a mental patient (very troublesome, if allowed to be so), in an institution in the Midlands, the charge not to exceed £45 per annum. Can any member tell me if there is a suitable asylum? or would it be better for him to go as a paying patient to the county asylum? He is at present in an institution, but his relatives will not continue the payment, as his case is quite hopeless.

DISINFECTION WITH PERCHLORIDE OF MERCURY.

R. J. C. asks where he can procure perchloride of mercury made in blocks for coarse disinfection of drains, etc., in typhoid fever? He desires, also, to be referred to medical works where they are recommended.

PUBLIC BATHS.

DR. NULVILLE THOMSON (Bradford-on-Avon, Wilt.) writes: Will any gentleman who has any experience of public baths for a small town kindly let me have any information he possesses on the subject as regards architecture, fittings, etc.

TREATMENT OF RHINITIS.

D. H. B. writes: Probably some of your readers can suggest treatment for a case of rhinitis in which a circular cast is thrown off by the nasal mucous membrane every three or four weeks. Sometimes there is profuse epistaxis after the membrane comes away, and then the patient feels better for eight or ten days. Alkalies and astringents have been tried locally with no result. At present he is using a 1 in 1,000 of perchloride of mercury douche and taking iodide of potassium internally with so far no benefit.

EXAMINATION FOR MEDICAL SERVICE, R.N.

MEXICO asks (1) if there are any textbooks which would be specially useful in reading for a surgery in the Royal Navy? (2) Is the competition severe? (3) Is there any method of preparing for the examination by correspondence?

"1. No special textbooks are required, and none are recommended.

2. The number of candidates is usually far in excess of the number of vacancies. We are informed that there may be as many as four candidates for each commission.

3. We know of no such method, nor is it likely to be of much value, as the examination is largely by viva voce questions, and in practical and clinical work.

ANSWERS.

CONSTANS FIDEL.—We have a much larger number of letters on the subject referred to than we can publish, but they are receiving attention.

W. P., M.B., in answer to "R.N. Medical," BRITISH MEDICAL JOURNAL, p. 1399, begs to recommend Adcote, Pilch Lane, Knolly Ash, Liverpool; Malton, Miss Foster.

A. R. B.—Our correspondent might in the first place communicate the circumstances of the case in which he is interested to Mr. Edward East, F.R.C.S., Honorary Secretary for Cases, British Medical Benevolent Fund, whose address is 14, Upper Berkeley Street, London, W.

E. A. L.—American degrees in medicine or dentistry are not recognised as qualifications to practise in the United Kingdom. Further particulars will be found in the Educational Number of the BRITISH MEDICAL JOURNAL, published on September 7th, 1895.

M. C. P.—The many disadvantages attending temporary hospitals for the isolation and treatment of infectious diseases have frequently been pointed out in the BRITISH MEDICAL JOURNAL. It is the duty of sanitary authorities to make adequate permanent provision, and this being so it seems desirable that all efforts should be directed to attaining this.

H. S.—This Association is one of those specially condemned in the resolution against medical aid societies passed by the Ethical Section of the British Medical Association at the annual meeting in London this year. We believe the Oxford Branch of the Association likewise has recently passed a resolution condemnatory of the same, so that we should advise our correspondent to reconsider the course he has adopted.

GAMMA.—A large number of papers on the Thyroid Treatment of Myxodema has been published in the BRITISH MEDICAL JOURNAL during the last three or four years. Dr. G. K. Murray's first paper was published in the JOURNAL of 1891, vol. ii, p. 796; Dr. H. W. G. Mackenzie's paper on Myxodema treated by Feeding with Fresh Thyroid Gland was published in the JOURNAL, vol. ii, 1892, p. 940. A discussion at the Edinburgh Medico-Chirurgical Society was reported in the JOURNAL of vol. i, 1892, and numerous references to the subject will be found in that volume as well as in the second volume of that year.

F.R.C.S. EDIN.—We do not know of any work on railway ambulance and transport. It is possible that some of the St. John Ambulance Lectures deal with the subject. On railway injuries there have been several works, namely, *Erichsen's Concussion of the Spine*, Thorburn's *Surgery of the Spinal Cord*, *Page's Injuries of the Spine and Railway Injuries*, 1894; *Oppenheim's Die traumatischen Neurosen*, Hirschwald, 1895; *Vibert's Etude Médico-légale sur les Blessures produites par les Accidents de Chemin de Fer*, of which a new edition was published not long ago.

EOSIN TEST IN PERNICIOUS ANEMIA.

DR. CAREY COOMBS (Castle Carey) sends the following method, from von Jaksch's *Clinical Diagnosis*, Chap. i, for the information of "A. M.": You must prepare cover glasses of blood (as of sputum when examined for bacilli), drying them for ten to twelve hours in a chamber at 100° C. Then drop eosin-glycerine on the glasses; allow it to stand, wash in water, dry and mount in balsam or oil of cloves.

STAMMERING.

L. M.—The scientific treatment of stammering is fully discussed by Dr. John Wylie in his recent work on *Disorders of Speech* (Oliver and Boyd). The method to which our correspondent refers is a secret one, and we have no knowledge of its results.

PUERPERAL INFECTION.

TIMIDUS.—No mere lapse of time will destroy the possibility of carrying puerperal infection; antiseptics alone will do this. If "Timidus" has thoroughly destroyed all microbes adhering to his person, his clothing, and his instruments, he need not discontinue practice for a day.

LACHNANTHES.

IN reply to several correspondents, we may state that the herb *Lachnanthes* (*Lachnanthes tinctoria*, nat. ord. *Hamamelidaceae*, the blood root order) is the red root or spirit weed, growing in sandy swamps on the eastern coast of the United States. The root is red and fibrous. According to Martindale and Westcott's *Extra Pharmacopœia*, a tincture, 1 of the dried herb in 10 of proof spirit, is prepared. The tincture given in doses of 1 to 10 minims is said to check the cough in phthisis and to be useful in arresting the destruction of lung tissue. Nothing appears to be known of the drug chemically, but the root has been used for dyeing in America.

J. W. T. states that he has seen improvement follow the use of the drug together with cod-liver oil and hypophosphites in one case.

DR. HENRY C. BUCK (Upper Clapton) states that for several years he has used this drug in phthisis as well as for asthma, both internally and as an inhalation. He prefers the tincture or an extract prepared in combination with the hypophosphite of manganese. He has used the remedy empirically, but firmly believes the treatment is essential in many cases in preventing extension of the tuberculous deposit, particularly in the early stages of phthisis.

PNEUMATIC TYRES FOR CARRIAGES.

EXPERIENCE writes: In the BRITISH MEDICAL JOURNAL of November 16th and November 23rd are inquiries from "Medicus" and "H.E.I." (Bradford) respectively, regarding pneumatic tyres for carriages. I have had over twelve months practical experience of them, and can answer some of their questions:

The outer casing is cut by new macadam, especially in wet weather,

but the cuts can easily be cleaned and sealed when the rubber is quite dry by the solution supplied with repairing set. The time when the casing is most damaged is when the tracks are formed on newly-laid macadam, and loose stones are about. This cuts the side of the tyre chiefly, and by letting in wet to inner canvas lining causes it to deteriorate and weaken. Mine gave way after six months of constant and hard work during this last winter. The Dunlop Company replaced them free of expense by new ones, with latest improvements.

The tyres decrease draught of carriage 30 per cent to 50 per cent, under any and all circumstances; they reduce wear and tear of carriage and fittings to a minimum; they lessen wear and tear of horses; and last, but by no means least, they lessen to a wonderful degree one's personal wear and tear by taking off jolting and noise. For close or hooded carriages (mine is a hooded buggy) they take away all the worrying burr and sound of the hood when up, so that conversation can be carried on in the lowest possible voice.

I have never found mine to skid on any kind of roads. The tighter the tyres are kept inflated the better they run. I have only had slight experience of solid tyres, but am certain that they cannot compare in any particular with pneumatic. Riding with pneumatic tyres is the same of comfort, but as all luxuries are of necessity expensive, the expense is fully compensated by the advantages and delightful comfort of this wonderful invention. For town work and country travelling with good roads they are insurpassable.

For all kinds of snow work they are superior to anything else, as they never bind whatever condition the snow may be in. I have driven over good roads, bad roads, frozen roads, stony roads, field roads, snowy roads, drizzle and otherwise, and the tyres have stood the test. But no rubber ever made but will wear and cut with hard work. My new pair have been on the road from May last to the end of October, and are as sound as when put on.

I shall be pleased to answer any more questions to the best of my experience, either privately or through the medium of the JOURNAL.

INSTITUTIONS FOR IDIOTS.

M. H. H.—There are several institutions which admit idiots, but some of them receive children only. There are the Earlwood Asylum for Idiots, Redhill, Surrey, which admits patients from all England; the Royal Albert Asylum for Idiots and Imbeciles, Lancaster, which admits patients belonging to the northern counties; Darenth Schools for Imbeciles, Dartford, Kent, for the children of parents who live in London; the Eastern Counties Asylum for Idiots, Essex Hall, Colchester; the Western Counties Asylum for Idiots, Star Cross, near Exeter; and the Midland Counties Asylum, Knowle. The Northampton County Asylum has a block for idiots. Failing these, the idiot might be admitted into the workhouse. In that case application should be made to the relieving officer of the parish in which the patient resides.

NOTES, LETTERS, Etc.

MEDICAL CRUSADES.

A CONTEMPORARY (the *Kensington News* of November 2nd) says: "Three crusades are at present going on in the medical profession: one against semi-qualified midwives; another against advertising doctors and quack medicines; and a third against improperly conducted clubs, where medical officers are employed to do the work at rates incompatible with its being properly performed, and the members of the club pocket the dividend which the officers have earned."

It is satisfactory to know this is the case, and the profession is to be wished "God speed" in its endeavour to put down such prominent abuses as are here indicated, at the same time the task will not be found too easy.

As to the "semi-qualified midwives," this is doubtless an allusion to the opposition that was manifested against the recent Midwives Registration Bill, which sought to place midwives almost on a level with medical practitioners in one branch of their profession, and which was specially hard on qualified medical women, who naturally look to the obstetric branch of the profession as the one on which they must chiefly rely for a living, and for which, indeed, they may claim to be more fitted than their brother practitioners. That any form of curriculum now in vogue to train midwives can be compared with the obstetrical training required of a candidate for a medical diploma few will contend, and until it can be shown that the training of the two is much more on a level, it would be highly dangerous both to the profession and to the public to countenance any legislation which would have the effect of obscuring the difference between a midwife and a legally qualified obstetrical practitioner, as the former ought to be, under the present system of education, never more than an obstetrical nurse in the eyes of the law.

As to "advertising doctors," this is an incubus under which the profession has laboured at all times; it is likewise a parasitic growth, extremely difficult to destroy, as it is intimately blended with much of the vitality of the profession. For advertising in some of its worst forms is by no means absent from a portion of the upper class of the profession, and vain is it to expect reform in the rank and file if the leaders go astray.

As to "quack medicines" the present time would seem to be their millennium; they meet us on every side, and it is a blot on the intelligence of the age to glance over the advertisement sheets of any newspaper. Where is the man so simple as to try quack remedies at law for the preservation of his property, and where the man so wise who has not at some time or other experimented with quack remedies on his body to preserve his health?

With regard to "improperly conducted clubs," it is to be feared there are few at the present time that merit any other appellation from a medical point of view, the amount paid by the best of them to their medical officer or being a pitance hardly worthy of acceptance by a member of an honourable profession. Many practitioners, who would shrink from taking a penny or twopenny fee for a consultation, put pride in their pocket when such fees come to them in the shape of a quarterly payment of a few pounds.

Our contemporary further remarks: "How cheaply, independently of any scheme of paying dividends to members, the work of provident medical clubs is done." It then mentions the Golborne Road Branch of the Metropolitan Provident Medical Association, where in one year 1,331 visits and 1,331 consultations at the dispensary were undertaken by the medical staff for the modest remuneration of £200 per annum, or £2 12s. 6d. per week, which it states to be a fair visit and consultation fee daily throughout the year. We feel, however, to follow when it says: "Taking the two classes of patients together" (that is, those at home and those at the dispensary), "the amount came to 2s. per inspection." We should have thought it came to something less than that.

The profession is hardly to be congratulated on the labours of the Metropolitan Provident Medical Association if it can get no better payment for its medical officers than this, though, doubtless, the answer would be that it is due to the competition with so many clubs and benefit societies in which the medical fees are even lower.

FILTERED AERATED WATER.

MESSES. M. B. FOSTER AND SONS forward us a statement showing the precautions which they take to prevent pollution of their artificial aerated waters. They write: "We prepare, as hitherto, the first three waters (potash, soda, plain aerated) with recently boiled and cooled main water subjected to a special process for the removal of earthy and the destruction of organic matters. In the case of lithia water, distilled is substituted for prepared main water. Boiling has always been strongly recommended by leading bacteriologists as a highly effective method for destroying most of those injurious germs with which common water is frequently polluted. As, however, micro-organisms of several descriptions are liable to be conveyed by air, and since it is extremely difficult to effectually guard, on a manufacturing scale, against aerial germs coming in contact with water, however carefully it may be stored and protected by the usual methods, we have deemed it well to add to our plant a Berkefeld filter and a Pasteur-Chamberland filter. Both kinds of filter have long been known to bacteriologists, and favourably regarded by them; but of the two, the Pasteur-Chamberland has been indisputably proved by laborious and exhaustive experiments to be the only filter that can be employed commercially for the absolute and constant removal of disease organisms from water and other fluids. The water, boiled, purified, and cooled as already described, or distilled, or any saline solution prepared therefrom—is passed through the Berkefeld, and then through the Pasteur-Chamberland filter into an adjoining small reservoir, so constructed that absolutely no air can find its way into the interior of the same without having slowly traversed a column of sterilised cotton-wool. This reservoir is within a few feet of the soda water pumps and the aerating cylinder, and no water can reach either unless it has passed first through the filters and the reservoir. To maintain efficient filtration the filters with their pipes, and also the reservoir, etc., are carefully cleansed and steamed every few days. After this the water is forced through at a given pressure and the rate of filtration from the Pasteur-Chamberland filter noted. We thus make sure that no fracture or other injury has occurred to any part of the apparatus. An abnormally high rate of filtration would be viewed with suspicion and would necessitate investigation. Siphons are chosen in preference to ordinary bottles for filling with these highly purified waters, since the latter vessels, in spite of every care in washing, may contract organic impurities from the dust always present in a busy factory, as well as from corks and other sources. Siphons are hermetically sealed up to the valve, and are, after their first filling for cleansing purposes, whether empty or full, devoid of atmospheric air and dust. It is recommended that before taking a siphon into use a small quantity of the contents should be run to waste so as to cleanse the interior of the siphon. The salts used are chemically pure, and the quantities contained in each siphon of 25.5 oz. are: soda water, 25.4 gr. bicarbonate of soda; potash water, 31.3 gr. bicarbonate of potash; lithia water, 14.2 gr. carbonate of lithia—or 9, 13, and 5 gr. respectively in every 10 oz. of water."

IN MEMORIAM.

DR. GEORGE MATHER, whose sudden death after making an after-dinner speech is referred to elsewhere, was one of the founders of the Sir Walter Scott Club. The following tribute to his memory is from the pen of the president of the Club:

There he lay dead with a brief space before
Had made a patriot's speech, a heart that told
Full of the chivalry of days of old;
Sir Walter Scott loved well a man who bore
The spotless crest of Paladins of yore,
And such was he who cast in brawny mould
Was fond of gentle things: a heart of gold,
Manly and tender, strong and true he wore.
And so farewell, our friend, a last farewell
To modest worth and unassuming mind;
Within our hearts your memory will dwell
As one whose peer was difficult to find
In high and generous qualities that tell
The noble soul and friends unwavering bind.

THE CRY IS "STILL THEY COME."

THOUGH an American contemporary is of opinion that the alleged claim put forth on behalf of hydrastin, that it has anti-cancer properties, is new, this drug has been administered in Canada in the treatment of alcoholism for many years. The last discoverer of a method of cure, which his states has resulted in only two failures, and who claims to have found beer drinkers more stubborn to treatment than any other variety, has made known his *modus operandi*. After a hot bath and a cathartic, the hydrastin is given a hypodermic injection of hydrastin sulphate, beginning with 4 gr. and increased to 1 gr. four times daily. If nervous, valerian and bromides are added. For some hours or days at first the inebriate patient is supplied with a generous allowance of liquor! The whiskey treatment to begin with seems to be in high favour with the "discoverers" of all these modern and nearly always successful "cures."

THE D.P.H. (SCOTTISH COMPOUND BOARD).

MR. JAA. C. G. MACNAB, M.B., F.R.C.S. (Ed.), writes: Dr. T. Harvey Thomson writes in the *BRITISH MEDICAL JOURNAL* of November 2nd in the Public Health Department: "This year's record appears to have been even worse, not one of ten candidates apparently having been awarded the diploma." Had he inquired a little more carefully into the matter, he would have found this statement to be incorrect. The facts of the October examination are as follows: Of the seven candidates who presented themselves for the first examination, two got through, and of the three that entered for the second examination, two were awarded the diploma, of whom I am one.

* The report of the Inspector of the General Medical Council on this examination presented last week is somewhat critical, and does not convey the impression that the examination is one of exceptional severity, but rather the contrary.

THE PHARMACOLOGY OF LOVE

The following comes to us from the practitioner who officiated on the occasion:

SCHNUG—A Lying-in Room.

Doctor: Nurse, come I in 1,000, if you please.

Patient (under chloroform): Ah! that's my Jack. He's one in a thousand. Dear Jack!

COMMON SALT FOR RINGWORM.

DR. GEO. STEELE PERKINS (Wimpole Street) writes: It is with much pleasure I endorse Mr. Perkins's statement as regards the beneficial results obtained from treating ringworm with common salt. More than twelve years ago a boy was brought me suffering from ringworm, who had been under constant treatment for the disease for over five years, a patch over the right ear proving intractable; it was evident all ordinary treatment was useless, and on thinking the case over I decided to try common salt, and this proved successful in a few weeks. Since that time I have treated all cases of untaria (a large number) with chloride of sodium, and in every case successfully and quickly. I was led to use this remedy because of its well known destructive powers to animal and vegetable life, and therefore why not to the trichophyton concerned?

In reply to "G's" queries in the *BRITISH MEDICAL JOURNAL* of November 10th, I always use equal parts of pure vaseline and chloride of sodium finely powdered, and thoroughly mixed so as to make an ointment. Have the part affected shaved, and then the above rubbed in night and morning until the place becomes very sore; the number of the applications depends upon the susceptibility of the skin to irritation and the energy of the rubber. When the above effect has been produced leave matters alone until healed, unless it is preferred to apply some simple ointment as a healing agent. In most cases a complete cure will result, but sometimes, especially when the disease is extensive, a small patch here and there may not be cured, in which case the process over the said patch should be repeated. My theory is that the salt thoroughly irritates the skin, which alone doubtless does some good, and that when the salt is able to penetrate to the roots of the hair and destroy the fungus.

A NEW SPECIALITY.

THE following advertisement, which we take from the *New York Medical Record*, illustrates the increasing tendency to specialisation which is one of the most striking characteristics of the medical profession in our day: "New York, September 1st, 1895.—Dr. ——— begs to announce that he makes a specialty of giving advice regarding the medical and surgical diseases associated with the use of the bicycle. He is also prepared to make physical examination of men, women, and children, and prescribe for them the kind of bicycle and the amount of bicycle exercise adapted to their constitution. The doctor will also provide, to those who desire it, suitable wheels, and arrange the gearing, seats, and handle so that the machine will accommodate itself to the physiological peculiarities of each patient. Dr. ——— has had a large experience in this specialty, and confines himself to it." If the cycle were a productive field, why not golf? Why do not enterprising specialists take up the diseases caused by dancing, by cigarettes, by drawing room music, by Parliamentary oratory?

LETTERS, COMMUNICATIONS, Etc., have been received from:

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

Eight lines and under	20	4	0
Each additional line	0	0	6
A whole column	1	17	6
A page	5	5	0

An average line contains six words.

Advertisements should be delivered, addressed to the Manager, at the Office, not later than noon on the Wednesday preceding publication; and if not paid for at the time, should be accompanied by a reference.

Post-Office Orders should be made payable to the British Medical Association at the General Post-Office, London. Small amounts may be paid in postage-stamps.

N.B.—It is against the rules of the Post Office to receive letters at Post-Offices addressed either to initials or numbers.

OBSERVATIONS

ON

THE CAUSES AND TREATMENT OF CHLOROSIS.

By RALPH STOCKMAN, M.D., F.R.C.P.E.,

Assistant Physician to the Royal Infirmary, Edinburgh; Lecturer on Materia Medica and Therapeutics in the School of Medicine.

MANY causes of chlorosis are enumerated by authors, chief among them being absence of light and fresh air, overwork, especially under unfavourable conditions, heated rooms, insufficient exercise, depressing emotions and unhealthy excitement, indigestion, constipation, insufficient food, and excessive or otherwise faulty menstruation, besides others which need not be here particularised. Most of these are probably predisposing rather than direct causes, and I hope to show in this paper that there are two great and direct causative factors in chlorosis, namely, blood-loss and an insufficient supply of iron by the food. If this be correct, then excessive menstruation or other blood-loss and insufficient supply of food from any cause, are the only two factors among those just mentioned which directly bring on the anemia, the others doing so only in as far as they contribute to produce these two.

Virchow's view that chlorosis is dependent on congenital hypoplasia of the arterial system is apparently contradicted by the fact that it is a condition which lasts at most for a few years, and often only for some weeks or months, being completely and permanently recovered from, and hence the causes which produce it must also be transient and avoidable. It is possible, however, that such individuals may be congenitally deficient in blood-forming power, and thus readily tend to become anemic when any strain is thrown on the blood.

The theory supported by the late Sir Andrew Clark¹ and others, that chlorosis results from constipation, with consequent absorption of ptomaines which break down the red blood corpuscles, is in no way supported by facts but rather the contrary. Many cases of chlorosis do not suffer from constipation, and, further, it has now been proved by trustworthy investigations that there is neither excessive formation of decomposition products in the intestinal canal, nor any excessive breaking down of the red corpuscles. As a matter of fact, fewer corpuscles break down in chlorosis than under normal conditions. The very pale colour of the urine, and frequently also of the feces,² indicates that less colouring matter than usual is being furnished by the hemoglobin, and hence that fewer red corpuscles are breaking down. When excessive decomposition is going on in the contents of the intestine, the products of this (compounds of skatol, phenol, etc.) become more abundant than usual in the urine, but Rethers³ and Möner⁴ have found that in chlorosis these products are generally diminished in amount, thus conclusively proving that there is no excessive sepsis in the alimentary canal. These researches help further to disprove the truth of Hannon's and Bunge's theory, which also rests on the assumption of increased intestinal decomposition, whereby the sulphuretted hydrogen and ammonium sulphide supposed to be formed are said to separate the iron out of the food, and thus prevent its absorption. I have already shown,⁵ however, that both Sir Andrew Clark's and Bunge's theories are untenable on other grounds.

It may now be held as proved, therefore, that in chlorosis there is no excessive breaking down of red corpuscles, and hence the anemia must result either from deficient formation or excessive loss of blood. What elements in the blood are specially affected? The blood serum seems to be very little or not at all deteriorated, for L. Beale found⁶ the specific gravity and solids to be practically the same in a girl before treatment and after recovery, while Quinquand⁷ found the

solids to be 83 to 94 per 1,000 in chlorosis and 92 to 94 in health, the several constituents being practically unaltered. On the other hand the hemoglobin is always deficient, and the number of red blood corpuscles is usually, but not invariably, so. In 63 cases of chlorosis which I have treated in hospital,⁸ the lowest estimate of hemoglobin (on Gowen's hemoglobinometer) was 20 per cent., the highest 66 per cent., while only 6 of these cases had over $4\frac{1}{2}$ million corpuscles per cubic millimetre, the others having from $4\frac{1}{2}$ down to slightly under 2 millions. Not only are the corpuscles deficient always in hemoglobin and usually in number, but often many of them are ill-formed and small. The hemoglobin, however, is invariably deficient whether the corpuscles be so or not, and the severity of the clinical symptoms depends chiefly on the extent of this diminution in hemoglobin. Quinquand found that in healthy women 100 c.cm. blood yielded 21 to 24 c.cm. oxygen, while in chlorotics the same amount of blood gave only 10 to 15 c.cm. It is the deficiency of hemoglobin combined with the consequent deficiency of oxygen which gives rise to the pallor, debility, breathlessness, and impairment of functions generally which all go to form the clinical picture of chlorosis.

In discussing the etiology of chlorotic anemia, as it is found in young girls at or not very long past the age of puberty, the chief points which attract attention are the sex, age, the condition of the digestive organs, the condition of the menstrual functions, and the frequent tendency to relapse. I shall consider these in the order named.

Sex.—Chlorosis is infinitely most frequent in very young women, and this suggests the question as to what influence sex exercises on the composition of the blood. Women generally in health have about 10 per cent. fewer corpuscles than men, 8 to 10 per cent. less hemoglobin, and 4 or 5 per cent. more water in the blood. Their blood is therefore less able to withstand any drain on it, and, as will be more particularly noticed immediately, it is well recognised that at puberty and for some time after, there is a greater drain than takes place in lads at the same age.

Age.—Leichtenstern⁹ found that from 18 to 25 the hemoglobin is about 8 per cent. less than from 25 to 45 years of age, and Sørensen¹⁰ that from 15 to 28 in healthy women the number of corpuscles is less than at other ages, which he attributes to menstruation. Further, girls develop with extreme rapidity from 15 to 18, throwing a great strain on the organism, which suffers in various ways besides in blood forming. Out of my 63 cases of chlorosis previously cited no fewer than 41 were between the ages of 15 and 20, and the highest age at which a first attack occurred was 23. Owing to the strain of rapid growth at this age all the various functions of the body suffer, and not only is blood formation deficient in itself, but digestion is impaired and appetite poor, so that an inadequate amount of food, and consequently of iron, is consumed. The onset of menstruation at a time when mere growth is making such demands on the organism still further drains it of blood and of iron and tends to the production of anemia.

The Condition of the Digestive Organs.—In growing girls and in chlorosis gastric digestion is very frequently impaired, and constipation is common, showing that the whole process of primary digestion is very ill-performed. Out of my 63 cases, 32 suffered from constipation, while 31 had marked dyspepsia, and in many cases where gastric dyspepsia was not complained of, it was found that the patient had learned by experience to be extremely careful in her diet. The dyspepsia and constipation lead to the consumption of a totally inadequate amount of food, and therefore of a totally inadequate amount of iron. I have recently analyzed¹¹ fifteen diets of healthy persons, taking in each case an exact duplicate of the cooked food and liquids consumed during one day, and it was found that, for persons with moderate appetite and not working very hard, the total amount of iron ingested was from a little over 6 to 8 milligrammes ($\frac{1}{16}$ to $\frac{1}{8}$ grain) per diem, while persons with larger appetite ingested from 8 to 11 milligrammes iron ($\frac{1}{16}$ to $\frac{1}{8}$ grain). Four analyses¹² of the daily dietary of two girls suffering from chlorosis gave only 2.8, 3, 3.2, and 1.3 milligrammes iron (about $\frac{1}{32}$ to $\frac{1}{16}$ grain), while

¹ Lancet, ii, 1897, 1302.² Von Noorden, *Intern. Arch. Wochenschr.*, 1898.³ *Internation. Berlin*, 1891.⁴ *Ztschr. f. physiol. Chemie*, xviii, 1893.⁵ BRITISH MEDICAL JOURNAL, 1905, i.⁶ *Med. Times*, 1901, i, 628.⁷ *Chimie Pathologique*, 1890.⁸ *Edinb. Med. Journal*, November, 1905.⁹ Untersuchungen über die Ernährung des Menschen, 1878.¹⁰ *Journal of Hygiene*, xviii, 1905.

the dietary of a third chlorotic girl who had lived for three months on a small quantity of bread and milk daily gave only 1.2 milligramme of iron per diem. It is difficult to reckon accurately the total daily excretion of iron from the body, and no doubt it varies within certain physiological limits, but it is probably somewhere about 6 milligrammes on an average. It is evident, however, that persons habitually ingesting a quantity of iron so much less than is excreted in health will gradually acquire a deficiency of hemoglobin in their blood, owing to the new corpuscles which are constantly being formed not finding enough iron in the organism to furnish them with a sufficient supply of hemoglobin.

An experiment which I made upon a dog illustrates this.¹¹ The animal, a collie, in its ordinary dietary consumed about 10 milligrammes iron per day, its red corpuscles equalling 6 millions per c.mm., and its hemoglobin 90 per cent. It was then put on a dietary which maintained its weight, but from which the iron had been as far as possible extracted, so that it only got 2 to 3 milligrammes per day. In forty-six days the hemoglobin had fallen to 64 per cent., although the corpuscles had slightly increased. When put back on its old diet the hemoglobin very gradually rose again, while the corpuscles also increased in number very considerably. There was no lack of power to form haemocytes, but simply a deficiency in them of hemoglobin, resulting from long-continued deficiency of iron in the food. Many cases of chlorosis present a similar condition.

The observation has frequently been made that during starvation the corpuscles and hemoglobin both rise, often very considerably, in a given bulk of blood, but this is due simply to less fluid being taken, and the blood becoming thereby more concentrated. The same increase has been observed in cases of phthisis and of diarrhoea where fluid is drained off by sweating or by the watery alvine discharges. The increase is only apparent, and there is abundant evidence to show that during partial or complete starvation both corpuscles and hemoglobin are reduced. Reinert¹² states that during inanition the corpuscles fall from the beginning if fluids be given, and Vierordt during the hibernation of a squirrel observed its red corpuscles fall from 7,748,000 per c.mm. to 2,355,000. Quinquand found a very large fall of hemoglobin in lunatics who refused food, and Piory relates the case of a man who committed suicide by eating less and less each day, dying ultimately after two months, during which time he developed all the symptoms of anemia.

Quality, as well as quantity, of food is of importance as regards the supply of iron. Verdel¹³ found that a dog fed for 18 days on flesh had 12.75 per cent. iron in its blood ash, while one fed on bread for 20 days had only 8.65 per cent., and Sabbotin¹⁴ confirms this on different species of animals, as regards the amount of hemoglobin.

My own analyses of iron¹⁵ in different articles of food showed that they contained very different amounts. Thus in two analyses of bread, one pound (undried) yielded 1.7 and 2.7 mg. ($\frac{1}{4}$ and $\frac{1}{2}$ gr.), one pint of milk 2.2 mg. (about $\frac{1}{16}$ gr.), and one pound of beefsteak 18 mg. (about $\frac{1}{4}$ gr.) iron.

There can be no doubt, therefore, that the quantity and kind of food consumed exercises an important influence on the amount of iron available for blood formation.

Menstruation or other Blood Loss.—The onset of menstruation while the body is actively growing makes a great demand on the blood. Gowers¹⁶ found that during a menstrual period in a chlorotic girl the corpuscles fell as much as 10 to 20 per cent. of their total number, and in one case during five days I found that they fell from 4,482,000 to 3,764,000 per c.mm. Hunt¹⁷ and Wilcocks¹⁸ also observed a diminution. The loss is easily borne by the vigorous and fully grown woman, who finds no difficulty in regenerating the corpuscles and hemoglobin, hence the rarity of chlorosis after the age of 25. In chlorotics, however, the corpuscle-forming power is often lessened temporarily, but this seems to be due largely to lack of iron and

possibly also to general impairment of nutritional activity, for as soon as iron is given and the patient put under favourable hygienic conditions, new corpuscles are formed with great rapidity. Further, the healthy woman has sufficient reserves of iron at once available for use stored in the liver and spleen, but in girls ill-nourished from any cause, or who have been drained of this iron by hemorrhage, there is little or no iron in the body to draw on for the manufacture of red corpuscles, and thus they become anemic.

A fatal case of gastric ulcer which I had in a girl, aged 18, illustrates how completely the body may be deprived of its iron by hemorrhage. During three days she had hæmatemesis to the extent of about 50 ounces, and then several smaller bleedings previous to death. The liver contained only 0.018 g. iron per 100 parts dried, and the spleen 0.041 g., calculated for 100 parts dried. It may give a better idea of the extreme poverty of these organs in iron when it is stated that the whole spleen only contained 5 mg. ($\frac{1}{4}$ gr.) of iron, and the whole liver 4 cgm. ($\frac{1}{2}$ gr.), amounts which are probably fully accounted for by the blood which was unavoidably left in the organs. The iron usually stored in the liver and spleen cells had disappeared.

An experiment made on a dog proved the same thing. The animal, a large collie, at the beginning of the experiment had 8,000,000 corpuscles per c.mm. and 108 per cent. hemoglobin, and during three weeks it was bled to the extent of 857 c.cm., when the corpuscles had fallen to 5,280,000 and the hemoglobin to 48 per cent. In twenty-eight days afterwards the corpuscles had risen to their original number and continued to increase, but the hemoglobin required ninety-seven days to reach 104 per cent. It was then killed, and only a mere trace of iron was found in the liver. During this time it had received no chalybeate treatment, and its food contained about 8 to 10 mg. iron daily.

It is certain, therefore, that loss of blood not only directly produces anemia, but prevents speedy recovery from it by draining off the reserves of iron in the body.

Most cases of chlorosis, when fully developed, have amenorrhœa, which must be regarded as beneficial and protecting against further loss of blood. In many cases the loss of blood by menstruation has never been actually large, but only relatively so, when compared with what the organism is able to withstand at a time when a very heavy strain is being put upon it otherwise. Many cases, however, begin with very distinct menorrhagia, and date their illness from this.

In looking through my notes, I find a considerable number of cases in which the patient menstruated for five to seven days, sometimes every second or third week; there is one in which the period lasted nine to ten days every month, and there are two cases in which the bleeding continued for a month. Both these last suffered from typical chlorotic anemia in consequence; in one of them a gynecological examination was made under chloroform, but nothing was found to account for the menorrhagia. One girl, aged 19, presenting all the most typical symptoms of chlorosis, had for some months been in the habit of passing blood daily when at stool, apparently from a bleeding polypus high up the rectum.

How important a loss of iron even moderate bleeding entails on the body can perhaps only be realised after calculation. Becquerel and Rodier reckon the iron in 100 g. blood as 0.0368 g., and Pelouze as 0.054 g., so that if we take the mean we have 45 mg. iron in 100 cc. of blood. Now, during menstruation, 3 to 6 ounces is the average loss of blood, and in this about 45 to 90 mg. iron is excreted, that is to say, about as much iron as a healthy person ingests as food during 5 to 10 days. If we reckon, however, that 5 or 6 mg.¹⁹ are excreted daily in other ways, it only leaves over 3 or 4 mg. per day to make good the loss of iron contained in the shed blood. In the intermenstrual periods the liver stores up from the food reserves of iron, which are immediately available for making new corpuscles, but if these reserves have been exhausted by menorrhagic or other bleeding, or have not been kept up owing to poverty of the food in iron, then the iron, even of a good dietary, is quite inadequate to meet the demand for hemoglobin, and anemia gradually results.

Tendency to Relapse.—The slighter cases of chlorosis do not very often seek medical advice, as they recover spontaneously on the iron of their food, while many even severe cases frequently have no recurrence after treatment, the conditions which induced the anemia having been evidently temporary. Many cases, however, are never really well, under treatment they recover more or less from one attack, and in a few months have another, this going on sometimes for years. The explanation is that such patients habitually eat too little, or habitually lose too much blood by menstruation, or there is most often a combination of both. In some cases also, there is possibly a deficiency in blood-forming activity.

Gastric Ulcer.—It is well known that obstinate anemia accompanies gastric ulcer, and this is not surprising, for here we have at work the two most potent factors in causing anemia, namely, blood loss and an insufficient dietary as regards iron.

Summary.—All the causes of chlorosis, ordinarily enumerated, may be reduced to two, or possibly three:—

1. Excessive menstrual loss, or (much less frequently) other blood loss. This may be relative, that is, too much for a weakly or rapidly-growing organism to bear, or it may be actually large.

2. Insufficient ingestion of iron with food. Anything which diminishes the appetite diminishes the consumption of iron, therefore dyspepsia, constipation, heated rooms, insufficient exercise, unhealthy atmosphere, mental depression, etc., all predispose to anemia by lessening the amount of food consumed. It is probably owing to change of habits, confinement indoors, and want of fresh air—all leading to small consumption of food—that so many girls from the country become anemic on coming into towns to live.

In a very large number of cases there is a combination of 1 and 2.

3. It is possible that certain persons are born inherently weak in blood-forming power, and tend to become anemic under very slight provocation. Such a constitution does not directly cause anemia, but simply predisposes to it. This would account for cases in which the consumption of food is fairly satisfactory, and there is no particular blood loss so far as can be made out. In such people, however, nutrition is never very active.

Chlorosis in Boys and in Non-menstruated Girls.—This can be explained by the strain thrown on the body by rapid growth and by the conditions mentioned under paragraph 2 above. The anemia of the menopause, in which the blood condition and symptoms are similar to what is seen in young girls is palpably due to dyspepsia, insufficient food, and excessive blood loss.

TREATMENT.

Iron.—When a fully-developed case of chlorosis presents itself for treatment, clinical experience has abundantly shown that the chief remedial measure is the administration of iron. Whether given by the mouth by the rectum, or subcutaneously it is absorbed and utilized for the formation of new corpuscles.²² There has been much discussion regarding this, but Metcalf²³ has recently demonstrated its direct absorption from the intestine. It appears to be stored in the liver and is there converted into an albuminous compound which is the predecessor of haemoglobin, but exact details regarding the steps of the process are wanting. Treatment by iron ought to be continued for eight or ten weeks, because comparatively little is absorbed, and the corpuscles which have been formed during the anemic state are poor in haemoglobin. They disappear slowly from the circulation, and are only gradually replaced by others rich in iron.

Any one of the ordinary Pharmacopoeial preparations suffices as they can all be absorbed and no one preparation in the present state of our knowledge can be definitely said to be much better than another merely as regards iron. The choice of the particular preparation to be used should be guided to a very large extent by the condition of the stomach. If, as is so often the case, the stomach is irritable, it is best to use the least irritating preparations such as reduced iron, ferrous carbonate in its various pharmaceutical forms, or one of the more soluble preparations, and these will be found most generally suitable. Hayem strongly recommends the osalate, while

lactate of iron is also much used in France. The protochloride and sulphate are distinctly more irritating, and the ferric salts still more so. Large doses are generally given, and are held to be most efficacious and rapid in action, probably because more iron becomes absorbed, but many cases recover well in which comparatively small doses, such as 1 g. of reduced iron twice or thrice daily, are administered.

Manganese and arsenic given along with the iron are supposed to increase its efficacy. The former is certainly of no use, and the latter is unnecessary. It is supposed to stimulate the formation of red corpuscles, but in chlorotic anemia such stimulation seems to be rarely required, for as soon as iron in sufficient quantity is supplied, the manufacture of haemocytes goes on with great rapidity, generally leaving the haemoglobin lagging behind.

Diet.—No specific dietetic rules can be laid down for all cases, as the diet must be regulated by the condition of digestion. The most easily absorbed and utilized diet is the best, although, as has been previously pointed out, farinaceous foods contain less iron than flesh. If gastric digestion is good, then an ordinary full mixed dietary is most suitable; on the other hand, if there be severe dyspepsia or gastric ulcer, the diet must be regulated accordingly, so as to give the patient most comfort and the food which can be digested most easily, and with most benefit to general nutrition.

Once a patient is markedly anemic the amount of iron furnished by an ordinary diet can go only a very little way towards providing the iron necessary for recovery. Say that the blood is deficient in iron to the extent of 20 gr., it is evident from what has been previously stated, that it will be a very long time indeed before this can be made up from the small amount of surplus iron in an ordinary dietary.

Nasse²⁴ states that fat hastens blood formation, which is confirmed by Cutler and Bradford,²⁵ and Ebstein²⁶ recommends the treatment of corpulent anemics by means of fatty and albuminous food.

Rest in Bed.—Many patients who are severely anemic do best when kept in bed, and some few recover only after this is enjoined. The explanation seems to be that the most distressing symptoms arise from lack of oxygen and debility of the heart and muscles, so that when complete rest is obtained there is less fatigue, and less oxygen is required for muscular exertion. The supply can therefore be used almost exclusively for purposes of nutrition, and thereby the digestion and general health are improved, so that the food and iron can be better absorbed and utilized. Slighter cases do best with an open-air life and a very moderate amount of exercise (taking care not to overstrain the heart) as the appetite and general nutrition are thereby stimulated.

Improvement of Appetite and Digestion.—Good general surroundings and personal hygiene, treatment of dyspepsia and of constipation are of the utmost importance, as thereby the appetite becomes larger and the patient gets into the habit of taking sufficient quantities of food. The same is true of country air spa treatment, hydrotherapy, and massage,²⁷ all of which may be useful adjuncts to more direct methods of cure. If the patient be not placed under favourable conditions or remain under the influence of the causes which originally produced the anemia, then treatment may be inefficient or very prolonged. For instance, in many factories the girls employed often take Bland's pills as regularly as their meals, and yet they remain more or less anemic chronically.

Prevention.—Seeing that undue menstrual losses and insufficient food are the two great, if not the only, immediate causes of chlorosis, prevention seems simple enough. If the menstruation is relatively or absolutely too abundant, it can be held in check by giving ergot. In two severe cases of menorrhagia, where ergot did not control the bleeding, I have ordered hot douching with successful results.

More important still is the cultivation of a habitually good appetite and vigorous health, because sufficient iron is thereby ingested, and, as has been previously pointed out, healthy women bear menstrual blood-loss without serious deterioration of the blood. Leichtenstern found that when he lived generously and put on weight his haemoglobin also

²⁵ *Stitt-Hall, Amer. Jour. Med. Sci.*, 1904.

²⁶ *Journal of Physiology*, vol. 20, 1904.

increased in amount, and it is obvious that abundance of food means a sufficiency of iron.

Good general surroundings, fresh air and exercise, are essential to a healthy appetite and digestion, and are of the utmost importance in preventing anemia. Tea has often been blamed for causing chlorosis, but if taken at proper times it can scarcely exercise any deleterious effect. Many women, however, use it as a substitute for food, or take it before their meals, thus diminishing appetite and bringing on dyspepsia, both of which interfere with the ingestion of a normal amount of iron by means of the food.

A DISCUSSION ON THE REQUIREMENTS OF THE PROFESSION WITH REFERENCE TO THE REVISION OF THE BRITISH PHARMACOPŒIA.¹

I.—D. J. LERCH, M.D., F.R.C.P.,

Professor of Materia Medica and Therapeutics, Victoria University, Manchester; Member of the General Medical Council.

THE discussion which I have the honour of opening to-day is for the purpose of eliciting the views of members of the British Medical Association as to the changes which may be advantageously made in the forthcoming edition of the *British Pharmacopœia*, with the view of adapting it to the present requirements of the medical profession. It may be well, however, if at the commencement I point out that, whilst the *Pharmacopœia* is specially issued for use by the medical profession, and should, therefore, be in accord with its needs, it is, in its legal relations, concerned chiefly with the protection of the public and with the guidance of pharmacists, for whom its provisions are laws, the infringement of which is punishable. Hence, the effect any changes made in the *Pharmacopœia* will have on the interests of the public and of pharmacists have to receive due consideration.

Furthermore, it must be remembered that the *Pharmacopœia* is published by the General Medical Council according to Act of Parliament, and the Council can make no alterations unless they be in keeping with this Act.

Fortunately, however, the instructions given by Parliament relating to the *Pharmacopœia* are very simple. By the Medical Act of 1858, Section 54, it has to contain (1) a list of medicines and compounds and the manner of preparing them, together with the true weights and measures by which they are prepared and made; (2) such other matter relating to them as the General Medical Council shall think fit.

No direction is given as to the nature or comprehensiveness of the list to be drawn up; but as in a subsequent Act, that of 1862, it is directed that the *Pharmacopœia* published by the Council shall take the place of the *Pharmacopœias* of London, Edinburgh, and Ireland, it is manifestly intended that the list shall be of the same kind as those published by these Colleges—that is, it shall refer to medicines used by members of the medical profession. It is clear, too, that though no mention is made of methods for determining the purity of drugs other than those furnished by a description of the method of preparation, the Act is intended to ensure uniformity in composition and the purity of drugs on the list set forth, for the benefit alike of the profession and the public.

The *Pharmacopœia* of 1864, in which, owing to the exertions of Sir Richard Quain, the best parts of the formularies of the three Colleges were so admirably welded, and that of 1885, have carried out the manifest intentions of the Act. Each of them has contained lists of drugs and compounds such as the existing state of medical practice required at the time of publication, with the means for establishing the uniformity and purity of the remedies named, an account of the weights and measures used in preparing them and accessory information, as, for example, with regard to dosage.

The advances made in chemistry, pharmacy, and botany, the changes in medical practice, and other circumstances now render another edition necessary; and we have to consider to-day what alterations and additions can be suggested which will add to its value, so far as the medical profession is concerned, without interfering with the value of the book in its legal aspects.

It seems to me that in this discussion it will be well if we avoid details which have no direct bearing on the use of the *Pharmacopœia* by medical men, as, for example, modifications of tests and alterations in the description of drugs or their botanical origin. It will, I think, be sufficient if we only deal with (1) the nature and extent of the list of remedies, (2) the mode of preparation of compounds so far as regards their medicinal use, (3) weights and measures, (4) the amount and extent of accessory information which should be given.

In alluding to such possible changes I propose for the most part only to introduce them for consideration. As a member of the General Medical Council, I am here to-day rather to learn the opinions of the members of this Association than to express definite opinions of my own.

List of Official Medicines.—Is the present list of official drugs and compounds satisfactory? If not, how can it be improved? A considerable number of drugs and preparations, both old and new, which are not now in the *Pharmacopœia* are used more or less frequently by practitioners. To include them all and give tests for their purity would mean the production of a *Pharmacopœia* three or four times as large as the present one, containing remedies of which a very small portion would be in general use. On the other hand, as is well known, there are a large number of substances in the present *Pharmacopœia* which the majority of practitioners never use. From the investigation made by the Therapeutic Committee of this Association, which has been published in the *JOURNAL*, it appears that out of 185 of the drugs which seem to the Committee least used, 54 were never employed at all by above 5,000 out of 5,609 who returned the circular forwarded to all members of the Association in England, Ireland, and Scotland, and of those who do use them the majority give them rarely. Many strongly urge that there should be a wholesale exclusion of little used drugs on the ground that they must be of small value. It has to be remembered, however, that every drug in the *Pharmacopœia* seemed to be prized by some practitioners out of the 5,609 who returned the circular. Of drugs, for example, nitrate of lead is often used by 80 out of this number, matricaria leaves by 67, sulphate of berberine by 48, lupulin by 39, and nitrate of copper by 22. Of preparations, confection of opium is often used by 56, confection of scammony by 34, confection of turpentine by 59, and ethereal extract of mezezon by 8. It would be interesting were it possible to determine why a small number used these and many other drugs often whilst 5,000 entirely discarded them.

We must not assume too hastily that the drugs and compounds which have not maintained their popularity are therefore without the utility entitling them to a place in the *Pharmacopœia*; several remedies of great value have in times past been excluded from the *Pharmacopœia* because the real purpose for which they ought to be employed was not at first fully known, and they were therefore little used. Bromide of potassium is an example of this. But if drugs cannot be shown on careful inquiry to possess the value formerly attributed to them they are better out of the *Pharmacopœia*, for the fact that drugs and preparations are in it gives a kind of official recognition of their utility. The retention of useless drugs seriously injures the *Pharmacopœia* in an educational point of view. The contents of the *Pharmacopœia* should be the basis of a student's work in materia medica in order that it may be the basis of his therapeutic work afterwards; but it is absurd to require men to acquire knowledge concerning substances which will be of no service to them in after-life.

As pointed out in the memorandum of the Therapeutic Committee on the *Pharmacopœia* the omission of a drug in no way prevents a practitioner ordering and obtaining it for his patients. It only takes away the guarantee for purity which arises from the fact that every drug on the official list sold or used by a pharmacist must conform to the pharmacopœial description and tests. Hitherto the General Medical Council have followed the example of the compilers of former *Pharmacopœias* in excluding a few of the least used remedies on the issue of a new edition, and adding others of which the value seemed proved. Whether the process of exclusion may with advantage to the profession be more fully carried out, or whether it would be well to deal as gently with remedies almost obsolete as heretofore, are points on which this meeting's opinion will doubtless be expressed.

¹ In the Section of Pharmacology and Therapeutics at the Annual Meeting of the British Medical Association, held in London, July-August, 1895.

In considering this question of the exclusion of preparations from the *Pharmacopœia*, two other points deserve notice. In our own *Pharmacopœia* and in the French *Codex*, descriptions are given of preparations which pertain rather to the methods in which medicines can be administered than to pharmaceutical preparations. The making of poultices, inhalations, and enemata is set forth in detail. Is it to the advantage of the profession that the *Pharmacopœia* should contain these details? Or should they be referred to books which deal with therapeutic procedures? It is very desirable that the views of members of the Association should be expressed on this subject, and also with regard to the multiplicity of preparations which consist of one active ingredient and one vehicle only, as, for example, solutions of lactic acid, chromic acid, and such ointments as those made with calomel and lard, acetate of lead and lard. That a few are wanted there is no doubt, but where the active ingredient has to be constantly modified to suit particular cases, as, for example, in liquor cocainæ hydrochloratis, the question arises whether owing to the difficulty in remembering the strength of the solutions there is any advantage in retaining many simple solutions in the *Pharmacopœia*.

The introduction of new remedies, like the exclusion of older ones, will probably give rise to considerable discussion to day. It may be well to remember in this discussion that as the main purpose of the *Pharmacopœia* is to ensure uniformity in composition and purity of the agents included in it, the introduction of substances which are patented, and concerning the preparation of which, therefore, no real indication can be given, is, apart from all other considerations, objectionable, and especially so if purity tests are not easy to establish.

Furthermore, it will be well to bear in mind that as by introduction into the *Pharmacopœia* a substance is stamped as being definitely proved of value, nothing should be accepted until its efficacy has been very fully established.

Modes of Preparation of Compounds.—Pharmacy has made great progress in the last few years, and it is evident that many of the methods of administering medicines which were formerly looked upon as satisfactory are capable of improvement. Our forefathers took boluses without a murmur, whilst at the present time people grumble at a 5-grain pill. The *Pharmacopœia*, however, must keep pace with the times, otherwise it will be little used. For improvement of methods of administration we shall be largely indebted to our pharmaceutical friends. Nevertheless, utility must not be sacrificed to less important matters, and each change in the form of a compound requires consideration from a therapeutic point of view. Many suggestions have already been made for the improvement of our official preparations, and I trust we shall have more to-day. Especially is it desirable that we should have an expression of opinion as to what should be done with those many forms of administration which the ingenuity of the large firms of manufacturing chemists has devised—tabloids, tablets, granules, etc. We cannot possibly put them all into the *Pharmacopœia*; can we leave them entirely without mention?

I have said that it is not necessary to day to discuss the question of tests for purity, but there is one point connected with these tests on which I should be glad to hear the views of members here present.

The tests for purity are given in the *Pharmacopœia* without any indication as to the impurity which they are meant to detect. A sufficient knowledge of chemistry of course enables anyone to see from the tests the impurities which may be present in a drug, but few of us retain our chemical knowledge sufficiently for this purpose. Nevertheless, it is of some importance in using a drug that the possible impurities which are present should be known. Would it not be an advantage if, after each test for impurity, the impurity itself were indicated as in the *American Pharmacopœia*?

Weights and Measures.—The English *Pharmacopœia* is the only one in which the metric system has not been adopted. It seems now certain, especially after the strong report which has been issued by the Committee, under the chairmanship of Sir Henry Roscoe, in favour of the metric system, that some general change in our weights and measures is impending. It has been suggested in the new edition of the *Pharmacopœia* to give them alternately with the present

weights and measures, and I think there is little doubt this will be done.

Accessory Information.—The Council has been empowered by Act of Parliament to insert any information relating to the list of medicines and compounds which it shall think fit. The nature and amount of the information given is perhaps of all subjects the one which concerns the profession most closely. In the edition published by the Council in 1893 doses were appended to the other information concerning the drugs and preparations.

This had not been the case in any of the previous *Pharmacopœias*, and it has no doubt added much to the utility of the *Pharmacopœia*. In none of the formularies of other countries are the doses of all the substances meant to be taken internally given. In the majority there is no allusion to the subject; in a few, as for example the *Pharmacopœias* of Switzerland and Germany, the maximum amount which can be given at once in one day is given in the case of the most potent remedies. It is manifestly an extremely difficult matter to give a minimum and a maximum dose of many of the drugs. The minimum dose of iodide of potassium, for example, may be in some cases half a grain, but it has been given without any ill-effect in doses of 300 grains. Hence it is necessary to state only the average dose, or rather the average variation, in the dose which is usually administered. It seems probable that this best meets the requirements of the medical profession, and that save as regards revision no change is called for in system.

The difficulty in remembering dosage is one which every practitioner from time to time feels, and it has long been the opinion of many that an attempt should be made to simplify dosage by altering the strength of some of the present preparations so that the various extracts, tinctures, etc., should not have the varying dosage they now have. If, for example, the tinctures were made of such a strength that all the more powerful of them should have one dose and the less powerful another, it would be manifestly more easy for practitioners to remember the proper dose to give. As a set-off to this advantage it may be pointed out that in this way the strength of the various tinctures would differ very much as regards the actual amount of ingredients contained in them. I can only say with regard to this matter that the importance of the subject has not been lost sight of by the General Medical Council.

The last point to which I shall draw the attention of the meeting is the addition of information not now given connected with the methods of administration of various preparations and their pharmacological and therapeutic effects. There can be no doubt that it is legally possible to add to the description of each drug some information which would be of service to the practitioner bearing on its use. Already indeed, this is done to some extent. The amount, for instance, of acid required to neutralise a certain amount of bicarbonate of potash in order to form an effervescent draught is appended to the amount of bicarbonate of potash. It may be well, too, to incorporate in the account given of the drugs and in the tests, information now not given which may be of service to the practitioner. It seems very doubtful, however, whether, in the present condition of pharmacology and therapeutics, more can be done. If the *Pharmacopœia* is to be a guide to the administration of medicines, it should be a complete guide, and contain full information on all points connected with administration. But this seems hardly possible, since it would lead to the insertion of details which are quite foreign to the purpose of a *Pharmacopœia*. Nor does it seem now feasible to introduce information with regard to the pharmacological action and therapeutic uses of drugs. There may arrive a time when it will be possible, but that time I hold has not yet come; the object of the *Pharmacopœia*, so far as the medical profession is concerned, is to ensure the purity of drugs in ordinary use. It is an official book which is taken as a guide to legal procedure, and should contain no doubtful matter. Now, to introduce pharmacological and therapeutic statements would certainly cause the *Pharmacopœia* to lose the definiteness it now possesses. It is true, indeed, that in pharmacology there is some exactness which therapeutics does not possess; we know beyond doubt the action of certain drugs on tissues and organs, but even in pharmacology

much that is put forth is rather inferred than assured, and it would be impossible to give under each drug a reliable account of its pharmacological action. Whether it ever will be possible or not remains to be seen. That it would vastly enhance the value of the *Pharmacopœia* if definite and incontestable statements on pharmacology and therapeutics could be introduced there can be no doubt, but the production of such a *Pharmacopœia* is, I fear, a dream of the future.

I confess my own dream of the future *Pharmacopœia* is somewhat different. I look forward to a time when we may have a *Pharmacopœia* containing a list of drugs and preparations concerning the utility of which there is a general consensus of opinion, when the advance of chemistry shall enable us better even than now to determine the strength and purity of every item in the *Pharmacopœia*; when the *Pharmacopœia* shall be the initial textbook of every student, who must become thoroughly conversant with every statement it contains—at least, with all which bear upon the use of medicine.

Such a *Pharmacopœia* would be the basis of advanced textbooks on materia medica just as the present *Pharmacopœia* is; but, containing as it would only an account of drugs and preparations generally employed, the editors of the textbooks would have a freer hand than at present. For now, instead of introducing an adequate account of the various new and much used substances used in medicine, they are often limited to a bare notice of them by the necessity for inserting an account of all official drugs rarely employed. It would be the basis of all examinations, and we should not have, as at present, only part of it recognised as such a basis, and an indication plainly given that certain portions of it are not to be known by medical men. Lastly, it would be a book which, having been thoroughly studied in student days, would be the sound basis of future work, from which, indeed, excursions might be made into the more doubtful region of the new remedies, but to which all medical men would return as the reliable groundwork for their therapeutic practice.

II.—DONALD MACALISTER, M.D., F.R.C.P.,

Linacre Lecturer and Physician to Addenbrooke's Hospital, Cambridge; Member of the General Medical Council.

As a member of the *Pharmacopœia* Committee which is now actively engaged in the work of revision, I would have preferred to hear rather than to speak on the present occasion. The contributions of experienced practitioners to this discussion cannot fail to be of service in suggesting improvements in the *Pharmacopœia*, and I for one can promise to offer an open mind to all that promises to be of advantage in this connexion. It may help, however, to carry on the discussion on useful lines if I confine myself to emphasising a simple general principle alluded to by Dr. Leech, which in my view should be carefully observed in the preparation of our official book of remedies. It has already emerged in the discussions of the Committee, and it has not a little to do with the usefulness of the book to men who are busily occupied with the details of practice.

The principle I would thus enunciate: It is important that the essential formulae of the *Pharmacopœia* should be so adjusted that they may be easily and accurately remembered. Most of us can call to mind the bewildering sense of hopeless difficulty which fell upon us when we first attempted to learn the doses, strengths, and varieties of the pharmacopœial preparations we were supposed to employ in our daily practice. We discovered no obvious law governing their innumerable variations, and we were fain to set ourselves to acquire, by a brute effort of mere memory, such of them as were most immediately needed. Continued practice has no doubt impressed the chief of these arbitrary and unconnected facts on our minds, until we have almost forgotten the early efforts they entailed. As in the case of English spelling, we have at last got more or less used to it, though we hold it no disgrace to have to look at the dictionary now and then, and to indulge in a British grumble at its lawlessness.

One way of diminishing this waste of mental energy is to strive after the greatest attainable uniformity in the formulae of similar classes of preparations. A step in this direction was taken ten years ago, when the majority of the liquors

were made into 1 per cent. solutions of their active ingredient. By general consent the step has been approved, and I trust that it will be followed by many others of the same kind. It would not be practicable, owing to pharmaceutical difficulties, to make all tinctures, for example, of one strength. Considering the widely differing potency and solubility in alcohol of the different drugs, one tincture would be too strong for convenient use, while another in sufficient doses would involve the administration of an undesirable amount of spirit. But it should be practicable to make two, or at most three, classes of tinctures, A, B, and C, such that the dose of all in the A group should be the same, say 5 to 10 minims; and that of the B group should be larger, say 30 minims to 2 drachms, and so on. It would be easy to learn and to remember that a given tincture was in the A or in the B group, as the case might be. And when that was mastered, the essential details of strength and dosage would be mastered at a stroke.

It will, of course, require careful experiment to determine what are the practical limits to the application of this principle, not only in the case of tinctures but of infusions, extracts, and the like. I am breaking no confidence if I say that I have every expectation that these experiments will be undertaken by competent hands, and that the next *Pharmacopœia* will be composed with full knowledge of the results.

There is another way in which the practitioner's memory, and therefore his power and facility, may be aided, namely, by extending this principle of classification and gradation to the different preparations of the same drug. Take the various compound preparations of opium, for example. Some of these can already be grouped by decimal gradations, 1 in 10, 1 in 20, 1 in 30 and so on; but there are others whose proportional strengths do not fit into such a convenient scale. If it could be managed, the principle of uniformity in the sense of uniform or at least decimal gradation might very helpfully be applied here.

In like manner, though the question has other and perhaps more important bearings, the standardisation of extracts, tinctures, etc., containing powerful and definite alkaloids is becoming not only practicable but necessary, and this too will tend in the direction of the desired uniformity. It is desirable, in my opinion, that when it can be done this standardisation should conform to some easily remembered sequence of gradation. The extracts, for example, should if possible be brought up say, to 5, 10, or 15 per cent. of alkaloid, as the case might be.

Lastly, it will undoubtedly make easier the quantitative improvement I have suggested if the metric system is introduced throughout the *Pharmacopœia*. The established system of grains and ounces, like what was once described as the "inspired British foot" it is, of course, impossible to ignore. But side by side with it there will certainly appear the alternative of grammes and cubic centimetres. The effect of this important innovation will, I take it, be not merely educational; it is bound to have some reflex effect on the proportions of the formulae that have to be metrically expressed, and so tend towards what, speaking in London, I may be allowed to call "tenification" in general.

A second principle of importance in rendering the *Pharmacopœia* of reader usefulness is that of simplicity. This may be furthered in numerous cases by the avoidance of what I may call unnecessary duplicity. Of many of the acids and saline solutions two forms are given differing merely in strength. We are provided with a "stronger" and with a "dilute" solution. This has several inconveniences. First, the relative strengths of the two are not easily remembered. Secondly, ambiguity and, therefore in some cases, danger, may be caused by the prescriber forgetting to give the qualifying adjective—"concentratum," "fortior," or "dilutum." The druggist has to use his own discretion in determining which strength is most likely to have been in the prescriber's mind. Thirdly, the official dilution is by no means certain to be the most appropriate for the prescriber's purpose; it may be too strong or too weak. Fourthly, the duplication increases needlessly the size of the book, and so its handiness for everyday use.

I would therefore suggest that in most cases a single solution, preferably the stronger, should alone be made official.

The strengths of these stronger solutions should be made as nearly as practicable uniform. The prescriber's memory would be thereby relieved, and he would be able to order the exact degree of dilution which he deemed appropriate in each instance.

Connected with this point of solution-strength is another on which many of those who have aided the Pharmacopœia Committee by their suggestions are agreed. This is the introduction in some convenient place of concise tables of solubility. These would give for ordinary temperatures and the usual menstrua the exact solubilities of the several salts, alkaloids, and the like, which have to be given in a state of solution. There is good reason to expect that such tables will be introduced, and when they are I venture to predict that even the most expert and experienced of prescribers will not infrequently turn to them with thankfulness.

On the same grounds that I have deprecated single official dilutions as not likely to be appropriate to all cases, I think the introduction of official enemata, cataplasmata, and vapores, to be uncalled for, and in themselves undesirable. To lay down as pharmacopœial law that an opiate enema shall contain a fixed quantity of opium, no more or less, is, in my opinion, neither wise nor necessary. The age, the condition, the needs of the patient, must be taken into account. If anything has to be said about enemata at all, let a suitable composition for a simple starch enema be given, and let the prescriber himself add thereto the exact proportion of the active remedy which he sees his patient requires.

There are so many eminent speakers to-day whose views I am myself anxious to hear, that it would ill become me to detain the Section longer. The greatest mistake I could make would be to try to cover the whole ground of the improvement of the *Pharmacopœia*. It cannot be done in ten minutes. I have therefore sought to emphasise only a single point, which has, however, wide relations. To be really useful to the practitioner the *Pharmacopœia* should be constructed on so orderly and intelligible a system that its quantitative details can be readily held in the memory. To this end the essential means are, as I have tried to indicate, uniformity, regular gradation, the metric system, and simplicity or the avoidance of the superfluous.

III.—J. B. BRADBURY, M.D., F.R.C.P.,

Downing Professor of Medicine, University of Cambridge; Physician to Addenbrooke's Hospital.

As the time for the revision of the *Pharmacopœia* is at hand or actually going on, no more appropriate subject could have been chosen for discussion by the promoters of this Section than the merits and demerits of this book. That the present *Pharmacopœia* inadequately represents the existing state of pharmaceutical and therapeutical knowledge is generally admitted. The descriptions of many of the substances contained in it and the tests for impurities are insufficient and not in accordance with the science of the day; many of the substances and Galenic preparations are not required, and the doses given are by no means representative. Moreover, it contains much matter useless both to the physician and to the pharmacist—for example, the preparation of various commercial substances, as chloroform, liquor ammoniæ fortior, etc. It would be sufficient to give adequate characters and tests of such products whereby a certain standard of purity could be ensured, without entering into detail as to how the compounds might be made.

It is very important that the bulk of the *Pharmacopœia* should not be increased and part of the space thus set at liberty might, as has been suggested, be utilised in giving fuller information as to the solubility of some substances under varying conditions, the neutralising equivalents of the commoner acid and alkaline substances, and similar information of a practical character.

I regard it, however, as very necessary that purely pharmaceutical processes should be retained, for example, the preparations of infusions, decoctions, etc., or at least that a general method for the production of such preparations should be included. Notwithstanding some advantages of concentrated infusions and fluid extracts I am inclined to regard the hastily made infusion in some instances as of greater therapeutic value.

With regard to some of the preparations in the present

Pharmacopœia, I believe that by improved methods, as, for example, cold percolation and the use of slightly different menstrua, better and more potent preparations might be made. Thus it would seem from the experiments of Wright and Farr that the introduction of a weaker spirit is desirable. There is also room for much improvement in the ointment bases.

Although it is very important that the preparation of drugs should be made as uniform as possible, I consider uniformity of dose as of much greater importance. In some instances the two run together, but in the majority they run in very diverse directions. As yet, however, our pharmacological knowledge of crude drugs is so incomplete that uniform dosage is not possible. Much may be done, however, to lessen the existing irregularities. The want of uniformity in the doses of the different preparations of the same drug is in many cases manifest, but as this has been fully dealt with in an able article by Dr. Whittle in the *JOURNAL*, and as it will doubtless be rectified by the Pharmacopœia Committee, it is unnecessary to allude further to the subject.

In some instances the doses of drugs or their preparations are too large. Those of aconite and dilute hydrocyanic acid are examples in point. In the latter case, instead of reducing the dose the official preparation might be made to contain 1 per cent. instead of 2 per cent. of acid, as at present. The preparation would thus be brought into uniformity with other powerful preparations, for example, the alkaloidal solutions. On the other hand, some of the doses given in the *Pharmacopœia* are too small. This is notably the case with the liquid extracts of ergot (xx to xxx) and male fern (xxv to xxx), and others might be mentioned, such as the subnitrate and carbonate of bismuth.

I think the introduction of maximum daily doses in the case of potent preparations, and especially in those in which there is a tendency to accumulation, would be an improvement. I would also replace in all circumstances a maximum dose for the present range of doses. The minimum doses are of doubtful utility, and do not represent what they are intended to do, inasmuch as the lowest dose likely to prove fatal will depend upon many other conditions, such as the number of times of administration, etc.

With regard to the process of elimination, the pruning knife should be used pretty freely. In this connection statistical information is of decided value, and admirable work has been done in this direction by the Therapeutic Committee of this Association and the Pharmacopœial Committee of the Pharmaceutical Society. I think it will be more profitable if I mention my disquisitions from these lists than to enumerate those drugs which I think might be excluded. Those I should like retained are—bismuthi oxidum, glycerinum acidi gallici, infusum caryophylli, liquor ferri pernitratæ, tinctura sambuli.

Where two solutions of the same drug exist—for example, ammonium acetate—it would be an advantage to exclude one of these. Such substances as elaterium, which are of very inconstant composition, and can be replaced by purer preparations, should also be omitted.

With regard to the introduction of new remedies, I think we ought to be very careful as to those which were admitted. I do not consider it so essential that we should have pure products as that we should have substances of proved therapeutic value. Thus, whatever the chemistry of gland extracts may lead us to, thyroid extract undoubtedly deserved a position in the new *Pharmacopœia*. I would suggest the inclusion of the following other substances: Bismuthi salicylas, chloralamide, cocaine (alkaloid), glycerinum acidi borici, glycerinum iodidæ, glycerinum pipæris acidum, lithii citr. liq., lithii salicylas, morphine tartaræ, naphthol, quinine salicylas, strychnine sulphas, syrupus pruni virginianæ, tinctura ergotæ ammoniata, troch. (or pastil.) cocainæ hydrochlor., ung. hydr. oxy. flav., ung. cocaine.

The weights and measures of the *Pharmacopœia* seemed to prove a great stumbling block. Personally, I strongly advocate the metric system as the safe method of preparing remedies. All chemists have for a number of years had to pass an examination in the metric system, and very few could be found who had not some knowledge of it.

The difficulty in my mind arises in prescribing. It was not easy to divest oneself of the idea of grains and ounces, but the innovation must come, and little good would be done by introducing the metric system as optional. England and Russia are the only two European countries which have not adopted it, and recently a Select Committee of the House of Commons has almost unanimously voted in favour of it. The United States of America has passed a law making it compulsory for pharmaceutical purposes. If the metric system should be adopted it would be advisable to give instructions concerning the relative abbreviations of gramme and grain, as in the absence of liquid ingredients the chemist might be in doubt as to which the prescriber meant. The Centigrade scale ought to supplant the Fahrenheit, to be in keeping with the metric system. In conclusion, I should like to add that I regard the constitution of the Pharmacopœia Committee as admirable in every way. The names which had been added to the list as experts were such as must inspire confidence, and I have no doubt our new *Pharmacopœia* will be one worthy of the profession and of the country.

Mr. A. G. MAHOMED (Bournemouth) was anxious that the pharmacopœial preparations should be standardised as far as possible. He suggested that the tinctures might well be made so that a drachm of tincture represented a gramme of the crude drug. Very potent drugs had better not be made into tinctures at all, but presented in the form either of solutions or elixirs. With regard to the question of omissions, he was of opinion that this required very careful consideration. The number of similar preparations of any given drug might with advantage be reduced, and poultices, vapors, and enemata might be altogether omitted.

Dr. TALFOURD JONES said the *British Pharmacopœia* contained nine medicated suppositories. The first on the list was that of carbolic acid, made with curd soap and glycerine of starch. This basis was a bad one, it took too long to melt, and it was not readily absorbed, and if it was wished to retain a carbolic suppository it must be made with some other basis. There were two suppositories of tannic acid, each containing the same quantity—that is, 3 grains—of tannin. Two tannin suppositories of equal strength were not wanted. One of them had the same basis as the carbolic suppository; this one ought to be expelled. Of the mercurial, the iodoform, and the compound lead suppositories he would say nothing. The new glycerine suppository which was introduced into the *Addendum* to the *Pharmacopœia* would be better if it contained a larger percentage of glycerine. There remained two other suppositories, and they were of more importance than all the others put together. He referred to the morphine, and to the morphine and soap suppositories. Each of these contained exactly the same quantity—half a grain of the same salt, the hydrochlorate. One had a curd soap and glycerine of starch base; and, like the other suppositories that were made with such a base, was so inferior to the morphine suppository made with oil of theobroma that it, too, ought to be expelled. Some new suppositories were needed: one of belladonna, also one of belladonna and opium; one of atropine, and one of atropine and morphine; one of cocaine, one of santalin, and one, say, of aloes or aloin; also a good nutrient suppository. The shape as well as the weight of the suppository ought to be defined. The old conical one was apt to slip out during the process of introduction. A better-shaped one had been designed by Messrs. Allen and Hanbury. It was largest about the middle, and tapered towards each end, the apex being pointed and the base being truncated. But the point was a bit too pointed, and the base might with advantage be tapered a little more. These new-shaped suppositories were a distinct improvement on the old ones; so, too, were the biconical suppositories of Lilly. Some medicated pessaries or vaginal suppositories were also needed in the *Pharmacopœia*; also, perhaps, a few medicated bougies or urethral suppositories. With regard to the dosage of suppositories, should the same dose of a medicine be given by rectum as by mouth? He asked the question with regard to drugs in general, but with more especial reference to the administration of morphine in any form and in any way by the bowel. He was inclined to think that the half-grain morphine suppository was unsafe for general use; and yet, since there was

neither a weaker nor a stronger morphine suppository in the *Pharmacopœia*, it might be inferred that this half-grain one was held to be a medium dose; also, that it was a safe one for introduction into the bowel; and that it was applicable to all sorts and conditions of men, and of women too, irrespective of body weight. But this half-grain dose was precisely that of the maximum dose of the morphine salts, as directed to be given by mouth. Was it not, therefore, to be inferred that the official maximum half-grain dose was held to be a suitable one for general administration by bowel; and, if so, was it not also to be inferred that it was held to be necessary to give a relatively bigger dose by bowel than by mouth? He would give his own reasons for holding the belief that it was unsafe to introduce so much as half a grain of morphine salt into the bowel of a patient for the first time—that is, as a commencing or initial dose; and the same reasons would explain why he believed that a dose of morphine given by bowel should, in fact, be a smaller one than when given by the mouth. The dose of a drug, all other things being equal, must chiefly depend upon two conditions—namely, the rapidity of its absorption, and the rapidity of its excretion. The maximum effect was produced by injecting the drug directly into the veins; a very rapid but less speedy effect by injecting into the subcutaneous cellular tissue; and a much slower effect by administration by mouth for absorption by the gastro-intestinal mucous membrane. With regard to the absorption of drugs from the stomach and intestines, it should be remembered, as was well described by Brunton, that this absorption might be considerably retarded and their action diminished by the liver. For before reaching the general circulation drugs absorbed from the gastro-intestinal canal must pass through the liver. "In this passage through the liver the drug may be partly arrested, and excreted again into the intestine with the bile, or it may be partly destroyed." Now it had been stated that drugs absorbed from the gastro-intestinal canal must all pass through the liver, and the inference was that all the blood which circulated in the gastro-intestinal canal passes through the liver. Speaking generally, this was perfectly true, but there was, he thought, an exception to this general rule. He referred to the way in which absorption by the blood vessels was carried on in the rectum. If, too, one considered the method of absorption in the whole length of the alimentary canal from the lips to the anus it would be found that there was one other exception to the same rule. This had reference to the process of absorption as carried on in the mouth, pharynx, and œsophagus. He would first refer to the rectum. The hæmorrhoidal plexus which surrounded the lower end of the rectum was formed first by the superior hæmorrhoidal veins, which were branches of the inferior mesenteric, and secondly by the middle and inferior hæmorrhoidal veins which terminated in the internal iliac veins. The portal and the general venous system had a free communication by means of the branches composing this plexus. The blood from the rectum flowed in part by the inferior mesenteric vein, which was a branch of the portal vein, direct to the liver, and in part by the internal iliac veins to the vena cava direct to the heart. It followed, therefore, that a drug introduced into the rectum was, when absorbed by the blood vessels, carried by two different channels: by one to the liver, by the other to the heart. That portion which traversed the entero-hepatic circulation was in part absorbed into the general circulation, but was in part excreted with the bile, and perhaps was in part absolutely destroyed. But that portion which traversed the vena cava entered the main blood stream direct and passed rapidly through the heart into the general vascular system. Absorption therefore by this direct channel must be more rapid, more certain, more complete than by the entero-hepatic circulation. Let it be supposed that half a grain of morphine, which, for sake of comparison, he would call two-quarters of a grain, was swallowed into the stomach. It all passed into the portal vein, to be dealt with as before described. Let a similar quantity be introduced into the rectum, and let it be assumed that half of it, that is, one-quarter of a grain, passed, like the whole of that from the stomach, into the portal vein, but that the remaining quarter of a grain, by taking the other channel and thus avoiding the liver, passed direct from the rectum to the heart. The

quarter grain of morphine entering the portal circulation from the rectum was exactly equivalent to one of the quarter grains absorbed from the stomach, but the quarter grain which entered the heart direct from the rectum was much more than equivalent to the other quarter grain absorbed from the stomach, which in its passage through the liver had been waylaid, in part stopped or excreted, and in part, perhaps, destroyed. If this were so the dose of a drug administered by the bowel ought to be less than that given by mouth. Some twenty-five years ago, soon after commencing practice and a few years after the introduction of chloral by Liebreich, he was struck by the excellent results obtained whenever he injected chloral into the rectum—results that often appeared to be better and more rapid than those usually obtained by mouth. Liebreich was of opinion that chloral on entering the circulation was split up by the alkalies of the blood into formic acid and chloroform. It was now generally held that this theory of the liberation of chloroform into the blood was wrong, but he had always fancied there might be some truth in it; and formerly he accounted to himself for the apparently quicker action of chloral administered *per rectum* by assuming that in consequence of the comparative alkalinity of the intestinal secretion as compared with that of the stomach that there occurred in the bowel perhaps a speedier liberation of chloroform. This better result, for such he conceived it to be, might in part be due to this cause, but more probably it was chiefly due to the direct way in which, by avoiding the liver, some of the chloral reached the heart. At any rate, ever since then he had held to the belief that 20 grains of chloral injected into the rectum was more than equivalent to 50 grains given by the mouth. Some five years after the time in question—say, twenty years ago—he saw, in consultation, a lady into whose rectum a half-grain morphine suppository had been introduced for the relief of pain, and who died comatose in about twelve hours afterwards. This case impressed him very much and made him timid of half-grain morphine suppositories, and ever since he had been very careful about the dosage of medicines so administered. It was his belief, formed on twenty years of observation, that morphine, introduced in solution or by means of a soluble suppository into the empty rectum, produced a more marked effect, dose for dose, not only locally but generally, than when given by the mouth. In *Kirk's Physiology* it was stated that some observations on the absorption of poisons made many years ago by Savory, brought to light what was considered the singular fact that in some cases absorption took place more rapidly from the rectum than from the stomach. Solution of strychnine, for example, produced its poisonous effects much more speedily when introduced into the rectum than into the stomach. The reason for this was not given. At a meeting of the Leeds Medical-Chirurgical Society, in 1849, Dr. Swann related a case of ptychitis: the patient became comatose after insertion of a suppository of only one-eighth of a grain of morphine. This patient, of course, might have died had the dose been given by the stomach; still it showed how very thoroughly absorption did take place in the rectum, and it also pointed to the danger attending the absorption of morphine into the system when elimination was defective. If they were to have but one morphine suppository in the *Pharmacopœia*, he would suggest that, in place of the existing half grain, one of a quarter of a grain should be substituted. If a smaller dose than this were specially needed for a patient, it was easy, by cutting off a portion from the base of the suppository, leaving the point entire, to reduce the quarter grain to about a sixth or an eighth of a grain. So, too, if a larger dose were wanted, a suppository and a half, or two whole ones, could be introduced at the same time. He was now simply referring to the official suppository. Doctors would of course continue to prescribe whatever they pleased. He concluded with a few words on absorption by the mouth, pharynx, and œsophagus. The mucous membrane of the soft parts of the mouth and palate was thin; that of the under surface of the tongue and the adjacent floor of the mouth was especially thin; the veins, too, were numerous, large, and superficial, and in these tissues absorption went on quickly; but what he especially wanted to point out was that the blood from the whole of the mucous membrane of the mouth, the palate, and the pharynx, was conveyed by the internal jugular veins in a direct stream to the heart; also, that the blood from the

œsophagus was conveyed by its own veins, and the azygos veins, to the superior cava, and so to the heart. The whole of the blood, therefore, from that portion of the alimentary canal, commencing at the lips and terminating at the cardiac orifice of the stomach, went direct to the heart, and could only reach the liver through the medium of the general arterial system. The inference was that absorption of drugs by this portion of the alimentary canal, and especially by the mucous membrane of the mouth, was more rapid and complete than absorption by the stomach; and that it was comparable, though probably even superior, to that one of the two different ways of absorption from the rectum, which he had termed the direct method.

Professor CHANTREIS (Glasgow) said the profession required the forthcoming edition of the *Pharmacopœia* to be accurate, especially in regard to (a) tests for purity, and (b) dosage. The tests for purity were in many instances in the present *Pharmacopœia* lamentably and radically defective. They required most careful revision in accordance with present chemical and pharmacological knowledge. For example, the melting point of salicylic acid was stated to be about 155° C. instead of 156.5°, and that of carbolic acid should be 40°, not 33°, as now stated. The maximum of daily doses as well as the maximum of single doses should be given. The present system of dosage, especially for young practitioners, was very misleading. In some cases the dosage was too large, in others too small. As examples of incorrect dosage the following might be instanced: Ext. fl. liq. $\pi 30$ should be $\pi 90$; pil. ferri, at present 1 to 4, should be given in a maximum daily dose of 15. Further, in some cases, there should be new preparations of old drugs. For instance, the small pilule and granule were more convenient and more hardy than the large forms at present official. In consequence they were largely employed, and experience testified that they were more readily taken by patients, and that their action in the smaller forms was in no way diminished. The profession required that new remedies, loudly advertised, should not be made official until their actions, uses, and doses had been carefully tested by trustworthy pharmacological and therapeutic experts. The time had come for the adoption of the metric system of weights and measures, and of the Centigrade scale of temperature. These should be introduced into the new edition of the *Pharmacopœia*. The equivalent in avoirdupois weight and imperial measure and the Fahrenheit scale of temperature might be added as alternatives. The adoption of these more reliable and more generally used methods would bring our *Pharmacopœia* into touch with the advanced *Pharmacopœia* of other countries. Our *Pharmacopœia* was at present antiquated. It should be the standard authority of scientific accuracy.

Professor W. CARTER (Liverpool) said the General Medical Council was limited by the terms of the Medical Act of 1858, which provided that they shall publish a book "containing a list of medicines and compounds, and the manner of preparing them." They might do other things; this they must do. This fact seemed scarcely sufficiently considered. They could have no security as to the composition of any medicine not included in the official list. An accurate standard was required for purposes of the Adulteration of Food and Drugs Act, which Act was indirectly of the greatest importance to medical men. The *Pharmacopœia* should contain certainties about which no question could be raised. For this reason he should differ from one of the many excellent suggestions of Dr. Lauder Brunton—namely, "that some indications of the actions of medicines should be given," for the moment we come to the actions of remedies differences of opinion arise. Such a difference had been shown in two of the recently published articles in the *BRITISH MEDICAL JOURNAL*, Dr. Brunton characterising the enema alone as one of the most valuable of official remedies, and Dr. Whittle suggesting that all the enemata should be struck out. Another of the principles enunciated for the guidance of the *Pharmacopœia* Committee in the articles alluded to was that active principles should be made to take the place of Galenic preparations, more especially where any diversity of action existed among the several principles which such preparations might contain. This is the main text of Dr. Cash's article, and to a certain extent that of Dr. Stockman. If they acted on this principle they would have to exclude some of the most valuable and trusted remedies, such as digitalis, opium, jaborandi, etc.,

for every one of these contained not only several distinct active principles, but these principles were physiological antagonists—for instance, digitalin and digitonin, morphine and thebaine, pilocarpin and jaborin.

Professor THOMAS (London) commenced by stating that in spite of his dissent on with the Pharmacopoeia Committee any remarks from him must be regarded as absolutely unofficial. In the course of the recent inquiry undertaken by the Therapeutic Committee numerous suggestions were made by members of the medical profession, and these gave clear indications of the requirements of the profession with reference to the revision of the *British Pharmacopoeia*. The remarks clearly indicated a general desire that the volume should be diminished in size, and the conviction that its utility would be thereby enhanced. The list sent to members of the Association was frequently called "a most useless set of remedies." Numerous suggestions of considerable value were referred to in some detail, while others appeared to indicate a lack of seriousness of purpose. There appeared to be a consensus of opinion that preparations should be rendered more portable, more certain in composition, and less numerous. The introduction of new remedies had been urged by many medical men, but this advice was generally associated with the opinion that only active preparations of definite composition and strength should be admitted. He regarded the position of the *British Pharmacopoeia* as somewhat unique. It belonged exclusively neither to the chemist nor to the practitioner; it really should form a standard for the guidance of both. To the chemist its great help should be to indicate precisely what was wanted by the practitioner; while to the prescriber it should supply the full assurance that he could rely upon obtaining the preparation he desired.

Dr. NEVILLE WOOD (London) said the plan he was about to describe for making the *Pharmacopoeia* more accessible he had already published in the *BRITISH MEDICAL JOURNAL* of April 30th. It had received strong commendation from a large number of general practitioners. He proposed that in addition to the present maximum and minimum doses, a third or medium dose should be officially sanctioned, this being as nearly as possible the ordinary working dose of the drug, which in many instances would be found not to be exactly intermediate between the maximum and minimum doses of the *Pharmacopoeia*. He proposed also that the convention should be established that the prescriber might, if he wished, use these doses thus: After naming a drug or its preparation, if he wrote "dose max." the druggist would dispense the maximum dose as laid down in the *Pharmacopoeia*, if he wrote "dose min." the minimum dose was intended, while if he added instead "dose med." the new or medium dose was obviously to be dispensed. The use of this notation would be purely optional, and would not interfere with the full liberty of indicating in figures the dose required. The *Pharmacopoeia* contained some 500 items, and one alone of its revisers proposed to add nearly 100 more. Taking it as it stood now, he calculated that about 260 drugs or preparations for internal use really required an effort of memory on the part of the prescriber. Very few prescribers were blessed with such a large share of the mechanical part of memory, and, in consequence, to quote Dr. Whitla: "The young physician soon breaks acquaintance with his official friends, and too often drifts into the daily use of semi-proprietary or ready-made pharmaceutical compounds, or else settles down to the routine use of a very limited selection of the pharmacopoeial drugs and their preparations." This, Dr. Neville Wood thought, was a striking admission from such an authority. He was not a drug man, but he thought that, if experience had furnished us with so many weapons of different temper, we ought to be put in a position to seize and use the precise one desired, even though in the stress of practice a weak spot was found in our arithmetical memory. What were the objections to this method? Obviously, first, that it might too largely encourage mechanical dosage. He held this to be unfounded, for dosage in the present state of knowledge was and must be largely mechanical, and it was better so than haphazard. It was certainly mechanical when we used drugs unfamiliar to us, and it was to this eventuality that his proposition chiefly applied. Another objection was that some difficulty might be found in applying it to every

drug in the *Pharmacopoeia*—say to those which in small and large doses had different or nearly opposite actions. He found that the number of these was very small, and he thought the difficulty could be overcome in almost every case by quite simple methods. He would mention one typical example of a drug requiring to be specially dealt with. Sulphate of zinc had a dose as a tonic of 1 to 3 grains; as an emetic of 10 to 30 grains. He proposed that to the smaller dose the new notation should apply, while for an emetic he would introduce a new solution of convenient strength, called *solutio zinci sulphatis emetica*; then the new notation would supply a ready means of its use in an emergency. Sulphate of copper, antimony, and ipecacuanha might be dealt with in a similar manner. He would not, for the mere sake of consistency, introduce a new solution of quinine for use in large doses, say as an antiperiodic. Opium was the one drug he would certainly exclude entirely from the scheme. Opium had no working dose. Its dose must be varied in such wide limits, according to age, temperament, and circumstances; and, moreover, they had such abundant opportunity of acquiring familiarity with its use that the man who required mechanical assistance in remembering the doses of the preparations which he used had better retire from practice till he had mastered them. Another advantage of the simplification of dosage was that a great objection would be removed to the frequent revision of the *Pharmacopoeia* and to the addition of new preparations; and, moreover, it would obviate largely the confusion likely to arise in the transition period when the metric system was adopted. In conclusion, he did not expect this scheme to meet with much sympathy from lecturers on materia medica, nor, perhaps, from physicians and surgeons. These should remember that the general practitioner must act in turn as physician, surgeon, and specialist in many departments, and that his plan to mobilise the materia medica was devised for general practitioners, who, though they so largely used the *Pharmacopoeia*, had no direct voice in its compilation.

Dr. W. FRAZER (Dublin) called attention to the necessity of a limited *Pharmacopoeia* for gentlemen commencing prescribing, whom he found in examinations could not be expected to remember or require accurate information on the very wide course at present forming our official lists. He suggested that medicines requiring special caution might be denoted by a special asterisk (possibly of red colour) as a danger mark.

Dr. STOCKMAN (Edinburgh) said the few remarks which he had intended to make on the *Pharmacopoeia* had been forestalled by previous speakers. He would therefore rather confine himself to a few points which had arisen during the discussion. He agreed cordially with Dr. Leitch that it was necessary to exclude a large number of crude drugs which were at present official, but it was still more necessary to diminish the number of their preparations, which had been increased in many if not most instances out of all proportion to their usefulness. Only a very limited number of Galenical preparations was required for each drug. With regard to what Dr. Carter had said about the advantages of Galenical preparations over pure active principles in some instances, there was no doubt that occasionally, as with morphine and atropine, it was advantageous to combine two drugs having somewhat different actions. Although the combination of pilocarpin and jaborin in the case of jaborandi preparations might have an advantage over pure pilocarpin, yet he (Dr. Stockman) submitted that here, as with morphine and atropine, it would be preferable to use a combination of the pure alkaloids rather than a mixture of them in indefinite proportions such as one got in the Galenical preparations, and if they had the active substances of digitalis, hyoscyamus, and other drugs ready to hand there was no doubt that they would soon acquire the habit of using them in preference to the older preparations. In conclusion, the Therapeutic Committee of the Association might direct or have done under its auspices a very large amount of useful work in the direction of substituting the use of active principles for preparations of varying and indefinite strength.

Professor LEITCH, in reply, said it was impossible to allude to all the important suggestions which had been made for improving the *Pharmacopoeia*. He was glad that Dr. MacAlister had alluded to the necessity for some system in the con-

struction of the formulae of compounds, and in the arrangement of their strengths. Considerable advantage would ensue if the idea could be carried out. Much interest had been shown in the question of dosage, and two opposite suggestions had been made. Dr. Mahomed would like to see an approach to symmetry in the strength of the preparations, that is, in the amount of the drug contained in them; this would, of course, mean that the doses would vary more than they now do. Other speakers had suggested that doses of similar kinds of preparations should be rendered more nearly alike than they now are; this would mean that the amount of drugs contained in such preparations would vary more than they now do. Dr. Leech preferred the latter plan, because if, as seems now possible, the most important preparations can be standardised, it will be easy to determine the exact amount of the active principles of a drug in each dose administered, and this, for the purpose of exact comparison of effects, would be more useful than knowing how much of the crude drug was contained in the preparation. He did not think Dr. Neville Wood's plan would be satisfactory, because the dose of any drug must be graduated to the patient and the ailment. It was not sufficient to say the maximum or minimum dose should be given, or an intermediate one. The dose had to be in many cases increased or decreased by degrees to suit the conditions of the case, and such additions and subtractions could not be made without a knowledge of the real amount given. As Dr. Bradbury had remarked, the dosage in the present *Pharmacopœia* would have to be revised, but it was manifest, considering the variation in views which had been expressed both here and elsewhere, that this revision would prove no easy task. The suggestion that the strength of hydrocyanic acid should be 1 per cent. instead of as at present seemed feasible. Dr. Telford Jones's views regarding morphine suppositories also called for serious consideration, and so did his suggestions for new suppositories. The defects to which Dr. Charteris had called attention, so far as regards tests, were deserving of consideration. The question of the value of introducing active principles, to which Dr. Carter and Dr. Stockman had alluded, was, as Dr. Stockman had pointed out, one which would probably receive different replies as time advanced. Doubtless the most exact method of giving drugs would be to determine accurately the amount of each active ingredient in the best specimens of a drug, and then give the active ingredients mixed in their exact proportion, for it seemed very probable that in some specimens of a drug the active principle might at times vary in relative amounts, and the same results, therefore, would not always follow the administration of a drug. But in the present state of chemistry and pharmacology this could not be done. It did not, however, appear impossible that at some future time active principles might be alone used.

THE ACTION OF BETA-NAPHTHOL AND BISMUTH SUBNITRATE AS INTESTINAL ANTISEPTICS.¹

By N. SURVEYOR, AND VAUGHAN HARLEY,

M.D., M.R.C.P.

M.D., M.R.C.P.

Honorary Physician, Janssens Hospital, Bombay.

Assistant Professor of Pathology and Teacher of Clinical Pathology, University College, London.

The investigation to determine the antiseptic value of β -naphthol and bismuth subnitrate was undertaken because, like most other intestinal antiseptics, they are largely used in intestinal troubles supposed to be of bacterial origin by one class of practitioners, while there is a very important class that considers any such attempt as simply futile, if not dangerous, to the patient.

Diseases of the type of cholera, dysentery, typhoid, summer diarrhoea of children, which are most probably due to bacterial infection, or are at least invariably associated with an enormous increase of one or several types of micro-organisms, are daily being treated with one or another kind of antiseptic that happens to be the latest favourite.

¹ Read in the Section of Pharmacology and Therapeutics at the Annual Meeting of the British Medical Association, held in London, July-August, 1894.

Creosote, carbolic acid, perchloride of mercury have been at one time or another used extensively and dropped either on account of their extreme toxicity, or because the clinical results have proved to be unsatisfactory in some hands.

One of the recent additions to this class of drugs is β -naphthol, a coal-tar product which M. Bouchard introduced to the medical profession in 1887 as a valuable intestinal antiseptic for typhoid fever and summer diarrhoea of children. Since that time, this drug has been used extensively with varying results.

The following experiments were consequently undertaken to determine definitely the real value of β -naphthol as an intestinal antiseptic. In the course of the experiments bismuth subnitrate was used at first as an indicator to determine the completion of antiseptics as is suggested by M. Bouchard. However, some observations made with bismuth subnitrate alone in the presence of putrefactive bacteria showed that this drug is not quite inert, but that it is capable of modifying, hindering, or destroying them.

Thus the paper treats of β -naphthol primarily and bismuth subnitrate secondarily. The observations were both chemical and bacteriological. Chemical experiments consisted in estimating the amount and ratio of alkaline and aromatic sulphates present in urine of man before, during, and after taking either of the drugs separately or together. The amount of urea was also estimated at the same time to see how far the body was kept on nitrogen equilibrium. The method of administration was always *per os* in the form of powders.

In the first series of experiments with β -naphthol, which lasted for nineteen days 1 g. was taken twice daily during twenty-four hours. The first dose was taken at breakfast, and the second at dinner time. The drug was taken during the last twelve days of the experiment, while during the first week the normal ratio of the sulphates was determined. The day and night urine was analysed separately. The day urine was collected from 9 A.M. till 7 P.M., and the night urine from 7 P.M. till 9 A.M.

The second series of experiments lasted for thirty-seven days. The first day's urine was tested for the normal ratio. On the succeeding seven days 0.5 g. of bismuth subnitrate was taken twice daily. The first dose was taken at breakfast and the second at dinner time. During the next week 1 g. of bismuth subnitrate was taken thrice daily. The third dose was taken at lunch time.

During the next four days 1 g. β -naphthol in the morning and evening, with bismuth subnitrate, which was continued in 1 g. doses thrice daily. During these days the urine was analysed daily except on Saturdays and Sundays. The urine was again analysed on the sixth day after the last day of β -naphthol and bismuth subnitrate, and again for three days at the end of another week.

The general result of these experiments was to show an increase of aromatic sulphates during the time when β -naphthol was taken either alone or with bismuth subnitrate. The total sulphates did not vary much during the same period as compared with normal periods. On the other hand, the alkaline sulphates were always diminished under the influence of β -naphthol. Consequently, the ratio between alkaline and aromatic sulphates, which was 10:1 during the normal periods, increased to 10:2 on an average, and on one occasion even went up as high as 10:4.

The general health remained the same during these periods, except that on the last day of bismuth subnitrate and β -naphthol, griping and slight looseness of bowels occurred. The urine did not show any other alteration except that it had a greenish violet fluorescence during the time β -naphthol was taken, and on addition of a few drops of 1 to 10 c.cm. of pure sulphuric acid it acquired a dirty green colour, as is stated by Hoppe-Seyler, thus proving the presence of β -naphthol in the urine.

From these experiments it is not possible to say how far β -naphthol serves to diminish the aromatic sulphates, because that is most probably masked by the drug itself, which is converted as an aromatic sulphate at expense of the alkaline sulphates. The aromatic sulphates, however, diminished considerably on stopping β -naphthol, and the ratio fell as low as 10:0.83. During the time when 1 g. bismuth subnitrate was taken daily the alkaline sulphates increased at the

expense of the aromatic while the total sulphates remained the same. The ratio of alkaline to aromatics fell from 10:1.3 to 10:0.8. However, the reverse happened when the dose was increased to 3 g. per diem; on one occasion the ratio increased to 10:1.38. During the time when the larger dose was taken there was slight constipation.

The bacteriological observations consisted of the ordinary test tube experiments with bismuth subnitrate and β -naphthol: 1 mg. to 1 cg. of β -naphthol was added to 10 c.cm. of sterilised glucose gelatine, and set in the indicator for a week before using them for inoculation. Most of the tubes that had less than 6 mg. of β -naphthol developed a growth, that is, 0.06 per cent.; β -naphthol tubes remained sterile. Similar bismuth subnitrate tubes were also prepared and treated in the same manner. None of them were found to be contaminated. Those tubes that remained sterile were used for subsequent inoculations from either pure cultures of cholera bacillus, the vibrio Metchnikovii, bacillus coli communis, and the typhoid bacillus, or from mixed growths of putrefactive bacteria from infusion of meat.

These mixed cultures consisted of different forms of micro-organisms, and one of the most evident results of their growth was the evolution of sulphuretted hydrogen, which could be easily detected by the reduction of bismuth subnitrate.

Thus the addition of bismuth subnitrate to a culture of these produced two effects. First, it was converted into a sulphide; and, secondly, the reaction of the culture medium, which was strongly alkaline before the addition of bismuth subnitrate, became strongly acid in a short time. Returning to the tubes to which the antiseptics were added previous to inoculation, it was found that tubes to which 8 mg. to 1 cg. of β -naphthol was added, that is, those that had 0.08 per cent. to 0.1 per cent. β -naphthol, always remained sterile, while β -naphthol in smaller amount was not invariably able to prevent a growth. In small doses (1 mg. to 3 mg.) it was not able to prevent the evolution of sulphuretted hydrogen. The reaction of these tubes was strongly alkaline. The subcultures from these tubes always grew feebly. The bismuth tubes that had 1 cg. for 10 c.cm., that is, 0.1 per cent., remained sterile after inoculation, while scanty growth occurred in those that had even 8 mg. with reduction of the bismuth. The reaction in these cases was acid.

Subcultures from these tubes either could not be obtained or were very feeble. Tubes with still less bismuth subnitrate showed a copious growth and reduction of bismuth. Subcultures from these were easily obtained. The experiments with the specific micro-organisms mentioned above showed almost identical results. All of them are capable of reducing bismuth subnitrate.

Indol reaction in the case of bacillus cholerae, vibrio Metchnikovii, and bacillus coli communis, and also in the case of mixed cultures, could not be obtained with any of the tubes that had bismuth subnitrate, although subcultures from the weaker tubes could be obtained which were capable of giving the reaction.

These tests could not be applied in the case of β -naphthol tubes because β -naphthol alone gives almost an identical colour reaction. All these facts point to the conclusion that both β -naphthol and bismuth subnitrate have the power of preventing or hindering the growth of micro-organisms, and that β -naphthol is the stronger of the two in some cases. The safest dose for β -naphthol is about 8 in 10,000; while for bismuth subnitrate it is 10 in 10,000.

These experiments only show how far the growth of these microbes is prevented or delayed in test tubes, when the antiseptic is added previous to the germs. However, we must recognise the fact that in determining the value of an intestinal antiseptic the microbes are already there in enormous numbers before the antiseptic could be added, and that every meal adds to that number.

Two sets of experiments were therefore undertaken to see how far these drugs could act as intestinal antiseptics. The first series consisted of determination of the approximate number of colonies present in the contents of the different parts of the alimentary canal of dogs, after feeding them for several days on the same kind of food. These numbers were compared with those obtained from dogs treated with bismuth subnitrate, β -naphthol, or both of them combined.

The total contents of each part were diluted with about half a litre of sterilised water. The weight of the flasks and the weight of the water being previously determined, the weight of the intestinal contents was easily ascertained. This gave the ratio of dilution. The contents of the whole canal were divided into five parts, namely, those of the stomach, the duodenum, the upper half of the small intestine, the lower half of the small intestine, and the large intestine; 0.1 c.cm. from these flasks was added to 20 c.cm. of nutrient gelatine for plate cultures. However, it was soon found that the contents of the lower part of the small intestine and of the large intestine contained an enormous number of liquefying micro-organisms. Consequently, for the later experiments agar was substituted, and the contents of the last two parts were further diluted. The faeces of the dogs which were treated with β -naphthol and bismuth subnitrate or with the latter alone were daily observed to see whether the blackening due to the reduction of bismuth subnitrate could be used as a reliable indicator for completion of intestinal antiseptics, as is suggested by M. Bouchard.

The results were unfortunately varying. The bismuth dogs as a rule passed black faeces for some days, then there would be no blackening for a day or two; nevertheless, the colour reappeared although bismuth was continued throughout the period. The faeces of the β -naphthol and bismuth subnitrate dogs showed the same variations.

Again, it was found that the plate cultures of two normal dogs were not able to reduce the bismuth subnitrate. On the other hand, plate cultures from some of the β -naphthol dogs reduced the bismuth at once. However, the number of colonies gave more satisfactory results. Dogs that were treated with β -naphthol and bismuth subnitrate showed considerable reduction of the colonies whole throughout the tract. Simple β -naphthol showed a similar reduction. The bismuth subnitrate produced a reduction in the number in the upper parts of the tract, while the colonies in the lower parts were hardly reduced.

The great disturbing factor for making a satisfactory comparison between different animals was the nature of food and the amount of contents found, as the number of colonies always varies with the food and the quantity of the contents. Dogs fed on biscuit showed an excessively large number as compared with those fed on meat alone. Again, the colonies from very scanty contents were very few even relatively to those from a tolerably fair amount of contents. Thus, for making any satisfactory comparison between the colonies from different animals these two disturbing factors have always to be taken into consideration.

The second set of experiments consisted in taking 50 c.cm. of the diluted contents of the large intestine of five dogs, and adding 0.5 g. of the antiseptics either singly or together, and these were left in the incubator at 37° C. for several days. Both the antiseptics being scarcely soluble in water, the flasks were shaken frequently. Subcultures from these were made daily to see whether the contents were sterilised or not. None of the β -naphthol flasks were sterilised even after thirty-five days.

After the sixteenth day all the bismuth subnitrate flasks were sterilised, while flasks having both the antiseptics showed very feeble growth at the same period. Subcultures were made in glucose-gelatine tubes and put in the incubator. Control flasks having none of the antiseptic showed a growth during the whole period. One of these five dogs was a normal one; one had bismuth subnitrate for twelve days; two dogs had β -naphthol for sixteen days; while one had bismuth subnitrate and β -naphthol for twelve days.

These experiments show that bismuth subnitrate is more powerful as a germicide than β -naphthol when large doses are used. However, internally β -naphthol appears to act better than bismuth subnitrate. The reason for this discrepancy is probably to be found in the fact that although bismuth subnitrate is the stronger antiseptic, its value is lowered on account of its constipating property. The explanation of the fact that in the test-tube experiments β -naphthol was found to be somewhat stronger than bismuth subnitrate is to be sought probably in the mode of action of bismuth subnitrate.

From the fact that this salt is easily converted into a sulphide in the presence of organisms that produce sulphuretted

hydrogen or some other sulphide, we might assume that nitric acid must be liberated at the same time. This is rendered highly probable by the fact that cultures that are alkaline before addition of bismuth subnitrate become acid after some time. However this acidity is not due to free nitric acid, but to some organic acid which the liberated nitric acid sets free from the culture medium.

However, to obtain some positive proof for the assumption the following experiment was performed. Bismuth subnitrate, when shaken up with boiled distilled water, gives a neutral reaction for about five minutes, after that it changes to acid. Ultimately it becomes so markedly acid that Congo red paper shows the presence of free nitric acid. Heat favours the reaction. This reaction gives a satisfactory explanation of the phenomena described above.

Why those flasks to which both drugs were added should not be sterilised earlier than those to which bismuth subnitrate was added alone is rather difficult to account for. A possible explanation is that the liberation of nitric acid is either delayed or retarded in the presence of β naphthol.

In the foregoing we have tried to state the facts as concisely as possible, and have avoided drawing any conclusions from them.

ON THE DIGITALIS GROUP AND THEIR USE IN THE TREATMENT OF DISEASE OF THE HEART.¹

By GEORGE W. BALFOUR, M.D., LL.D.,
Consulting Physician Edinburgh Royal Infirmary.

THE digitalis group comprises a considerable number of plants of different botanical families and of varying activities, ranging from the deadly upas to the comparatively innocuous convallaria and adonis, all of which have an action on the heart more or less resembling that of the plant which gives its name to the group.

The fundamental action of the members of this group is to increase the elasticity of muscular fibre so that it expands more slowly and contracts more perfectly. The effect of this upon a hollow muscle like the heart is that it dilates more slowly and empties itself more completely; residual accumulation is thus prevented and any dilating influences are counteracted. The heart is affected earlier and more powerfully than the other muscles because the blood passes so frequently through it that it receives a larger dose of the drug within the same space of time. For a similar reason the muscular coat of the arterioles also gets a disproportionate share of the drug and is early and strongly affected, though not nearly to the same extent as the heart, as the arterioles are only stimulated by the comparatively small quantity of blood passing to their own district. The more perfect contraction of the heart throws a larger blood wave into the arteries, and as the effect of the increased elasticity of the muscular coat of the arterioles is to keep their calibre contracted, the blood escapes more slowly into the veins, it accumulates within the arteries and the blood pressure within them is raised. The effect of this is that every muscle in the body, and amongst them the myocardium, is flushed with blood at an increased pressure and their nutrition and energy are improved and augmented by a more perfect metabolism.

The action just described is that of digitalis itself; it seems probable that, besides the general action on the muscles, each of the members of this group has a common action on the heart, coupled with specific differences of its own. We know, for example, that digitalis acts powerfully on the heart and arteries, and less so on the uterus and bladder; and that ergot acts energetically on the uterus and bladder, and less so on the heart and arteries; and Professor Fraser tells us that strophanthus acts powerfully on the heart, and but slightly on the muscular fibres of the arterioles. Fraser claims this as an advantage in favour of strophanthus; it seems to be a very doubtful advantage, and it distinctly shows that the action of strophanthus specifically differs from that of digitalis. From the absence of any marked constriction of the arterioles, any rise in the blood pressure follow-

ing the use of strophanthus must be due to ventricular action only; it is not, therefore, persistent, and can only feebly affect the muscular metabolism. We need not, therefore, wonder that when the action of the drug is withdrawn the heart is not found to have received permanent benefit, but remains pretty much as it was. Strophanthus forces on the ventricles an increase in the strength and duration of the systole, which ceases with the action of the drug. It acts as a cardiac poison and not as a cardiac tonic. In cases of valvular lesion with ruptured compensation and dropsy, strophanthus acts doubtless as a diuretic, but in this respect it is uncertain. Apart from the experience of myself and others, the very discrepancy in the dose prescribed indicates this, for while some find 5 minims of the tincture every four hours amply sufficient, others find as much as 10 or more minims every two hours to be required. Past history and present experience alike teach us that to restore a ruptured compensation in cases of valvular lesion drugs are not always required. If such a patient is put to bed, the recumbent posture at once reduces the work of the heart by ten or twelve beats per minute, and this coupled with warmth and good food, is sufficient to rehabilitate the hearts of most hospital patients, to raise their blood pressure, increase the flow of urine, and drain their cavities. The addition of a few doses of strophanthus will not prevent this improvement, even if it does not materially assist it.

Strophanthin has, however, two advantages over digitalin: it is readily soluble in water, and it is rapidly absorbed; it is thus available for hypodermic injection, and, as it acts with great rapidity, it may be of service when administration of any drug by the mouth would be of little use. There may thus be circumstances in which strophanthin is to be preferred to digitalin, though it may be doubtful whether the hypodermic injection of ether is not more likely to be more useful than either, when the failing heart stands in need of an immediate filip.

Strophanthus is the only member of this group which has any pretensions to rival digitalis, yet it is so much more uncertain in its action, and so devoid of tonic properties, that we are not tempted to displace in its favour our own indigenous drug.

Dotted all over our upland pastures there is no nobler plant in our indigenous flora than the digitalis purpurea, and there is no more potent benefactor to mankind among the many constituents of our materia medica. For more than a hundred years digitalis has been known as a sovereign remedy for dropsy, but it is only within the last twenty years that its true properties have begun to be recognised. And even yet the profession are hampered in its use by the continued prevalence of the idea that digitalis is a most powerful but dangerous sedative to the heart—an idea that dates from those not so far back days when digitalis was supposed to possess a number of distinct actions, all more or less antagonistic to one another. Now we know that digitalis is a tonic to the muscular fibre, and that it acts chiefly on the heart and on the muscular coat of the arterioles. From this action flow all the benefits we obtain from this drug, while any unpleasantness that may happen to follow its employment is due to the effects of an overdose, and for this the prescriber is to blame and not the drug.

Digitalis in every form is absorbed with difficulty and only slowly excreted, hence if the dose is repeated at too short an interval the drug accumulates within the system, and ere long symptoms of poisoning appear. This faculty of accumulation digitalis shares with many other drugs. Unfortunately for its own reputation its sphere of usefulness lies among a class of cases in which sudden death is no uncommon occurrence, and for many a day any sudden death in a patient taking digitalis was always ascribed to the cumulative action of the drug quite irrespective of the dose administered. Even yet there is an idea of danger connected with this drug which hinders the usefulness of this invaluable remedy. Deaths from digitalis poisoning in those otherwise healthy are amongst the rarest of occurrences; only a very few are on record. A full account of one has been published in which 211 grains of the powdered leaves were taken within five weeks before the fatal result.² Nausea, diarrhoea, faintness, and slow pulse had preceded during fully four of these

¹ Read in the Section of Pharmacology and Therapeutics at the Annual Meeting of the British Medical Association, held in London, July-August, 1886.

² Robinson, *Vierteljahrsschrift für gerichtliche Medizin*, 1872, p. 274.

weeks. Using ordinary medicinal doses with reasonable care we need have no apprehension, and in all my experience of many years I have never seen any unpleasant result follow even a somewhat free use of digitalis. As may be readily supposed, saturation is more easily brought about in small and anæmic individuals than in those who are more bulky and robust.

A tonic dose fitted to improve the nutrition and increase the energy of a feeble heart must always be a moderate one, and only repeated after the lapse of an interval sufficient to permit the preceding dose to be wholly excreted. In this way we secure that at the end of the interval there is a slight increase of the cardiac tone and energy, no digitalis remaining within the system. A usual and efficient dose to secure this end is 1 gr. of the powdered leaves, or an equivalent of any of the other preparations of the drug, every twelve hours. Such a dose may be continued safely for so long as may be required without risk of saturation. The feeble heart slowly and steadily improves, an imperceptible impulse becomes perceptible, and a feeble impulse a strong one, the patient meanwhile slowly acquiring an increasing sense of well being and capacity for exertion. Such a tonic dose may be safely continued for years with nothing but increasing benefit to the patient, and without the slightest need for any anxiety as to the possible occurrence of any disturbing saturation.

When we wish to contract young hearts which have got dilated, or to excite diuresis, we must employ larger doses than such as are merely tonic, and as these larger doses have a cumulative effect the patient taking them requires a little more attention.

The young dilated hearts we wish to contract are either such as follow various febrile affections occurring in early youth, or are the flabby dilated hearts of those who are chlorotic or anæmic. Such heart affections are often called functional, and the sufferers are supposed to grow out of them. But it is distressing to find a few years later that a want of timely attention has left this so-called functional affection as an obstacle to entering a profession or a hindrance to making provision for a family.

When the heart is feeble and dilated it beats more quickly and less forcibly than in health, the ventricles empty themselves less completely, there is residual accumulation within their cavities, the arteries get depleted and the veins over-filled. The result of this venous stasis is a soaking of all the tissues, and by persistence of all the conditions this ultimately collects as dropsy in the more dependent parts of the body and within its cavities. This dropsical accumulation is chiefly of consequence as an indication of heart failure, but in the tissue interspaces, and especially in the extremities, it constitutes an important peripheral obstruction to the circulation, increasing the work of an already failing heart.

In such cases our forefathers employed digitalis empirically as a diuretic, often with a dangerous freedom, sometimes giving as much as from 10 to 20 gr. in powder or infusion every hour or every two hours till nausea or sickness occurred. This sickness was accompanied by great diminution or complete suppression of urine, and was followed in two or three days by copious diuresis. Nowadays we know that digitalis has little if any action on the kidneys, and that it produces diuresis by improving the condition of the heart and circulation. As the arteries fill and the veins empty the effusion is absorbed, the blood gets more watery, and this excess of water is excreted by the kidneys. We need not, therefore, run any risk by giving absurdly large doses; a simple tonic dose acts as a diuretic by maintaining the integrity of the circulation; but when the heart is dilated as well as feeble and the accumulation of fluid considerable, we require to act a little more energetically. A moderate dose is, however, quite sufficient; 3 gr. of digitalis, either in powder or infusion, every eight hours, will be found a very efficient diuretic. Only exceptionally will a larger dose be required, and we must always remember that the larger the dose and the shorter the interval between the doses the more watchful we must be for symptoms of saturation. These symptoms may be looked for as soon as 30 to 40 gr. of the drug have been ingested; they are—diminution of a primary diuresis, slowing of the pulse, or nausea, more rarely diarrhoea. If the medicine is stopped on the first occurrence of one or other of these symptoms, the patient

will suffer no damage, nor will the physician ever be disappointed in any reasonable expectation. This is Withering's statement, and with him I entirely agree. When symptoms of saturation occur diuresis diminishes, and almost complete suppression may last for two or three days; diuresis then recurs and may continue till all the fluid is drained off, or it may be readily kept up by a moderate dose at regular intervals of eight to twelve hours. Apart from any diuretic action, these cumulative doses, by gradually improving the tone and elasticity of the myocardium, not only enable it to resist dilating influences, but in favourable circumstances are able to restore a dilated heart to its normal dimensions.

Much larger doses than those indicated are frequently given without detriment. It is on record that a young woman affected with mitral stenosis took for six years $\frac{1}{4}$ gr. of digitalis leaves in infusion night and morning, with nothing but continuous benefit. Without her medicine she was unable to work, her limbs were oedematous, flashes of light dazzled her eyes, a rushing sound disturbed her hearing, her heart felt full to bursting, and her urine was suppressed. All these symptoms disappeared within a few hours after her medicine was repeated, and she was once more an active woman.² But such a case must be exceptional, and so large a dose cannot be recommended.

The first effect of a moderate but cumulative dose of digitalis is slight slowing of the pulse, with increased tension, and a gradually increasing flow of urine. After the ingestion of about 30 gr. we look out for signs of saturation; with moderate doses there are a more marked slowing of the pulse, and a diminution in the flow of the urine, immediately followed by a tendency to cardiac irregularity, the slow heart beat quickens, falters, and intermits on the slightest exertion. Unless we remember that after the administration of 30 gr. of digitalis we approach the point of saturation and are watchful, a slight drop in the pulse rate, or in the quantity of urine is apt to pass unnoticed, and the patient may get plunged into all the discomforts incident to vagus paralysis, while we are sorely aware that the drug has begun to affect him. This, however, is not the fault of the drug, but an error on the part of the practitioner.

The slow pulse of digitalis action seems quite devoid of danger, but the rapid irregular pulse of digitalis poisoning certainly indicates a condition that is not free from risk, though it may be safely tided over by strict adherence to the recumbent posture and the moderate use of stimulants.

It is well to remember that after symptoms of saturation have appeared, the full diuretic effect of digitalis is often displayed for two or three days. The remembrance of this may help to prevent needless dissatisfaction with the action of the remedy, and in some cases it may avert the ascription of this postponed action to some much less effective drug. Now and then we meet with a constitution so sensitive to the action of digitalis that symptoms of saturation follow the ingestion of less than half the usual quantity, such cases are rare, and when met with must be treated on ordinary principles, with the necessary limitation of the maximum dose.

Digitalis may be beneficially employed in all cases of heart failure whatever may be the cause or the nature of the concomitant lesion. In cases of valvular lesion, apparently fully compensated, digitalis may not be imperatively called for, but as in all such cases heart failure is steadily if slowly progressive, no harm can ever result from giving tonic doses of the remedy sufficient to maintain the normal elasticity of the myocardium. Some object to this, especially in certain forms of valvular lesion, from an idea that "the heart may be thus unduly stimulated, and the left ventricle hypertrophied beyond the needs of the circulation," so that it gets prematurely beyond the feeding power of its arteries, and the final and irremediable breakdown of compensation thus inaugurated and hastened by the very means employed to avert it.

It is a curious commentary on the changes in medical opinion that in these latter days the production of active hypertrophy of the heart should be ascribed to that drug, which, for the first half of this century, was thought to be a

² *Blitz, Archiv der Heilkunde*, 1773, 8. 495.

¹ *Edinburgh Medical Journal*, April, 1895, p. 871.

sovereign cure for that affection. Neither opinion is founded on either pathology or fact. We have many drugs which produce atrophy. I know of none that cause hypertrophy. Hypertrophy of a muscular organ is the result of a call for increased exertion, and arises in no other way. The heart has a large reserve of energy, and even when called upon for increased exertion does not at once hypertrophy; it is only when dilatation has occurred that the needful compensating hypertrophy follows. And so throughout the future progress of the affection the dilatation is ever in advance, the hypertrophy lags somewhat behind. Digitalis increases the elasticity and improves the nutrition of the myocardium, and enables it to withstand the dilating influences to which it is subjected. Far from unduly stimulating the heart and forcing upon it a needless hypertrophy, the tonic action of digitalis checks the progress of dilatation, and retards instead of precipitating hypertrophy.

Corrigan long ago raised a warning voice against the use of digitalis in aortic regurgitation, because he looked upon it as a pure sedative, and regarded the prolongation of the diastole as a source of increased danger to the heart. It is an indication how ill understood the true action of digitalis still is that a similar idea is yet held by some. But the increased elasticity and energy that the myocardium acquires from the action of digitalis is not only sufficient to enable it successfully to resist the dilating influences to which it is exposed during the prolonged diastole, but is even adequate to produce a certain amount of contraction of the ventricular cavity, as shown by the recession of the apex beat upwards and to the right.

About a couple of months ago I found an old professional friend suffering from the effects of influenza upon a heart labouring under aortic regurgitation. I prescribed digitalis for him, and a fortnight afterwards asked him to detail his experience for your benefit. In his case the regurgitation is simple, and without mitral complication.

He writes: "When first I saw you my pulse was irregular and feeble. In the morning I could only walk about 250 yards. This took me from nine to twelve minutes, and I had to pause to gain breath three or four times on each occasion. In the afternoon, with usually the assistance of an arm, I could walk half a mile, resting say three times, but being troubled with occasional dull pain in the heart, constant distress from a feeling of constriction in the lungs, and a feeling of strain and weakness in the muscles. My stride was little more than half its natural length; and this half mile took me always over half an hour to accomplish. The night before I first took the digitalis was the most trying and distressing which I can remember. My breathing was just a succession of rapid gasps, which ceased whenever I seemed about to fall asleep, when I had to draw a breath by an effort of will. The inhaled air did not seem to get fully into the chest. There was mental confusion, if not absolute cowardice. The feebleness and irregularity of the pulse were extreme, and my condition was altogether so painful that a sense of duty alone restrained me from desiring death. I had to walk all night till 5 in the morning. After the first day of taking digitalis all this was for the most part changed. Even then, as I expressed myself to you, I was 'a different man.' I think anyone might be satisfied who has a pulse like mine now, I sleep well, the stride has lengthened out, five to six minutes now suffice for the 250 yards; with sometimes no rest at all I have walked about a mile and a half. Though there is occasionally a little panting, the air seems to get to the bottom of my chest, which is altogether free from any feeling of constriction. In fact, for a week I have been enjoying life, there is a kick in my pulse which tells of everything firming up, and there is not in my mind an atom of doubt as to the *post hoc propter hoc* in my case.—Ever yours, M. F. H."

Such as digitalis can do, it acts within certain limitations, and it fails occasionally when we most desire its success. It has no action whatever on the often protracted ingravescent asthete of a moribund heart, but as we are not always able at once to recognise this form of terminal failure we are bound to employ that remedy which holds out most hope, but we have no right to be disappointed when it fails. Since the days of Withering it has been known that when "the limbs in anasarca are solid and resisting we have but little to

hope" from digitalis. But in these cases as soon as the tension is relieved by purgation, or local drainage from incisions, digitalis acts well, the rest of the fluid is absorbed and the heart improves. In dilatation of the right ventricle following marked stenosis of the mitral valve, or originating in that limitation of the area of the pulmonary capillaries always present in emphysema of the lungs, we cannot expect much from digitalis, it acts as a tonic and improves the condition of the heart, but it cannot in either case contract the right ventricle because of the permanent and ineradicable nature of the obstacle to the circulation that has produced its dilatation. Where loss of arterial elasticity from any cause has produced dilatation of the left ventricle digitalis acts badly, and may even increase the dilatation unless it is combined with some vascular stimulant, but with this proviso it acts well and is most useful in all such cases. Lastly, digitalis is said to act badly or to be even positively injurious in cases of fatty heart. But as hearts diagnosed as fatty are as a rule only feeble and dilated it would be a sad mistake to be deterred from giving such hearts all the benefits they are so likely to receive from digitalis by the baseless dread of an unrecognisable chimera. I may add that I have never seen any damage accrue from acting on this principle.

The most suitable preparations of digitalis to employ are first of all the powdered leaves carefully prepared, and not over a year old. The infusion ranks next to the powdered leaves; it seems to contain all the most active principles of the plant, and it lends itself readily to combination with vascular stimulants, which are so often necessary adjuncts to secure the full benefit of the remedy without discomfort to the patient. From the very small dose of the powdered leaves employed it is scarcely necessary to have recourse to any more concentrated preparation, but Nativelle's and Merck's digitalin are both active and convenient preparations, and are useful when merely a cardiac tonic is required; if given in larger doses for any other purpose they are both prone to excite nausea, and do not act so favourably as either the leaves or their infusion. The tincture is an intermediate preparation; it acts well as a tonic, and combines readily with other tonics, less readily with vascular stimulants; it ranks next to the infusion, and is a suitable and convenient form in which to employ the remedy.

To enter more at large into the various combinations of remedies or of other forms of treatment that may be advantageously conjoined with digitalis in the treatment of different heart affections would plunge us into the wide field of general cardiac therapeutics, into which I have no intention to enter at present.

In conclusion I have only to add that with attention to the selection of a suitable dose, and the ordinary precautions which every form of treatment demands, if we are to expect any benefit from it, digitalis will do everything that can be reasonably expected of it, and will confer more benefit on cases of cardiac disease than any other drug in the *Pharmacopœia*; not because it is a diuretic, a sedative, or a stimulant to the heart, but because it maintains and improves its metabolism; for failure of metabolism is, under all circumstances, the great source of danger to that important organ.

Professor LARCH said that the influence of digitalis as a tonic and sedative was a question of degree. Such doses as Dr. Balfour had indicated were free from danger; yet in some cases very slightly larger doses may easily affect the heart and do unforeseen harm. The remedies with which comparatively small doses render the heart's beat unduly slow or irregular point to real danger from a slight excess of dose, and although it is impossible to judge when a patient dies with heart disease taking digitalis there have not been wanting cases in which it was indicated that the digitalis was to blame. It is worthy of notice that in experiments on the excised heart of the frog the cessation of the heart's action is usually permanent; there is no such recovery when the poison comes to circulate through the heart, as we see in the case of some other drugs. This points in the direction of the view that in cardiac diseases digitalis may readily become a dangerous remedy. The records of the treatment in *pericarditis* show that in this ailment digitalis can usually be given without danger, and the same seems to be the case in *dilatation tricuspidalis*.

Dr. ILLINGWORTH did not consider that digitalis was a cardiac tonic. If given in doses of 6 to 10 minims in cases of pneumonia, the pulse-rate might be very considerably reduced, and syncope or even death might occur. He considered this to indicate a depressant or calumative action. He admitted, however, that in cases of nervous palpitation the pulse-rate appeared to be slowed and the volume increased, but in his opinion this was a mere side issue, and not a main question.

THE SUBCUTANEOUS USE OF CREASOTE AND GUAIACOL IN PULMONARY PHTHISIS.¹

By F. R. WALTERS, M.D., M.R.C.P.,

Physician to the North London Hospital for Consumption.

Of all the drugs which have been used in the treatment of phthisis there are probably none which have been so widely adopted as wood creasote and its derivations. Advocated in 1833 by Rubchenbach, condemned in 1835 by Martin Solon, it fell into disrepute until revived by Bouchard and Gimbert in 1877, since which it has been tried and approved by a long list of authorities—Jaccoud and Dujardin-Beaumeiz, Dieulafoy and Germain Sée, Sommerbrodt, Von Brun and Guttman, Douglas Powell, Burney Yeo, and many more, who all agree as to its utility, while they differ as to its mode of action, dosage, and modes of administration. At the present time some are enthusiastic in its praises while others are as strongly opposed to it; and it must be admitted that it has a nasty way of failing in some of the cases where its help is most needed. It is, however, not surprising that this should be the case. To begin with, in a disease like pulmonary phthisis, where destruction and repair go on side by side, and the same process is sometimes useful and necessary, at other times disastrous, it is very difficult to estimate the effect of any remedy, owing to the impossibility of obtaining strictly comparable cases. In the next place, not only is there true or wood creasote and sham or coal-tar creasote, but several varieties of wood creasote, such as pinewood creasote, which contains more creosol, and beechwood creasote, consisting largely of guaiacol; and even beechwood creasote (which is usually preferred) varies in its composition. To add to these difficulties, the dose of creasote which can be borne with impunity varies considerably with individual idiosyncrasies and with the type of the disease, perhaps more than is the case with any other commonly used drug. Bearing these facts in mind, it is not so much remarkable that authorities should differ as to its utility as that there should be as great a unanimity. The concord becomes more striking than the discord. The number of cases dealt with by some of these observers is so considerable that there is at least strong *prima facie* evidence, in favour of the utility of the creasote compounds.

Bouchard in his first paper gave the results of 83 cases, and subsequently published more; Sommerbrodt's cases numbered over 5,000, Von Brun's 1,700.

Bouchard and Gimbert's early results were obtained by the administration of comparatively small doses of creasote—3 to 6 minims—over long periods of time, although they subsequently increased their doses in certain cases. They gave it either in cod-liver oil, or in alcohol with a bitter tonic on an empty stomach. Sommerbrodt, writing in 1887, recommended the administration of three capsules, each containing 1 minim of pure beech-wood creasote, increasing the dose by one daily until the eighteenth day, when this quantity (20 minims) was to be continued for many months.

As a rule patients can be readily brought in one way or another to tolerate large doses if these are sufficiently gradually increased; but it is by no means certain whether more than 15 or 20 minims per day can be absorbed by the alimentary canal, judging by Poggi's results with guaiacol. And some patients are quickly nauseated by quite small doses which do not appear to be of any use. To overcome this difficulty several methods have been adopted. A less irritating ingredient may be given, such as guaiacol, introduced by Sahli in 1887, or the creasote may be prescribed

with some bland fluid such as milk, or with a gastric sedative. Another method is to give it in capsules, or in keratin-coated pills which are only dissolved beyond the stomach. The administration of carbonate of guaiacol or creasote depends on a similar principle, as the combination is only exceptionally broken up in the stomach.

There seems to be some doubt as to the equal efficacy of guaiacol and creasote, the experiments of Main² appearing to show that the crude drug was more reliable. Hudeod, of Geneva, is strongly impressed with the advantages of rectal administration, and Burlureaux also adopts this method amongst others. Germain-Sée has recently advocated the employment of inhalations of compressed air containing creasote. Another plan is that of external applications, as guaiacol has been shown to be largely absorbed by the skin. But the method which I wish to dwell upon to-day is that by subcutaneous injection. This has been adopted in one form or another by Schetelig, Ploot, Diamantherger and Weil, Burlureaux, and others. Schetelig uses 20 to 30 per cent. solutions of creasote in oil of cloves, injecting 16 minims into the thigh or abdomen from four to twelve times daily, leaving the needle in and applying gentle massage between the injections, which are repeated at intervals of a quarter of an hour to an hour. He states that, although the taste of creasote was sometimes noticed after the injection, there was no digestive disturbance, and marked antipyretic effects were observed. He gives guaiacol in the same way, in one-third to one-fourth the dose. Meunier, of Lyons, prefers liquid vaseline as a medium. Picot, of Bordeaux, injects a mixture of sterilised olive oil and vaseline containing 1 per cent. iodoform and 5 per cent. guaiacol, beginning with 1 c.cm. of the mixture and increasing to 3 c.cm. He remarks that no swelling or other local reaction follows. Burney Yeo has used the same method with a more concentrated formula.

The method, advocated by Diamantherger and Weil at the Paris Congress for Tuberculosis in 1891, was to inject creasote dissolved in an equal volume of sterilised almond oil. Of this they injected two Pravaz syringefuls in twenty-four hours, and after over 1,000 injections have had no accidents. Shingleton Smith adopts this method. Prévost, on the other hand, declares that a chemical combination of guaiacol with oleic acid is much less irritating than a mere oily solution. The chief advocate of the subcutaneous injection of oily solutions of creasote and guaiacol is Burlureaux, of the Val de Grâce. He lays stress on the importance of using a pure preparation such as creasote prepared by Choy's method dissolved in sterilised olive oil free from oleic acid, and on the gradual introduction of large quantities into the body up to the capacity of the individual, which is a variable quantity. He uses a special apparatus originally contrived by Gimbert and modified by Guerdner and himself, one form of which I am able to show you to-day. The oily solution is driven into the body by atmospheric pressure, the degree of which is indicated by a manometer. Not more than 20 grammes (say 5 fluid drachms) per hour must be introduced, so that as most of his patients receive from 50 to 100 grammes of creasoted oil per diem at the height of the treatment, a single injection may last several hours. He begins with 5 grammes of a 1 in 15 solution, and if there are no signs of intolerance increases it to 50 grammes or more. One of his patients received 5 kilos, under the skin in as many months, besides 1 kilo. per rectum. This represents between 30 and 40 minims of pure creasote per day. The largest quantity which appears to have been injected at one sitting was 220 grammes, or nearly 8 ounces, of a 1 in 15 solution. Some patients of his were, however, less tolerant, as in one case 5 grammes of a 1 per cent. solution caused distress. Whenever small doses are persistently badly borne, he regards the prognosis as highly unfavourable. Where the treatment is doing good the appetite improves, flesh is gained, and the local lesions show signs of healing. Intolerance is shown by shivering, perspirations, and a condition resembling the collapse of pernicious malarial fevers, with or without high temperature. A persistent taste of creasote or black urine are of bad import when they come after small doses.

To come to my own results, which are unfortunately incomplete, as some of my notes have been mislaid or not yet returned. I have had some 6 or 8 cases treated in this

¹ Read in the Section of Pharmacology and Therapeutics at the Annual Meeting of the British Medical Association held in London, July-August, 1895.

² *Bull. de Thérapie*, cxxii, 265.

way, and can refer to-day to 4: A married woman, aged 36, with early affection of one apex; a clerk, aged 21, with unilateral consolidation, with perhaps a few small cavities; a bookbinder, aged 30, in the second stage, both lungs affected; and a clerk, aged 27, with one lung in the first and the other in the second stage.

My material is insufficient to determine the value as regards cure of the pulmonary condition, but is of interest in showing the doses which can be tolerated. I have used three different solutions: (1) a solution of creosote, 1 in 15—a Parisian product, creosote *a*; (2) a similar solution of English manufacture; (3) a solution of gualacol, 1 in 5, of French manufacture; all three solutions in sterilised and purified oil.

Burlureaux depended mainly on subcutaneous injections, and gave them nearly daily. My own cases only had them from once to three times a week, as daily injections are not convenient in out-patient practice. They all took creosote or gualacol in some other form to about 10 to 15 minims daily. The injections were given in one of three ways: by the apparatus of Burlureaux and Guerder; by injection with a small hypodermic syringe holding 20 minims, the barrel being sometimes refilled while the needle was left *in situ*; and a large hypodermic syringe holding about 2 drachms; both syringes have asbestos plugs and are readily sterilisable. The doses injected varied from 20 to 30 minims of a 1 in 15 solution to begin with, to 5j to 5ij twice or thrice a week. The largest doses injected were 300 minims of 1 in 15 creosote solution, and 165 minims of 1 in 5 gualacol. The treatment was continued in two cases for two months, in a third case for eight months, in a fourth for nine months.

The local effects were, slight burning at the seat of injection, which usually soon passed off unless the injection was made where the skin was tight. A swelling was left, which felt hard and indurated, the induration passing off, as a rule, in about a week, but sometimes lasting longer. There was usually no pain or inflammation afterwards, with two exceptions. In one case I had an accident with the Burlureaux apparatus, due to my own impatience, and a little air probably escaped into the cellular tissue. In the other the syringe had been rinsed out with carbolic solution, and probably incompletely freed from it. In neither case was there suppuration.

As regards the general effects, I did not find any complaint of tasting the creosote directly after injection, and am satisfied this was not usually the case. In one case there was slight collapse after the first injection of 20 minims of a 1 in 15 creosote solution; the same case subsequently readily stood drachm doses. In one case the appetite greatly improved, the lung trouble nearly disappeared, the cough disappeared, and weight was increased. This patient remains in good health. In another the lung trouble had increased, but much more slowly than was to be expected, while the general health remains exceptionally good. The two others were not long enough under treatment to be able to judge.

In conclusion, I believe the treatment is well borne, and may be useful where other methods fail. The doses should be very cautiously increased, and the treatment should not be tried where the kidneys are unsound, or there is a large area of inflamed lung, or decided signs of intolerance. No form of creosote treatment is of use unless it is long continued. I believe it to be useful in many cases if judiciously applied. One in 5 gualacol appears to me to be as well borne as 1 in 15 creosote solution; and notwithstanding the results obtained by various observers, I do not think it is finally settled that gualacol is inferior to creosote in the treatment of phthisis. The results with an ordinary syringe are apparently quite as good as with the Burlureaux apparatus, which should, I think, be reserved for exceptional cases.

THE NEW YORK ACADEMY OF MEDICINE.—The list of Fellows of the New York Academy of Medicine for 1895, which has just been issued, shows that the Academy is in a very prosperous condition. Organised in 1847 and incorporated in 1861, it grew slowly for a time. At present it numbers 792 resident and 70 non-resident Fellows, 29 corresponding Fellows, and 6 honorary Fellows. The Academy has a commodious and well-appointed house of its own, in a good situation.

REMARKS ON GONORRHOEAL IRITIS.

By H. PERCY DUNN, F.R.C.S.,

Assistant Ophthalmic Surgeon, West London Hospital.

THE eye is a small organ, and upon reflection the fact seems a strange one that the delicate tissues of which it is composed should so often exhibit inflammatory changes, associated with so-called constitutional disease. What, for example, determines the outbreak of a rheumatic iritis when the rheumatic taint has, so to speak, almost the whole of the body upon which to expend itself? What, again, leads to a syphilitic iritis when the syphilitic virus has so wide a scope for attacking the other tissues and organs of the body? Why, further, it may be asked, should a sarcoma develop from the pericostium of the orbit when so vast an expanse of pericostal tissue exists elsewhere? And oftentimes no exciting cause can be shown to which the outbreak of induratio and neoplastic attacks can be traced. Patients suffering from rheumatic iritis in its acutest form seldom have any other defined symptom of rheumatism. In cases of sarcoma of the orbit no history can be obtained, generally speaking, of any blow or disturbance of nutrition which might be regarded as exciting the outbreak. It was while reflecting upon this aspect of the subject that my mind recently reverted to the connection subsisting between gonorrhoea and gonorrhoeal iritis.

In the only case of this form of iritis which has come under my notice, a detailed account of which is given below, there were several interesting features; but after all it is difficult to say how much of the iritis in a given case of gonorrhoeal iritis is due to the gonorrhoea, and how much to the existence of a rheumatic taint in the patient. Upon the subject of the pathology of so-called gonorrhoeal rheumatism authorities are still divided, and until we possess more information of a definite nature in regard thereto, it must still remain an open question whether we can correctly describe any cases of iritis as really due to gonorrhoea. Nevertheless, among the writers of textbooks a general consensus of opinion prevails that gonorrhoeal iritis is a distinct form of iritis inflammation. By one and all the statement is repeated that it is a mixture of the plastic and serous forms. Wecker, in testifying to this fact, also remarks that "we never see an inflammation of the urethra followed by iritis without some joint having been attacked previously. The iritis is easily cured and leaves no traces, while appearing very readily whenever the patient has the least tendency to urethritis. It differs from the rheumatic form by the sudden onset, and its plastic nature is less pronounced. It shows a very peculiar predilection to alternate or succeed a rheumatic attack of the knee. Generally gonorrhoeal iritis disappears quickly under treatment, without leaving synechia. This proves its absence of plasticity. Its rheumatic nature is shown by its tendency to recur, even when no synechia are present after the first attack."

Again, Duplay and Reclus observe: "It has for long been observed that cases of iritis occur in individuals who have had arthritic symptoms after gonorrhoea. Recently, Despagne has noted the presence of gonorrhoeal iritis without arthritis." This latter condition, however, appears to be altogether exceptional. Fuchs states that "gonorrhoeal iritis develops in those cases in which gonorrhoea has given rise to a general infection. This latter runs a course similar to that of acute articular rheumatism. First, the knee joint is attacked by inflammation, which may afterwards migrate to the other joints also; associated cardiac complications may even occur. This disease is known as gonorrhoeal rheumatism. Iritis does not generally set in until after the outbreak of the arthritis, and frequently attacks both eyes. Just as the gonorrhoeal lesion of the joints is very similar to articular rheumatism, so also gonorrhoeal iritis resembles in external features the rheumatic variety. Like the latter, too, it has very frequent recurrences, with which is frequently associated a renewal of the discharge from the urethra or a return of swelling in the affected joints." Lastly, Swaney says: "Gonorrhoeal iritis does not attend on, nor immediately follow, a gonorrhoea; but an attack of rheumatic arthritis, usually of the knees, always intervenes. The disease is extremely rare."

Thus the close connection subsisting between "rheumatism" and the iritis seen after gonorrhoea is shown by the fact that the iritis always succeeds the arthritic symptoms. In other words, experience teaches that no iritis occurs unless and until signs of joint inflammation have developed. The following are the notes of the case to which I refer above: Mr. S., aged 26, consulted me for acute iritis of his left eye. The history was that the eye became inflamed three days before I saw him. Some twelve or fifteen months previously the patient, who admitted that he lived freely, contracted gonorrhoea, and had suffered much from gonorrhoeal arthritis. On asking him subsequently to show me his tongue, he said "That's impossible; I have not been able to do such a thing for the last six months." I then found that he had ankylosis of his temporo-maxillary articulation, which barely allowed him room enough to pass the tip of his tongue between his teeth. On examining the eye the globe was deeply injected, the pupil was small and inactive, and much pain was complained of.

Two days later, by means of leeching, instillations of atropine, with the administration of a mixture containing aconite and colchicum, considerable improvement took place; but the pupil was irregular though dilated. However, in view of the improvement, he asked permission to accompany a theatrical company on a day's outing, including a drive to Richmond. The excursion was to take place on the following day. I strongly advised him to remain quiet, but he was bent upon going. On the morning afterwards I had an early summons to see him, and on reaching his house he met me with the remark, "I wish I had taken your advice and not gone to Richmond. I am much worse; my eye is blind." On examination of the eye the anterior chamber was found to be more than half full of blood. An adhesion had probably given way, causing the hemorrhage. The patient now agreed to submit to a regular course of treatment. He undertook to remain indoors and to follow the instructions as to his living, while, in addition to the treatment above prescribed, he was ordered a morning dose of Hunyadi Janos water. The pain in the eye, which was chiefly felt at night, was relieved by dry heat in the form of hot bran poultices. In ten days' time all the blood in the anterior chamber had disappeared. At the end of three weeks the eye was quite well, the pupil being regular and free. On subsequently testing his vision I found that he was myopic, and with correction - 4.20 in the left and - 3 in the right eye; he was able to see $\frac{1}{2}$ and $\frac{1}{3}$ respectively. This was the first attack from which he had suffered.

The case was interesting as showing the results of gonorrhoeal infection upon his joints. Both knees had been the seat of a prolonged attack of arthritis, and in addition the temporo-maxillary articulation became involved. The adhesions remaining in the latter joint accounted for the fibrous ankylosis which was present. The hemorrhage into the anterior chamber which sometimes occurs in cases of acute iritis is commonly attributed to the rupture of a synchia following repeated instillations of atropine. I have found that the severe pain accompanying acute iritis, and especially rheumatic, in the early stages is best relieved by free leeching. In the later stages, or when the pain mainly occurs at night time, nothing is so effective as dry heat, applied in the form of hot bran poultices. Lastly, I think that some saline aperient is indicated in all cases of acute iritis, and for this purpose I always prescribe the Hunyadi Janos water, the good effects of which I have frequently seen.

THE UNIVERSITY OF VIRGINIA.—On October 27th the main building of the University of Virginia was destroyed by fire. The whole building was completely gutted, the loss being variously estimated at £20,000 to £30,000. The old chapel and the students' reading room were blown up with dynamite so as to prevent the fire from spreading to the professors' residences and dormitories. Owing to the efforts of the firemen, aided by students and ladies, a large proportion of the books, portraits, and statues belonging to the library were saved. A large copy of Raphael's picture of the School of Athens, which adorned the public hall, and which was valued at £1,000, was destroyed. Mr. Floyd Williams, a medical student, was seriously injured by the flames while assisting to subdue the fire.

ON THE TREATMENT OF ENCYSTED VESICAL CALCULI,

WITH A CASE WHERE SUPRAPUBIC LITHOTOMY WAS TWICE PERFORMED, AND A PERMANENT SUPRAPUBIC OPENING AFTERWARDS ESTABLISHED.¹

By F. A. SOUTHAM, M.B. Oxon., F.R.C.S.

Surgeon to the Manchester Royal Infirmary; Lecturer on Operative Surgery, Owens College.

THOUGH encysted vesical calculi are of somewhat rare occurrence, it is probable that they are present more frequently than is generally believed, and that they account for some of those obscure cases of chronic cystitis for which it is often difficult to find a cause.

The following case illustrates the advantage of suprapubic cystotomy as a means, first, of recognising the presence of encysted calculi; and, secondly, of effecting their removal; for when purely encysted—that is, lying entirely within a sacculus which communicates with the bladder by a narrow neck—it is almost impossible to detect them by sounding, or to extract them, except through a suprapubic opening.

In the literature of the subject little is said as to the means which should be taken, after their removal by operation, to prevent the recurrence of calculi in such a pouch, and though the method adopted in the case to be described—namely, the establishment of a suprapubic fistula—has obvious disadvantages, it appeared to be the only one which was likely to prove successful.

Diagram showing the situation behind the prostate of the sacculus in which the calculi were encysted, and the vulcanite plug and catheter as worn in the suprapubic opening.

The patient, a gentleman, aged 49, was sent to me in May, 1891, by Dr. Anderson, of New Mills, with the following history. Three years previously he began to be troubled with difficulty in micturition, and for two years and a-half he had passed no urine except by catheter, which he was obliged to use very frequently, sometimes as often as once an hour, otherwise he suffered great pain, which was always referred

¹ A communication to the Manchester Clinical Society, October, 1895.

to the neck of the bladder. No blood had ever been observed in the urine, which was alkaline and purulent. There was no perceptible enlargement of the prostate, and no stone could be detected on sounding the bladder, which was extremely sensitive, especially at its neck, the introduction of any instrument exciting very severe spasm. As the symptoms were somewhat obscure, it was resolved to explore the bladder from above the pubes, and the patient came into a private home for this purpose.

May 14th, 1891. Suprapubic cystotomy was performed in the ordinary way, and upon exploring the bladder a small phosphatic calculus was found lying loose in its interior. On further examination an opening, just large enough to admit the tip of the finger, was detected at the base of the bladder, a short distance behind the prostate; this led into a distinct sacculus, the size of a pigeon's egg, and contained within it were a number of phosphatic calculi, the largest being almost $\frac{1}{2}$ inch in diameter. The prostate was slightly enlarged, a collar-like projection surrounding the vesical orifice of the urethra. The calculi were all extracted from the sacculus and the collar projection of the prostate was removed as completely as possible with a scissor. The patient made a good recovery and returned home at the end of six weeks, the suprapubic wound being completely healed three weeks subsequently. The operation was followed by marked relief to his symptoms, as he could hold the urine, which became clear and acid in reaction, for five or six hours without any discomfort, though he still required a catheter to empty the bladder. The relief continued for about twelve months; at the end of this period, in spite of the fact that he had regularly washed out the bladder since the operation, he began to suffer from the same symptoms as before, the urine again becoming alkaline and containing a large quantity of pus and mucus. The patient was again sent to me by Dr. Anderson in April, 1893, and upon sounding the bladder a small calculus was felt lying loose in its interior.

As the cystitis had recurred and a fresh formation of stone had taken place, although the greatest attention had been paid to the toilet of the bladder, it was resolved to again perform suprapubic cystotomy, explore the sacculus, in which more calculi had probably formed, and, after removing them, establish a permanent opening above the pubes, so as to allow of more thorough irrigation of the bladder than was possible by simply washing it out *per urethram*, in the hope that by this means a recurrence of the cystitis might be prevented, and at the same time an exit provided for any calculi that might afterwards form.

April 21st, 1893. The bladder having again been opened from above the pubes, a small phosphatic stone was removed from its interior, and a number of similar calculi were extracted from the same sacculus as at the previous operation.

The question of excising the sacculus and suturing its communication with the bladder was considered; but as this procedure would have involved opening the peritoneal cavity—for the sacculus was situated well behind the prostate gland, and could only just be reached with the tip of the finger upon deep pressure, when passed into the rectum—it was not thought safe to attempt it, especially as the urine was in a foul and toxic condition. A suprapubic fistula was therefore established, and for two years after the second operation the patient continually wore in the wound a slightly curved vulcanite plug ($\frac{3}{4}$ inches in length and $\frac{1}{2}$ inch in diameter), with a flange at its outer end to prevent it from slipping altogether into the bladder. The plug, which accurately fitted the wound, was retained in position by a canvas belt, and bored, so as to admit a No. 8 Jacques's catheter, one end of which projected into the bladder, while the other was connected with a urinal attached to the patient's leg. In this way the bladder could be kept continually drained, while by the removal of the plug its interior could be washed out much more thoroughly than was possible in the usual way—namely, through the urethra alone.

Since April, 1893, he has worn a solid plug in the opening by day; by this means he is able to dispense with the urinal in the daytime, and he finds that if he draws off the urine *per urethram* every three or four hours he can keep quite dry even when walking about. The perforated plug, catheter, and urinal he still, however, wears when in bed, in order that he

may not be disturbed by having to get up to empty the bladder during the night.

At the beginning of the present year he suffered from another attack of cystitis, brought on, as he believed, by exposure to cold; and last February, on washing out the bladder (as is still his daily custom), the plug having been removed as usual, a small phosphatic calculus came away through the suprapubic opening. The escape of the stone was followed by a subsidence of the cystitis, of which there has since been no recurrence.

As two years and a-half have now elapsed since the second operation, the advantage of the suprapubic fistula as a means, first, of thoroughly irrigating the bladder and keeping in check the cystitis; secondly, of allowing the escape of calculi which may form in the bladder—is therefore well established.

At the present time he is in the enjoyment of very good health, being able to mix in society and walk several miles without any inconvenience; he is quite free from bladder symptoms, and suffers remarkably little discomfort from the presence of the permanent suprapubic opening.

I am indebted to my house-surgeon, Mr. J. P. Hall, for the diagram which accompanies this paper.

THE CHEMICAL AND PHYSIOLOGICAL CHANGES IN MILK CAUSED BY BOILING.

By J. L. KERR, M.D., G.M., F.R.S.E.,

Late Examiner in Chemistry and in Medical Jurisprudence, University of Aberdeen; Public Analyst, Rantounath Savings.

MILK consists of a multitude of cells suspended in serum. The cells are fat cells which form the cream; the remaining cells are nucleated, and of the nature of white blood corpuscles. The serum consists of water, in which is dissolved milk sugar, and serum albumin, with various salts, and chief of all casein. The cells, with the exception of the fat corpuscles, are all living cells, and they retain their vitality for a considerable time after the milk is drawn from the mammary gland.

Milk kept a few days may be perfectly sweet—that is, un-soured, but it has a different taste and appearance, and shows a tendency to separate into serum and the more solid portions, which tend to sink to the bottom of the vessel. This change in taste and emulsification is due to the death of the white blood corpuscle-like bodies contained in the milk.

There is reason for supposing that when fresh milk is ingested the living cells are at once absorbed without any process of digestion, and enter the blood stream and are utilised in building up the tissues. The casein of the milk is digested in the usual way of other albuminoids by the gastric juice, and absorbed as peptone. There is also absorption of serum albumin by osmosis.

The chemical result of boiling milk is to kill all the living cells, and to coagulate all the albuminoid constituents. Milk after boiling is thicker than it was before.

The physiological results are that all the constituents of the milk must be digested before it can be absorbed into the system; therefore there is a distinct loss of utility in the milk, because the living cells of fresh milk do not enter into the circulation direct as living protoplasm, and build up the tissues direct, as they would do in fresh unboiled milk.

In practice it will have been noticed by most medical practitioners that there is a very distinctly appreciable lowered vitality in infants which are fed on boiled milk. The process of absorption is more delayed, and the quantity of milk required is distinctly larger for the same amount of growth and nourishment of the child than is the case when fresh milk is used.

The Alvarenga Prize for 1895 of the College of Physicians of Philadelphia has been awarded to Dr. Guy H. Haddad, of Philadelphia, for an essay on Typhus fevers. The prize, which may be upon any subject in medicine, intended to compete for the prize (which is of the value of about 100 dollars) for 1896 must be received by the Secretary of the College on or before May 1st, 1896.

MEMORANDA:

MEDICAL, SURGICAL, OBSTETRICAL, THERAPEUTICAL, PATHOLOGICAL, Etc.

THE DANGERS OF COCAINE.

In connection with Mr. J. H. Marsh's notes on the dangers of cocaine as a local anæsthetic in the *BRITISH MEDICAL JOURNAL* of September 28th, p. 780, the following case may be of some interest.

Having occasion to evacuate a chalazion from each eyelid in a man aged 25, I instilled into each conjunctival sac three or four drops of a 5 per cent. solution of cocaine hydrochlorate, and a few minutes afterwards proceeded to incise the cysts and scrape them out; but while operating on the second the patient suddenly became blanched, perspiration broke out on the forehead, the pupils dilated, the respirations became sobbing, and after a slight convulsion he became rigid, only his shoulders and hips touching the chair in which he was sitting. All these symptoms passed off in a few seconds, though the patient remained pale and complained of feeling faint for some time.

Both this and another case I observed some time ago occurred during very warm weather, but this may be a mere coincidence.

H. CARTER MACFIE, M.B., B.Ch.T.O.D.,
House-Surgeon, Wolverhampton Eye Infirmary.

THE TREATMENT BY SETON OF ABSCESSSES, SINUSES, AND SEROUS AND MUCOID CYSTS.

There is nothing new possibly in the treatment of abscesses by seton, but the practice is not general and it is not referred to in textbooks, so that the following remarks may not be without interest to some of your readers who, like myself, meet with many such cases. It suggested itself to me some time ago, as I found it successful in the treatment of a large submaxillary mucoid cyst in a dog in which I had tried an india-rubber tube. This he tore out, and it was replaced by a tight seton of quadrupled cord. The wound gave no further trouble, and the dog was well in a fortnight, no trace of the tumour remaining beyond the scars where the cords had passed through.

I next applied the seton treatment with success to diffuse abscesses of the hand, then to superficial and deep abscesses in other parts of the body, as the parotid, axilla, female breast, knee, lumbar region, etc., and to sinuses. Many of the abscesses were large and some huge. One completely covered the abdomen below the umbilicus to the pubes and extended laterally to the iliac crests. The man, a perfect wreck, recovered without a bad symptom, and left the hospital in a month. I have treated serous cysts in the popliteal space and other situations about the knee in the same way with equally good results. I have passed setons through sinuses beneath the gracilis and sartorius tendons from the popliteal space; and also through the muscles of the arm and forearm at the elbow, in positions where it would have been impossible to lay open the tracts sufficiently to ensure their cure.

In order to obtain free drainage the incisions through which the cords pass must be reasonably free and as far apart as possible. The tight cord may cause some inconvenience, but this soon wears off. The treatment is much less feared than large incisions. It leaves only insignificant scars. The wounds heal faster than when large cavities are laid open by incision, and the after-dressings are more simple and less painful than those of large open wounds. The constricted parts do not slough, and they quickly recover their normal conditions when the cord is removed.

An expeditious and simple, and at the same time successful, treatment of such cases is a matter of some consideration where large numbers of ignorant and dirty patients have to be treated outdoors, since many will not remain in hospital. Small openings into abscesses in such persons invariably lead to troublesome and extensive sinuses; and large openings require frequent and careful dressing, which natives do not understand. The seton ensures constant drainage,

requires comparatively little dressing beyond keeping the part clean and the application of an absorbent pad and bandage. It is applicable alike to deep and superficial abscesses, and appears, therefore, worthy of a more extended use in cases in which incision and the drainage tube are now employed.

Sttara.

J. O. H. PRACOCKE,
Surgeon-Major I.M.S.

MELENA NEONATORUM.

The following case may be of some interest, partly on account of the rarity of the disease and partly because of the similarity between it and the one published by Mr. Pringle in the *BRITISH MEDICAL JOURNAL* of November 23rd:

On November 11th I was called in to see an infant girl, forty-eight hours old, by an old midwife who had attended the confinement. From her and the mother I elicited the following history: About thirty hours subsequent to the birth of the child the mother stated that she heard "something go off" inside its body, and then a gurgling, bubbling sound. Shortly afterwards a motion was passed, which was composed of foul-smelling, dark blood—as far as I could judge by the napkin, about half a pint. Vomiting came on in about an hour, and about 4 ounces of blood and meconium were voided by the stomach. The midwife stated that the cord was tightly wound around the neck three times.

I found the child in a very collapsed condition, perfectly anæmic and comatose, with a slight general icteric tinge—in fact presenting all the symptoms of severe internal hæmorrhage, and evidently with but a few hours to live. Having passed two more similar motions and again vomited blood and meconium, it died about twelve hours later.

It was the twelfth child, and there was nothing in the family history (such as hæmophilia) to account for the condition. I made a necropsy with the following result:

There was general jaundice and great anæmia. Rigor mortis was absent. The body was well developed. On opening the abdominal cavity, the intestines were seen to be congested, and of a deep purple colour generally, but much more so towards the descending colon. From the duodenum to the ileum the mucous coat was covered with a very viscid pink coating, which gradually got darker in colour towards the ileum. This portion showed dark red patches of mucus, which, when washed off, left the surface quite anæmic, giving the impression of the tinted mucus having cozed through from great congestion. The cæcum, colon, and rectum were full of dark blood and meconium. The pyloric end of the stomach was covered with pink glairy mucus, the cardiac end was smeared with meconium, but neither it nor the œsophagus contained blood. There was absolutely no lesion to account for the hæmorrhage. All the other organs were normal, with the exception of being perfectly anæmic. The lungs, however, were of a whitish colour, about half the usual size, and only partially inflated and crepitant.

REPORTS

MEDICAL & SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF GREAT BRITAIN, IRELAND, AND THE COLONIES.

LIVERPOOL ROYAL INFIRMARY.

CASE OF PYLOROPLASTY.

(Under the care of Mr. RUSHTON PARKER, Professor of Surgery in University College, Liverpool.)

A MARRIED woman, aged 37, had suffered from indigestion for twenty-four years, and had, during some months before her admission on April 2nd, 1895, been under treatment for ulceration of the stomach. She remained in a medical ward until July, and was treated by washing out the stomach. The stomach was greatly dilated, and visible in outline through the abdominal wall. Before admission she had pain, worse after food, and only relieved by vomiting, which took place about three times a day. The movements of her stomach

and rumbling were violent and kept her awake at night. Temporary relief was given by the washing out, and later by curtailing her diet; but distress returned, and she begged for relief, and readily consented to operation. This was done on August 14th, 1895, after washing out with salt solution three or four times (on the day of operation and preceding day).

An incision about 4 inches long was made in the middle line in the epigastrium, and the pyloric end of the stomach found much marked with cicatrices. The pylorus itself was greatly narrowed, appearing no thicker than a cedar pencil outside all. The narrowed part was laid freely open (for about 2½ inches), and one of Mr. Mayo Robson's bone bobbins inserted, as suggested by him in the *BRITISH MEDICAL JOURNAL* of July 30th, 1895. The stomach was washed out again at the operation with salt solution, and found to be quite clean.

Some difficulty existed at first in getting the pylorus into an accessible part of the wound, and in putting in the bobbin, which was of large size; but when once in, although at first greatly stretching the edge of the wound, the bobbin facilitated the sewing up, and kept the edges well together. A continuous silk suture was put through the mucous layer and another through the peritoneum. Sponge packing was used round the part operated on, and hot water irrigation of the exposed tissues. The abdominal wound was sutured through all layers simultaneously without drainage tube, and the skin well carbolicised before operation and after putting in the sutures. A dressing of carbolicised cyanide gauze was put on, and the wound healed quickly without suppuration. The greater part healed by first intention in two or three days, and the small gaps under dry soaks of blood and collodion. The patient had no inconvenience after the operation, which, on the contrary, gave complete relief to the previous discomfort. For two days she had only tea and weak brandy and water, and then, in addition, about half a pint of milk daily, diluted with an equal part of hot water; on the seventh day rice pudding, and on the tenth meat, and afterwards ordinary full diet. She was not hurried either in feeding or getting up for fear of too early resuming her long discontinued and unaccustomed daily habits, but by the end of a fortnight she was evidently quite well.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

JONATHAN HUTCHINSON, F.R.S., President, in the Chair.

Tuesday, December 10th, 1895.

ADJOURNED DISCUSSION ON THE POSSIBILITIES AS TO THE LATENCY OF PARASITIC GERMS OR SPECIFIC POISONS IN ANIMAL TISSUES, AS IN HYDROPHOBIA, ERYSIPELAS, SYPHILIS, LEPROSY, RINGWORM, TUBERCULOSIS, ETC.

THE adjourned discussion was resumed by Dr. PHINEAS ABRAHAM, who said that there were many facts in connection with leprosy which bore upon the question of latency. Numerous instances were before us in which the symptoms of that disease had not made their appearance until long and irregular periods had elapsed since the individual could have been subjected to infection; and there were many cases on record in which the symptoms appeared to have become dormant during the course of the malady or subsequently to its full development. We might thus distinguish an initial or "primary" and a "secondary" latency. The study of the subject was beset with considerable difficulty, as might be seen from the following considerations: (1) In the present state of knowledge we could not speak of any definite period of incubation for the bacillus of leprosy, since no one had yet succeeded in cultivating it, and of its life-history we knew nothing. (2) We could not clinically determine the entry of the microbe into the human body, for as a general rule no initial lesion or particular symptom was observed. In a few cases there might be a history of some previous trauma with localised persistent inflammation or difficulty of healing; but the vast majority of patients did not point to anything of the kind or give any precise date as to when they could have contracted the malady. In point of fact it was not yet proved that the virus of leprosy might not gain entry by the stomach or by as many

different channels as the sister disease, tuberculosis. (3) It was not easy to distinguish between the true latent and the incubatory periods. We might, with M. Beulier, consider that the incubatory stage only commenced when the latent spore found the soil and other conditions suitable for its proper growth and development, but the subjective and objective phenomenon of the incubation might be slight and overlooked, and it must often be practically impossible to draw a line of demarcation between the two stages, which nevertheless must be theoretically admitted to exist. A period could only be regarded as one of latency (a) if there was absolutely no concomitant, general, or local disturbance, and (b) if the interval between infection and the appearance of symptoms was more or less prolonged and of indefinite duration. (4) From the above considerations, and from the fact that the inhabitants of an infected country might at any time be unknowingly placed under conditions for contracting the disease, we could only—to be quite free from doubt—take into view (a) those individuals who were of a leprosy-free race and who had recently come from a leprosy-free district, and (b) those, natives or others, who, having sojourned in a leprosy district, had subsequently manifested the disease after removal to a country free from leprosy. The field of accurate observation was therefore much narrowed. When facts of some definiteness were obtainable, the main thing observed was the irregularity of the period between the probable time of entry of the virus and the first appearance of the usual erythematous patches and other early pathognomonic signs. Some observers gave two to five years, others much longer. Instances were known of the disease appearing a few weeks after a patient had come from an unaffected to an affected district, as in a case related by Arning; and, on the other hand, there were many examples of a prolonged retardation, as in cases mentioned by Leloir, Hoegh, Thim, etc. Three remarkable instances of prolonged primary latency had come under his notice. The first was the well-known Whitechapel case, exhibited at the Epidemiological Society in 1889. The man had been in his youth, upwards of forty years previously, on voyages to the Baltic and Mediterranean, had been for years selling meat in London, and had never mixed with sailors or others from foreign parts. He declared that he had no spots or other symptoms until six years before the speaker saw him. Although difficult to prove absolutely, it was most improbable that this man could have been exposed to any new source of infection during these forty years. It was more likely that the germ had really remained somewhere quiescent in his system for a great number of years, although perhaps not so many as he thought, seeing that he might have overlooked, as many lepers do, the very earliest signs of the disease. In the following two cases, the facts were tolerably certain. An Englishman had been taken to India as an infant, and brought home when 10 years old. When 21 he married a young English girl, and shortly afterwards developed spots. He died a few months ago a confirmed nodular leper. Since his return home, he had lived in a humble way in a small inland town, and had never had communication with anyone or anything from India. A young lady, now a typical case of nodular leprosy, was born in Ceylon of English parentage, and brought to England when quite a young child. She remained perfectly healthy for some seven years, when she had an attack of what was thought to be rheumatic fever, accompanied with persistent erythematous swellings. The family had had no communication directly or indirectly with the East, and we were driven to admit that in her case also the microbe must have remained dormant for many years. Instances of so-called arrested or dormant leprosy, in which the symptoms remained in abeyance for a number of years, were frequently met with in asylums and leprosy countries, and might be taken to illustrate the secondary latency of the disease. If, as in rare cases, a recrudescence did not take place, the patients might be regarded as in a condition of permanent arrest or real cure. Manson's views and the investigations of the Cape Commission were referred to. A case of temporary arrest of early symptoms in a boy now in England was also mentioned. In such cases the microbes had for some reason ceased growing and multiplying, and had assumed a latent condition. Manson's hypo-

this was quoted as affording a plausible explanation of the vagaries of leprosy, its periods of quiescence, its prolonged and uncertain incubations, its difficulty of inoculation, and many other points. It was shortly as follows: the bacillus was the cause of leprosy; it grew only in a medium existing in the bodies of certain human beings, and then perhaps only intermittently; if the bacillus fell upon such a person it grew if the medium was present, or when it was produced; it grew at the expense of the material, and until the latter was exhausted; it then passed into a condition powerless to resist certain cells, not phagocytes, which incorporated it, and in which it became encysted, until fresh cultivating medium was supplied; the bacilli then became active, passed by the vessels and lymphatics, and established other foci, when the cultivating medium became exhausted, and the bacillus again became intercellular and passive.

Mr. J. BASSETT LAW continued the discussion, taking for his subject the latency of syphilis. He first alluded to the interval which might elapse between the appearance of the initial lesion and the first manifestation of constitutional infection. The minimum recorded period of "this second stage of incubation" was 12 days and the maximum 159. The latency of syphilis was next exemplified by cases in which after the disease had apparently disappeared, it again manifested itself by the appearance of unmistakable symptoms after a lengthy period of complete immunity. While the possibilities in the direction of long latency were infinite, the duration of this period might continue for only two years. In hereditary syphilis the disease might be latent in the father, who, though apparently healthy, might infect his wife and children; or it might be latent in the mother, who having suffered from syphilis and having been presumably cured, might on marrying a healthy man produce a long series of syphilitic children. Further, Collie's law on the immunity of the mothers of syphilitic children was another example of the latency of the disease, for such mothers, though to all appearances perfectly healthy, had been proved by inoculation with syphilitic secretions to be protected from the disease. Lastly, cases of syphilis hereditaria tarda were instanced as proof that the disease might remain latent for a long time in the subjects of congenital syphilis.

Mr. SPENCER WARREN said that the discussion would be of great value if it improved and rendered more accurate the diagnosis of latent disease. Diseases were often thought to be cured when really they were only latent. In syphilis glandular enlargement during quiescent periods was evidence of the disease being latent, and gave indication for continued treatment. The experiments of Professor Marshall Ward on the bactericidal power of sunlight were interesting in connection with the possible cure of tuberculosis by the actinic rays of the sun. In conclusion, he thought that the remarkably long latent period of forty years in Dr. J. K. Fowler's case depended on the conditions of the patient, and insisted on the difference between attenuation of the bacilli and the cure of the disease.

Dr. LAZARUS BARLOW thought that, given the micro-organism, the question whether it remained latent or no depended almost entirely upon its environment. He instanced the microbe which was shown by Pasteur to be the cause of pébrine. This microbe can be seen in the silkworm's egg immediately after laying, but it remains inactive throughout the winter, though the eggs are kept at a temperature not prohibitive of growth for the microbe, and only commences to reproduce itself in the spring, when the young caterpillar is forming. Another marked case of latency was related by Boussingault in 1855. He made experiments to determine whether plants absorb atmospheric nitrogen when that element is absent from the soil. Two seeds of *mimulus speciosus* under such conditions germinated, but remained, after putting forth their first leaves, in an arrested, though perfectly natural, condition for two months. They were at the end of that time unfortunately killed by undue exposure to the sun's rays. The speaker cited these cases as examples among many of the fact that the peculiarities of the soil are of essential importance in dealing with the question of latency, and suggested it was probable that, from the widespread occurrence of pathogenic micro-organisms in congregations of persons, they were far more commonly latent than was generally supposed, and that it was only in a minority of cases that the conditions

under which they found themselves were such as to allow of their taking on active growth and causing disease.

Dr. THEODORE WILLIAMS had difficulty in distinguishing between latency and arrest of tubercle. Dr. J. K. Fowler had with characteristic caution only gone so far as to say that in arrested tuberculosis the bacilli might be dead, and with this he agreed. In a patient who died from renal disease thirty-six years after the onset of pulmonary tuberculosis and sixteen years after arrest had taken place, caseous material was found in one lung; if this caseous material had passed in to the circulation the man might have died, as in Dr. Fowler's case, from acute tuberculosis. He would prefer to say that no case of tubercle was arrested until the patient was dead. He referred to numerous examples of latent tubercle becoming active, and thought that the development of tuberculosis after scarlet fever might be due to tubercle latent in the bronchial glands infecting the system.

Sir W. BROADBENT thought the introductory papers so complete that further criticism was difficult. Clinically latency was foreseen before the experimental proof was forthcoming, and great interest attached to the experimental explanation of the clinical observation. He referred to a case of latent tuberculosis in a young man in whom a fall from a horse was followed in six weeks by death from acute tuberculosis. Here the bacilli had for a time been encapsuled and prevented from gaining access to the organism, and had been liberated by the injury. In typhoid fever it was sometimes impossible to trace the origin of infection during the normal period of incubation. Influenza had in the last five years so frequently ushered in typhoid fever that it seemed probable that the typhoid germ being latent in the body had been able to multiply, when the resistance of the host was impaired by influenza. In the same way the frequent incidence of scarlet fever after surgical operations might be explained. Experimental changes in the environment of animals were followed by a disorder the development of which they were previously able to resist.

Dr. P. MANSON remarked that the causes of latency were various even for the same micro-organism. The malarial germ was not killed, but rendered latent by quinine; similarly, improved health and vitality of the host rendered the malarial organism latent for the time. The same was true of fungi, as was shown by a form of itch in the scrotum, due to fungi which remained latent in the cold season and became active in warm weather. In filarial disease no symptoms as a rule were present, but mere change in the mechanical position of the parent worm might, by blocking up the thoracic duct, produce elephantiasis.

Mr. JONATHAN HUTCHINSON, jun., quoted the case of a man with a primary syphilitic sore on the penis, who, six weeks after treatment was begun, infected his finger and developed a typical chancre there. A patient was exposed to infection, and two weeks later developed an indolent bubo. Though frequently seen, the primary sore did not develop till seven weeks after exposure; here the poison must have remained latent on the situation of the primary sore. He also referred to a girl who, after ten weeks' solitary confinement in prison, developed a primary sore. The development of secondary manifestations might be very considerably delayed by the occurrence of severe fevers.

Dr. GEORGE COLEMAN pointed out the difference between immunity and latency, and criticised the distinction which the President in his introductory remarks had drawn between "true" and "apparent" latency in syphilis. Remarkable statements had been made as to the duration of latency in syphilis; its possible duration had been artificially extended by putting down non-specific diseases to the agency of syphilis merely because they occurred in syphilitic subjects. So-called syphilitic nervous diseases did not in reality differ from the ordinary forms of disease. Irritation and other factors played a part in bringing out manifestations of latent syphilis; thus, in cases of congenital taint, injury, or disease such as rheumatic fever might give rise to typical interstitial keratitis. A solitary inoculation experiment was not sufficient to prove that the mother of a syphilitic child was protected and not capable of infection, inasmuch as inoculation of healthy subjects with the blood of syphilitic patients was only successful in one out of every four trials.

Dr. J. E. SQUIRE pointed out that latency of the disease and

latency of the cause of the disease were separate and distinct. The disease, for example phthisis, was often latent, but it was another thing to say that the bacilli were also latent. If the latter contention was accepted, it followed that all tuberculosis might be hereditary—a conclusion which he did not believe to be true.

Dr. W. K. SMILEY thought latency was equivalent to hybernation of the germs of the disease. This he had shown in snakes, in whom tubercle bacilli could not grow at the ordinary bodily temperature; if, however, an infected snake was put into an incubator, tuberculosis developed. On removing the snake from the incubator the tuberculous process remained stationary. He thought it probable that tubercle would similarly become latent in hibernating animals.

Dr. J. A. HAYWARD quoted as an example of the latency of the diphtheria bacilli the case of a child who, after recovery from diphtheria, developed measles, and then a second attack of diphtheria, which proved fatal twenty-eight days after the primary attack.

The President said, in reply to Dr. GEORGE OGILVIE, that in real latency there was absolute quiescence; if the germ was in any degree active the latency was only apparent. Thus, if a man passed through the secondary stage of syphilis without any obvious manifestations, and then had tertiary symptoms, the latency was apparent, for the poison was quietly at work, and very careful investigation might have shown some evidence of this, such as elevation of temperature.

Dr. WASHINGTON replied very briefly to Dr. LAZARUS BARLOW.

Dr. J. K. FOWLER agreed with Dr. SQUIRE in drawing a distinction between latency of the disease and latency of the germ.

MEDICAL SOCIETY OF LONDON.

Monday, December 9th, 1895.

Sir J. CRAIGTON BROWNE, M.D., F.R.S., President, in the Chair.

OF THE DIAGNOSIS AND TREATMENT OF EARLY CANCER AND CYSTS OF THE BREAST.

MR. THOMAS BRYANT said he had been induced to write this paper on account of a series of cases of cystic disease of the breast he had met with, most of which had been diagnosed as cancerous. He pointed out that such errors of diagnosis might be diminished by due care and thought. He admitted that typical examples of cancer, as well as of adeno-sarcoma, were usually readily recognizable, and that difficulties of diagnosis, and consequent uncertainty of treatment chiefly occurred when any or many deviations from the typical examples presented themselves. He divided the cases in which difficulties of diagnosis were liable to occur into three groups, the divisions being based on chemical symptoms alone: Group 1. This group included cases in which, either in a young, middle-aged, or even old married or unmarried woman, there was some enlargement or thickening of a mammary gland without external evidence of anything being wrong, either in the integument covering the affected lobe of the breast, the nipple, or the lymphatic glands. Group 2. This comprised cases in which there was a distinct and very evident lump the size of a hazel nut or walnut, encapsuled or unencapsuled, and inseparable from the breast gland, with some of the local conditions generally accepted as indicative of a cancerous tumour, such as a flattened or retracted nipple with or without enlarged lymphatic glands in the axilla. Group 3. In this group fell the cases in which, in the middle-aged woman just past childbearing, the breast gland was felt to be generally, or in one or more of its lobes, harder than natural, the knots varying in size from small to large peas, and in which there might be at times, with or without the application of pressure upon the gland, some discharge from the nipple of either a clear yellow or blood stained fluid or some cheesy pulsatious material, associated or not with an enlargement of some lymphatic glands. He remarked in respect of the first group that the main question was to decide whether the local lump or induration was an early cancerous tumour or a cyst, or, if in any way connected with lactation, a chronic abscess. If the probabilities pointed to its being cancerous

it was, he said, hardly necessary to point out how important it was to have the diagnosis clear and the local tumour removed. Such a measure, when undertaken at the very earliest stage of incipient infiltration, was far more likely to be followed by permanent cure than when performed at a later stage. For this purpose he thought the best course was an early exploratory incision as a preliminary measure to excision of the growth and gland should the diagnosis of carcinoma be verified. He had followed this practice for many years with the best possible results. In Group 2, in which there was a distinct tumour and the diagnosis lay between a local cancer and a cyst, he urged the desirability of the possibility of its being a cyst being always present in the surgeon's mind. It was, he believed, owing to a neglect of this that so many mistakes of diagnosis were met with. He said he was aware that cysts did sometimes disappear by time and treatment, of which he had met with several examples; but he pointed out that such cases were not common, and their occurrence did not justify the practice of allowing the local trouble to continue without treatment. He believed that cases of reputed disappearance of adeno-sarcoma and of cancer were probably instances of mistaken diagnosis, and that they were really cysts. He said he had never known a tumour which was solid disappear without surgical assistance. Instances were numerous in which cysts, said to have disappeared spontaneously, had subsequently reappeared. In some cases the re-enlargement of the cyst might be genuine, while in others the cysts might be of the proliferating kind. In respect of Group 3, the cases falling into this group were too often regarded as cancerous without going carefully into the points which ought to guide them in deciding that question. In conclusion, he stated his belief that in the three groups of cases a place would be found for most, if not all, the doubtful and difficult cases which came before them. He particularly insisted on the fact that if surgeons always took with them to the bedside the thoughts and methods of investigation to which he had called attention, many of the difficulties would be lessened, if not altogether avoided, and a conclusion would be arrived at on which a sound treatment could be based, to the advantage of the patient and to the credit of the surgeon.

Mr. MARMADUKE SHEILD said that, in looking over the literature of the subject, he had been struck by the difficulty of arriving at a reliable diagnosis of tumours of the breast, as to whether they were or were not sarcomatous. On looking through the records he had found that a large number of tumours of the breast described as adenoma even after microscopical examination, had ultimately proved to be sarcomatous. He related a case of his which occurred some years ago, and had brought this difficulty very prominently before him, the patient being a woman of 40, with a tumour growing fairly rapidly, and obviously not cancerous. Even with the aid of a microscope it was difficult to say definitely whether or not such a tumour was likely to recur. He believed that a large proportion of indurations of the breast were syphilitic, and these often improved under appropriate treatment. The author, he remarked, had insisted on elasticity and fluctuation as characteristic of cysts of the breast, but he pointed out that the cyst might be so tense that neither of these qualities were present. In the absence of distinct signs of malignancy he always went on the assumption that a lump in the breast was a cyst. Many patients objected to the wear resulting from incision, and he did not see why the doubtful cases should not be treated by aspiration. He observed that it was easy enough to make a mistaken diagnosis, even with the help of the trepan, as in the case of a patient aged 40, who came with a hard lump in the centre of the breast, which he thought was probably a cyst. He punctured it, but nothing came out, and he removed the breast, and then he found that it had a hard fibrous wall, within which was a petty-like mass, evidently the remains of a long standing galactothelal cyst. The cyst cases were the ones which recovered under various quack remedies, and it was therefore highly important to make a correct diagnosis. He asked whether the author had ever met with a dermoid cyst of the breast. Personally he doubted whether such cysts ever occurred in that organ.

Dr. SNOW referred to the case of a patient with a lump in the breast which had been stated by a very eminent surgeon

to be only a cyst. Some time later this woman came to him with a fungating mass involving the whole of the breast tissue, which was in an advanced stage of degeneration. He did not put this forward as a case of mistaken diagnosis, but he supposed the surgeon had overlooked the association between cysts in the breast and malignant disease. In patients over 34 years of age he held that every tumour of the breast, whether cyst, fibroma, or what not, sooner or later underwent malignant development in one form or another. Personally he always removed such tumours, and he had never once met with a simple cyst. The whole breast was usually undergoing cystic degeneration. One came across one or two cysts, but many others might be present. Cysts were rare during the adolescent period, but he had never seen a genuine cyst disappear. He added that the quality of the fluid was by no means a certain guide in respect of the nature of the tumour, and he said he had seen many cysts in connection with malignant disease giving issue to straw-coloured or pale fluid.

Mr. TUNNIE mentioned a case of sebaceous tumour of the breast which had given rise to a doubtful diagnosis. It had the appearance of being a dermoid cyst. The patient was a woman aged 30, who had borne children, and the growth only dated from some months previously. He also referred to a case of sarcoma of the thyroid which disappeared. He performed tracheotomy, and the growth subsided almost completely, but it recurred, and then he cut down again and removed a portion for microscopical examination when it proved to be undoubtedly sarcomatous. That patient died a year after the first operation, and *post mortem* there was a distinct, though small, sarcomatous growth in the gland. There were many cases on record of supposed disappearance of sarcomatous tumours, but he agreed that in all probability many of these were inflammatory.

Mr. BROWELL mentioned two cases of cyst of the breast which did not refill after aspiration. That fact, he thought, suggested the possibility of spontaneous cure, seeing that the tapping could not in itself be curative. He agreed with Dr. SNOW that the escape of clear fluid from the nipple was not absolute evidence of non-malignancy, for he had seen two cases of malignant growths in which clear fluid escaped.

Mr. LOCKWOOD agreed that the injunction to cut into the tumour and see what it was would, if observed, save surgeons much humiliation. He related a case in which he had been called to a patient with ascites, evidently due to growths in the liver and great omentum. It transpired that ten years before a cyst in the left breast had been punctured and injected with iodine, and he believed that the subsequent growths were secondary to the breast affection. She had a large hard mass in that breast at the time.

Mr. BRYANT, in reply, observed that he had never seen a dermoid cyst of the breast except, perhaps, in one instance. He insisted on the importance of the clinical history in deciding on the nature of the lump. He admitted that many of these cysts might go on to malignancy if the patients lived long enough but he did not think it was justifiable to tell patients that cysts, unless removed, were certain to be followed by cancer.

OBSTETRICAL SOCIETY OF LONDON.

F. H. CHAMPEYS, M.D., President, in the Chair.

SPECIMEN.

DR. CULLINGWORTH, Supposed Tubo-ovarian Cyst.

TUBO-UTERINE PREGNANCY; PRIMARY INTRAPERITONEAL RUPTURE; RECOVERY.

Mr. BLAND SUTTON read a paper on this subject, in which he detailed the possible modes of termination of a tubo-uterine (interstitial) pregnancy, and compared them with those of a purely tubal one. He related a case occurring in his practice of a woman aged 25, who had been married two and a-half years and had not been pregnant. Menstruation was fourteen days overdue when she was seized with severe pain in the belly and vomiting. When seen she was blanched, and the physical signs pointed to rupture of a gravid tube. On opening the abdomen a large quantity of blood was evacuated, and a rent was found at the right angle of the uterus from

which arterial blood was issuing at several points. The bleeding surfaces were secured by silk ligatures passed through the substance of the uterus, and the tube and ovary cut away. The uterus was found to be unusually large, and, probably owing to the large decidua which had to come away, the patient vomited frequently during the seventy hours after operation. After the decidua had come away the patient recovered quite satisfactorily. The author believed this to be the first recorded example of primary rupture of the sac of a tubo-uterine gestation treated by a surgical operation. The ovum was not found, but no other explanation of the condition of affairs suggested itself than that of tubo-uterine pregnancy.

Mr. ALBAN DOBAN considered that Mr. Sutton had shown that the treatment of a ruptured interstitial pregnancy was relatively simple, though the danger was usually extreme. Amputation of the uterus was the course which had so often been recommended on partly theoretical grounds. But Dr. DUNNING¹ recently lost a case of this kind during operation. In his report he very properly dwelt on the dangers of performing hysterectomy on a patient already in a profound state of shock. In regard to the decidua, Pilliet² had shown that so far from it being ill-developed in ectopic gestation, it was particularly well-formed and bulky. This fact must be remembered in association with the theory that the foetus was relatively ill-developed.

Dr. HONROCKS asked if the size of the uterus had been measured in any way. It was only stated in the paper that it was enlarged. He agreed that the case was probably one of gestation. As a result of investigations he had found that in cases of extrauterine gestation the uterus began to grow in size just in the same way as it did in intrauterine gestation, and if the embryo lived it went on growing, and did not stop at the end of a few months. If the foetus died involution of the uterus commenced, and was completed unless prevented by complications such as would cause involution ordinarily. Hence in any given case the size of the uterus was a most important factor in the diagnosis. If the uterus were not enlarged one could say that either the case was not extrauterine gestation at all, or if it were the foetus was dead, and had been dead long enough to have allowed involution to be completed. Of course it was to be remembered that the uterus was not so great absolutely as in intrauterine pregnancy; what was meant was that at any given date of pregnancy the uterus was as great in extrauterine as in intrauterine gestation when in the latter case the uterus had been emptied of its contents. He asked also whether the rupture in this case had taken place through the substance of the wall of the uterus or close to the edge where the Fallopian tube emerges.

Dr. BOXALL inquired if, apart from the absence of menstruation for six weeks there existed any evidence, for example, morning sickness, of pregnancy having exceeded that duration; and also if Mr. Sutton, from a comparison with the character of preceding periods was disposed to regard the last flow prior to the operation as a regular period or as a hæmorrhage accompanying the abnormal gestation and symptomatic of it.

Mr. SUTTON replied.

UTERUS DIDELPHYS.

Dr. ARTHUR GILES read this paper. He recalled the three principal types of double uterus, namely, uterus septus, uterus bicornis, and uterus didelphys. A description of these was given, with outline figures. He next described his case, observed at the Middlesex Hospital. The patient complained of a protrusion from the vagina; this was found to be the remains of the vaginal septum. Under ether the exact condition was ascertained; it was illustrated by a drawing. The author discussed the clinical features of uterus didelphys as illustrated by recorded cases. Abstracts of these were given under five headings: (1) Cases of unilateral atresia with retained menstrual products, 5 cases; (2) pregnancy in one-half the uterus, 8 cases; (3) simultaneous pregnancy in both halves, 2 cases; (4) cases uncomplicated by atresia or pregnancy, 6 cases. These 21 cases (including the author's) were all that he could find recorded during the last twenty-five years

¹ Amer. Gyn. and Obstet. Journ., October, 1895.

² Annales de Gynéc. et d'Obstet., October, 1895.

as occurring in living adults. [Two recently-published cases were also given which were met with after the paper had been sent into the Secretaries.] (5) Cases discovered on the post-mortem table, 4 cases. A table was given of the 21 clinical cases, illustrating the following points: (1) Age: Most of the patients were under 30. (2) Marriage: Fifteen were married; in 2 there was dyspareunia. (3) Parity: Pregnancy occurred in 14 of the 15 married cases; 11 had borne children and 3 had miscarried. Among the 11 sixteen labours occurred, of which ten were natural. The 6 cases of dystocia were as follows: Obstruction to labour by the empty retroverted half, 3 cases; obstruction by the vaginal septum, 1 case; forceps, 2 cases. (4) In 4 cases the two halves were of equal size; the right was the larger in 6 and the left in 11. (5) In only 1 case the vagina was originally single; in 6 there was atresia of one half; in the remainder the two vaginæ were patent and separate. (6) Menstruation was slightly delayed; it occurred at 14 in 3 cases, at 15 in 4 cases, at 16 in 4 cases, at 17 in 1 case, at 18 in 1 case, at 23 in 1 case. It was regular in 12 out of 16 recorded cases, and painless in 12 out of 15. In 1 case the two halves menstruated separately. In the 8 cases of single pregnancy there is mention in 4 of a decidua in the non-gravid half. The clinical complications that might arise: (1) Unilateral atresia, with retained menstrual products; (2) dyspareunia; (3) double vaginitis or endometritis, unsuccessfully treated by application to one half only; (4) obstruction to labour by the retroverted non-gravid half; (5) obstruction due to the vaginal septum; (6) retained and undiscovered products of conception in one half in cases of double pregnancy. A bibliography was appended.

Dr. GALABIN referred first to two cases of uterus didelphys, one associated with congenital absence of the vagina, one with fibroid tumour of one uterus only, notes of which are appended to Dr. Giles's paper. In a third case he had met with dystocia of a very unusual kind arising from a double uterus—not a complete uterus didelphys, but rather a uterus bicornis, yet not of the usual kind, for the uteri were completely separate, without any uniting band, even below the level of the internal os. The lower part of the cervix, however, was common. The woman had had several children normally; but, for some unexplained reason, in her last pregnancy the poles of the two uteri became turned in opposite directions. The result was that the ovum, which began in one uterus, made its way also into the other. At full term one fundus was in the normal position, the other fundus lay in a reversed position in the pelvis, and contained the head of the foetus. The patient was admitted into Guy's Hospital in labour, and the true state of affairs was naturally not discovered till abdominal section had been performed. A large hard mass filled the pelvis, and was thought to be a fibroid tumour. The os was quite out of reach, the liquor amnii had escaped, and a hand of the foetus could just be touched. Caesarean section having been performed, and the foetus removed, the displaced body of the uterus at once sprang back to its normal position, and the two halves lay side by side. The incision, at first straight, was thus converted into an elongated U shape, and the centre of the U ran through very thin over-stretched cervical tissue. The edges had become so distorted that it was very difficult to sew up the incision satisfactorily. This was at length accomplished, and the patient recovered without a bad symptom, the child also being alive.

Dr. AMAND ROUTH thought these cases were not so rare as the scanty bibliography appeared to indicate. He had seen two cases. The first was described and pictured in the *Illustrated Medical News*, March, 1889. The woman was married, 3 para, aged 24 years. Catamenia began at 13½. There was amenorrhœa during pregnancy. The vaginal septum had been torn through, but the two uteri were quite distinct, one being anteverted, 2½ inches long; the other (right) being 3½ inches long and retroverted. Bimanually the uteri were felt to be quite separate, but joined loosely by a thick transverse band. She was suffering from subinvolution in the larger uterus. His second case was that of a single woman, aged 27, who was under the care of Dr. C. H. F. Routh. She was found to have a tense vaginal ridge on the left side continuous with an elastic mass in the pelvis, on the

left of what appeared to be a normal uterus. The vaginal ridge was incised, and its contents allowed to escape. It was then found to be a case of distinct double uterus and double vagina, with left vaginal atresia producing left hemato-colpos and hamatometra. The left uterus eventually contracted down to 2½ inches, but remained retroverted.

Dr. GILES, in reply, agreed with Dr. Amand Routh as to the degree of rarity of these cases. He was interested in the cases related by Dr. Galabin, and would ask permission of the Society and of Dr. Galabin to include a short account of the two cases of uterus didelphys in the paper in the form of an appendix.

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

D. ARGYLL ROBERTSON, President, in the Chair.

Wednesday, December 4th, 1895.

CASES.

Dr. R. A. LUNDIE showed a case of Rare Tumour of the Upper Lip in a boy, aged 13. It was of six months' growth, slow at first, but fast later. It appeared in the form of a beak or supernumerary nose. A wedge-shaped portion of the lip was removed, and when the tumour was examined afterwards by Mr. Stiles it was found to be an endothelioma with myxomatous degeneration, or, as it used to be called, a myxochondro-sarcoma.—Mr. STILES showed a Low and a High Power Slide from the case.—Dr. W. ALLAN JAMIESON showed a case of Morphaea under the right eye in a boy, aged 10.

EXHIBITS.

Mr. HODSDON, for Dr. FELKIN, showed a new Safety Pin, which by means of a sliding spring was locked after being closed, and was opened by pressure on the spring by the thumb nail. It was made by Mr. Robb, of Kincardine O'Neil.—Mr. STILES showed several Pneumatic Rubber Trusses for double inguinal hernia in infants, which seemed to meet most of the difficulties of that particular time of life, and the rapid growth.

OXALURIA.

Dr. J. C. DUNLOP read a paper on oxaluria and the physiological excretion of oxalic acid in urine. In all men eating a mixed diet oxalic acid was a normal product in excretion. It was precipitated a calcium salt in octahedral form and in dumb-bell crystals, the latter soluble in acetic acid. In 36 per cent. of the urines he examined he found deposition of oxalate of lime. Excess of lime or excess of oxalic acid might prevent the precipitation, the latter most. A deposit of crystals of oxalate of lime meant an excess of oxalic acid. Dr. Dunlop restricted those under observation to a diet absolutely free from oxalic acid, and then found a deficiency in excretion. He then added tea, which contained oxalic acid, and that substance was present in the urine. The amount of oxalic acid excreted varied much from day to day. Various figures were given—from 5½ to 25 milligrammes in the twenty-four hours. He found 17.2. The excretion of oxalic acid was affected by two factors—the ingestion of oxalic acid in the food and the acidity of the stomach after food. The clinical symptoms said to be concomitants of what was called "oxaluria" in the books were discussed, and shown to be of little help. Many of them occurred in merely acid dyspepsia as well as when oxalates were present. An artificially produced acidity increased the excretion of oxalic acid in oxaluria, as also did the ingestion of oxalic acid. The nervous symptoms were due to the dyspepsia present and not to an accumulation of the oxalic acid. Oxaluria, therefore, did not differ essentially from acid dyspepsia, and should not be differently treated.

Dr. NORM PATON agreed that the symptoms were simply those of acid dyspepsia.

Dr. GRAHAM was inclined to stand up for his old friend oxaluria on the grounds given by Dr. Dunlop on the ground of those cases in which undoubtedly oxaluria and diabetes alternated, and on the ground of recent experiments on dogs in regard to respiration and dyspepsia.

Dr. LOCKHART GILLIES thought Dr. Dunlop had proved his thesis, but was rather dogmatic in saying that in no other circumstances could oxaluria occur. Might not oxaluria be due to fermentation? Then in what form of acid dys-

pepsia did oxalates appear—in lactic, acetic, or hydrochloric? Might we not get oxalic acid from the decomposition of proteids?

Dr. JAMES said he also wished to take up the cudgels on behalf of the physicians as against laboratory investigators. He believed oxaluria might result from deficient metabolism. With long-continued milk diet, or milk diet followed by acids you get acid dyspepsia—what then?

Dr. BROCKMAN doubted if oxalates were not formed from starches and sugars. Certain persons alternately excreted oxalates and sugars. If Dr. Dunlop went on long enough, he might get more typical cases of this. He thought too much stress had been laid on oxalate of lime crystals in the urine. There might or might not be oxalic acid present, but all that the microscope showed was that there was something present in the urine which threw down oxalic acid. He had never yet seen a case of oxaluria in the sense in which it was understood in this country.

After some remarks from Dr. R. F. C. LEITH,

Dr. W. RUSSELL said he was not inclined to accept laboratory work as a sole guide to the physician. After all, oxaluria, despite Dr. Noel Paton, was referred to even in students' books as an exploded disease. He was taught that it was an associate of certain intestinal disturbances. Could Dr. Dunlop exclude all the processes in the gastro-intestinal tract as possible producers of oxalic acid?

Dr. DUNLOP replied.

BRAIN SURGERY.

Dr. GEORGE GINSON read a paper entitled Remarks on the Results of Surgical Measures in a Series of Cerebral Cases. He referred to six cases that had been under his own care: (1) A gliosarcoma, which had been operated on, and recovered; (2) a glioma of the corpus striatum, operated on, died; (3) a cyst plus fibrous sarcoma in the middle lobe of cerebellum, operation and uninterrupted recovery; (4) boy with alleged compression of the skull at birth, convulsions for two months, when the results of trephining were negative; (5) a woman—a fright and a blow—"fits" eight years later; became a dement; operation was followed by hyperemia and death; histologically a condition of general paralysis was found; (6) a man who had received a blow on the head, and presented various symptoms of intracranial pressure; on trephining there was found thick red membranes, and increase of cerebro-spinal fluid only; the patient recovered. The conclusion forced upon one by the experience of this series of cases was the necessity for bringing in surgical help at the earliest possible moment.

Mr. CAINE desired information as to optic neuritis in such cases. How often was it recovered from? What was the limit?

The PRESIDENT, answering these questions, said he thought that if the optic neuritis had not lasted so long as to lead to permanent changes in the fibres of the optic nerve there was recovery. The time limit was difficult to fix.

Dr. W. RUSSELL spoke of the value of a series of observations of this kind from one person.

Dr. GINSON replied.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

LONDON ATTRILL, M.D., President, in the Chair.

Friday, November 22nd, 1895.

SPECIMENS.

Dr. W. J. SMYLY showed the following specimens: Ectopic Gestation, three specimens. (1) The right tube was enlarged and ruptured, the left also enlarged, and the ovary of the same side cystic. Operation in consequence of commencing putrefaction of hematocoele; recovery. (2) Uterus and gestation sac containing placenta, also full-term macerated foetus 21 inches long, removed two months after term. The uterus was so much involved in the gestation sac, which had evidently been originally interstitial, that its total removal was considered advisable; recovery. (3) Ruptured tubal pregnancy of right tube; left tube and ovary had been previously removed for suppurating following birth of only child fifteen months previously. Admitted to hospital in very bad health. Enlarged right tube ruptured during bimanual examination,

collapse, abdominal section; recovery delayed by inflammation of left kidney. Double Pyosalpinx, two specimens. Both recovered. Uterus removed in a similar case. Abdominal section. Attempt to remove tubes failed after rupture of one with extravasation of pus; vaginal hysterectomy; abdominal cavity shut off with Mikulicz's bag; recovery. Pedunculated Myoma larger than adult fist. The soft tumour was diagnosed as dermoid of left ovary, but found to be a myoma; recovery. Myomatous Uteri, four specimens. (1) Patient had been greatly reduced by weeks of septic fever and constant pain; uterus curetted and cancer diagnosed by microscope. The organ, which was about twice the normal size, was removed *per vaginam* by morcellation; immediate relief from pain and fever; recovery rapid. (2) Uterus weighing 2 lbs. removed for bladder symptoms. A myoma as large as an adult fist enucleated from left broad ligament with difficulty, and a pedunculated myoma of same size easily removed after the uterus. Bladder trouble continued, but was improving; convalescence otherwise good. (3) Myomatous Uterus removed twelve hours previously; fragments weighed 3 lbs.; doing well; pulse 88, temperature 98.2°. (4) Myomatous Uterus removed by abdominal section by Martin's method—panhysterectomy. Patient, who was very anæmic at time of operation, died in twelve hours. Cancerous Tumour of Left Ovary: Operation simple; sudden and severe internal hæmorrhage same evening; abdomen reopened, bleeding controlled, and abdomen cleared of clots; convalescence uneventful until ninth day; complete paraplegia with anaesthesia, loss of reflexes in lower limbs, and paralysis of bladder; some fever for a week, then normal temperature, but paralysis persisted.—Dr. E. WINIFRED DICKSON exhibited a Fibromyoma removed from the Cervix Uteri in a 4 para, aged 30. The last pregnancy had ended a few weeks previously, at 6½ months; there had been severe hæmorrhage on this occasion, and the tumour had been then diagnosed. The symptoms had been slight. The tumour was removed with scissors, and the edges of the wound united with sutures. There was not much hæmorrhage. The patient made an uninterrupted recovery.—Dr. ALFRED SMITH showed a Uterus with large Fibro-cystic Tumour, which was removed by complete hysterectomy; recovery was rapid.—Dr. R. A. FLYNN exhibited a Uterus removed by vaginal hysterectomy for cancer in a woman aged 46, who had had ten children. The operation was performed on November 14th, the broad ligament being secured with Landon's clamp forceps; the clamps were removed in forty-eight hours. The patient had up to the present (November 22nd), nine days after the operation, made an uninterrupted recovery.

PAPER.

Dr. WALTER BERNARD (Londonderry) read a paper entitled, "Brief Sketches copied from my Breviary of the Priceless Sayings of other Men; with some remarks showing what valuable outposts they were in helping me to extend the boundaries of my knowledge, and to avert death while practising the obstetric art."

LIVERPOOL MEDICAL INSTITUTION.

G. G. HAMILTON, M.B., F.R.C.S. Edin., in the Chair.

Thursday, December 5th 1895.

PATHOLOGICAL SECTION.

LAMELLAR FIBROMATA.

Dr. ABRAHAM read a short paper upon lamellar fibromata, which was illustrated by specimens and lantern slides; he expressed his indebtedness to Professor Boyce for the latter.

Dr. BUCHANAN had examined one of the specimens, and considered the structure to be identical with that of hydatid membrane. He had not observed any cellular elements.

Dr. WICKLESWORTH called attention to the similarity in microscopical structure shown by Dr. Abraham's specimens and the fibrous thickenings of cartilaginous consistence which are not infrequently met with on the splenic capsule in old people and alcoholic subjects, and said the latter formations might be described as lamellar fibromata.

Professors BOYCE and SHERRINGTON, Messrs. HAMILTON, PAUL, and LARKIN discussed the subject, and Dr. ABRAHAM replied.

LESIONS AFTER CARBOLIC ACID POISONING.

Dr. BUCHANAN showed the stomach from a case of carbolic acid poisoning, also a beautiful drawing of the appearance of the specimen in the fresh state. He drew attention to the escape of the tongue and glosso-epiglottidean folds from injury, and pointed out that the duodenum was intact. The stomach was greatly contracted, and the mucous membrane in the fresh state had a greyish brilliant pearly lustre like oily putty.

BRAIN TUMOURS.

Dr. WIGLESWORTH showed (1) Brain from a case of Hydrocephalus; (2) Brain from a case of Cerebral Tumour.

Mr. PARKER referred to a case of brain tumour in which some six years ago he had removed a growth from the right Rolandic area, the patient being still alive and well. In his case, however, the diagnosis had not been one of great difficulty, unlike Dr. Wiglesworth's, in which diagnosis of the condition was impossible.

CEREBRAL HÆMORRHAGE.

Dr. A. W. CAMPBELL showed some brain sections from a case of cerebral hæmorrhage prepared by a new method. They were made in March, 1895, and had retained their colour satisfactorily. The following is the method of procedure: 1. Immersion of the brain in 1 in 20 carbolic acid for a few days. 2. Sections $\frac{1}{8}$ to $\frac{1}{4}$ of an inch in thickness are then cut. 3. The sections are placed face downward upon a piece of glass, surrounded by a framework of wood, and covered with melted paraffin (46° C.); the paraffin is allowed to set. 4. The glass is then lifted up, some Farrant's solution poured upon the section, and the glass replaced, the edges being sealed by Canada balsam. 5. A plaster-of-paris frame is then moulded on to the sides and back of the specimen.

LYMPHANGIOMA.

Mr. MURRAY exhibited some patients suffering from lymphangioma, and sections of the growth.

Dr. PARKER had lately had a similar case. He discussed the question of angiomas and lymphangiomas, and asked for an opinion on the subject of "degenerated nævi," which he considered to be lymphangiomas.

Professor BOYCE, Mr. HAMILTON, and Dr. BARENDT spoke.

SACROCOCCYGEAL TUMOUR.

Messrs. MURRAY and PAUL brought forward a case of sacro-coccygeal tumour in a boy, aged 2 years. Mr. Paul said the growth measured 5 inches by 4 inches by 3 inches, and was situated between the rectum and the coccyx, projecting on the surface behind the anus, where the skin was ulcerated over it. The central part consisted of a soft fungating growth of malignant appearance, composed for the most part of trabeculae of connective tissue set with one or more layers of cubical epithelium, but also containing tracts of skin with hairs, sebaceous and sweat glands. The outer parts of the growth were dense and fibrous, and contained miniature bone. In another part Lieberkühn's follicles were recognised. The structure, therefore, was very complex, and discussing the relation of this with other tumours, Mr. Paul thought it should be grouped with the congenital renal and thyroid growths.

Mr. PARKER said Mr. Paul had not mentioned the adenoid variety of these growths, of which he had shown a specimen at the previous meeting. He considered the growth was not malignant, but simulated the malignant state from the rupture of a cyst, and subsequent septic inflammation.

MISCELLANEOUS SPECIMENS.

Mr. THREHALL THOMAS exhibited (1) Specimens of Tuberculosis of the Peritoneum snipped out during an operation. The specimen showed typical tuberculous granulations. The boy 18 months after operation was in perfect health. (2) Implantation Cyst from the head of the metatarsal bone of the great toe. The epithelial graft had no doubt been made in the process of scraping for caries, which operation had been performed on three occasions. (3) Multiple Epithelioma (a) epithelioma in centre of the lower lip removed by operation, followed three years later by two separate and distinct growths in the same lip, but away from the scar; (b) Hard Warty Epithelioma of the Lip and Juicy Epithelioma

of the Under Surface of the Tongue, from a man, aged 30. —The CHAIRMAN showed (a) Union of Intestine by Murphy's Button; (b) Cholecystocolostomy. —Dr. LEIGH showed photographs of a "freak" now on exhibition in Liverpool. He considered it to be a case of osteomalacia. —Dr. ASHBY showed Microscopic Sections from a case of Meningo-Encephalitis.

HUNTERIAN SOCIETY. —At a meeting on November 27th, the PRESIDENT in the chair, Messrs. H. Byrne, J. McClymont, R. Jones and H. E. Blandford were elected Fellows of the Society. —Dr. HERMAN read a paper on Vaginismus and Allied Affections. He divided these into three classes, namely: 1. Simple smallness of the vaginal orifice. The treatment was to enlarge the orifice—(a) by gradual dilatation, (b) by rapid dilatation, (c) by incision. The last method was the best. 2. Disease of the vulva such as to make it tender. One such condition was that to which the late Professor Breisky of Vienna had given the name of kraurosis vulvæ. It was characterised by progressive contraction and tenderness of the vaginal orifice. Mr. Lawson Tait had described a condition having similar features, but in addition patches of purple to brown discoloration. He thought Tait right in thinking that his cases were examples of the disease described by Breisky, but that the coloration was not an essential part of the disease. Kraurosis came on towards the climacteric age. Sometimes it followed oophorectomy. It was often associated with vaginitis, and with itching and burning of the vulva without contact. The best treatment was the use of sedative vaginal injections, such as lead or boric acid; and dusting the vulva with sedative powder, such as boric acid or dermatol. If such treatment failed, or if the patient were a married woman, the only treatment was to excise the tender and shrunken mucous surface. He had done this in one case with success. 3. Vaginismus. This was a nervous disease, attended with hyperæsthesia of the vulva and spasmodic contraction of the levator ani and other muscles, often associated with dysmenorrhœa and hyperæsthesia of the rectum. This disease was generally discovered on marriage, but might suddenly appear after years of healthy married life. Sometimes it was cured by curing dysmenorrhœa; otherwise genuine vaginismus was incurable, even by childbirth, though in the course of years it got somewhat less. It was sometimes difficult to distinguish genuine vaginismus from mere smallness of the vaginal orifice in a sensitive patient. In a doubtful case the best treatment was to give the patient the benefit of the doubt and enlarge the vaginal orifice by operation. Dr. HERMAN exhibited a drawing of a case of kraurosis vulvæ. Mr. STEVENS asked if herpes vulvæ might not be the actual lesion in some cases. Dr. F. J. SMITH thought that kraurosis vulvæ was a trophoneurosis allied to morphea. Mr. SYMONDS (President) mentioned leucoplakia of the tongue and a fibrous condition of the male prepuce as probably pathologically identical with kraurosis vulvæ. Dr. COITMAN and Dr. SHADWELL also discussed the condition; and Dr. HERMAN replied. —Dr. ARNOLD CHAPLIN read a paper on Physiological Rest for the Lung in Phthisis, which was a plea for non-intervention by mechanical means in cases of pleural effusion, whether of serum or pus, where the underlying lung was the seat of tuberculous processes, and was based on clinical experience of some two or three cases in which, after aspiration, the patient had rapidly gone down hill. He also advocated artificial restraint of the movements of a tuberculous lung. The PRESIDENT said he had actually been asked by the late Dr. Mahomed to produce an artificial pneumothorax in a case of phthisis. Mr. OPENSHAW remarked that the late Dr. Sutton agreed with Dr. Chaplin in objecting to aspiration in such cases. Mr. HUMPHREYS, Sir H. BRYCE, Dr. COITMAN, Mr. STEVENS, Dr. J. H. SEQUIRA and Dr. F. J. SMITH also discussed the paper; and Dr. CHAPLIN replied.

HARVEIAN SOCIETY OF LONDON. —At a meeting on November 21st, Sir JOHN WILLIAMS, Bart., M.D., President, in the chair, Mr. HENRY JULER read a paper on Some Forms of Intia. Excluding the traumatic and sympathetic forms, he divided it into two main groups, plastic and serous. Dismissing the latter with a few remarks Mr. Juler entered more fully

into the causes of plastic iritis. He considered all kinds arising spontaneously to be due to some dyscrasia, whether it were gout, rheumatism, syphilis, tuberculosis, or any other constitutional disease. The uric acid diathesis could exist, in his opinion, and give rise to this affection without any other evidence of gout, and it was very necessary to examine the urine, and make a quantitative estimation of the nitrogenous excreta. Certain local signs by which the different varieties could be differentiated were pointed out, but the importance of examining the patient as to his general health was emphasised. Speaking of the treatment, Mr. Juler said he could not lay enough stress upon the vital importance of adopting both general and local rest. The latter was best carried out by means of sulphate of atropine, which paralysed the sphincter pupillæ and the ciliary muscles. Besides giving rest to the intrinsic muscles of the eye, it prevented or, if present, broke down iritic adhesions, and was also a local sedative. To relieve pain by the use of several leeches, and to give sleep by administering opium or bromidia, were useful adjuncts. In gouty subjects the exhibition of hot air baths, attention to diet and regular habits, and depletion, were essentials. Mercury in syphilitic iritis, salicylate of soda in rheumatic iritis, and such-like constitutional treatment, were not to be forgotten.

SOCIETY OF ANÆSTHETISTS.—At a meeting on November 21st, Mr. G. H. BAILEY, the President, delivered his introductory address, in which he commented upon the large number of fatalities from chloroform administration reported in the medical journals this year. He suggested that the meetings of the Society should be occupied more in the discussion of clinical cases, and trusted that thereby the Society might gather valuable information tending to diminish the present alarming mortality due to chloroform administration.—Mr. RICHARD W. LLOYD read notes of a case of Strychnine Poisoning by Hypodermic Injection, in which he administered chloroform for upwards of six hours. He referred to the address of Dr. Horatio C. Wood on Anæsthesia at the Berlin International Medical Congress in 1890, in which that physician said that for many years chloroform had been used as the antagonist to strychnine, and it seemed rather odd that strychnine should not have been employed as the antagonist to chloroform. Several recorded cases of strychnine poisoning treated by the administration of chloroform were cited. The difficulty or inability to swallow, and the promptness with which rectal injections were expelled in cases of strychnine poisoning, rendered medication by hypodermic injection and inhalation of vapour especially valuable methods of treatment, and therefore when the strychnine had been swallowed apomorphine by hypodermic injection was the most suitable emetic; and chloroform by inhalation was another most applicable antidote when the spasms are severe. Dr. SILK thought that Mr. Lloyd's paper was of great value to anæsthetists, as raising the whole question of the use of strychnine in cases of exhaustion or "shock" under anæsthesia. Dr. Silk had no experience of the antidotal action of chloroform in cases of strychnine poisoning, but he had a very high opinion of the value of strychnine in conditions of "shock." He had employed hypodermic injections of strychnine for this purpose with increasing frequency since Professor Wood, of Philadelphia, had drawn attention to it, and of late he had been in the habit of injecting one-sixtieth of a grain hypodermically immediately after anæsthesia had been induced in cases in which there was reason to anticipate any serious degree of exhaustion from whatever cause, repeating the dose, if need be, towards the end of the operation. Dr. Silk had seen no cumulative effects following the use of the drug, but, in the face of Mr. Lloyd's experience, this was obviously a possibility to be borne in mind. From some cases which had come under his notice, Dr. Silk was further inclined to think that the drug was of value in preventing after-sickness, but he should not like to speak with certainty upon this point, although Mr. Lloyd's case rather supported that view. Mr. WHITE referred to the great benefit which frequently attended the prolonged administration of chloroform in cases of tetanus, and alluded to a number of cases of traumatic tetanus in which the use of chloroform during the more acute spasms, and extending at

intervals over many hours, had proved of the greatest advantage. Dr. DUDLEY BUXTON, after referring to the President's address, for which he thought the Society owed him a cordial vote of thanks, said, with regard to Mr. Lloyd's paper, that he regarded the right time to use strychnine as an antagonist to chloroform just before the administration of the anæsthetic was commenced. If used when dangerous symptoms had occurred it was of less value, probably because it was imperfectly absorbed. The best method of its exhibition was by hypodermic injection. Although the employment of very large doses of strychnine in critical cases—even gr. $\frac{1}{2}$ had been recommended—he (the speaker) had seen dangerous interference with respiration from this drug, and believed its use must be less heroic. In persons blanched and pulseless from prolonged bleeding strychnine was invaluable as an adjuvant in chloroform narcosis. Mr. EASTES recalled to mind a case of tetanus in a boy, aged 15, treated at Guy's Hospital in 1864 for seventy-one hours, but unsuccessfully, with inhalation of chloroform, of which from 2 to 8 drachms were used every hour. The anæsthetic was pushed during the tetanic spasms, which it greatly controlled, but withdrawn in the intervals or when food was given. At the necropsy the bronchi were filled with dark purulent secretion, whilst the other organs were healthy. Here, therefore, the prolonged use of chloroform vapour apparently caused bronchitis, a result rarely ascribed to that anæsthetic, though often charged against ether. Mr. Eastes had also given chloroform for six hours continuously to a lady suffering severely from the passage of biliary calculi, in whom no unpleasant after-effect was produced by the anæsthetic. Mr. TYRRELL said it would be interesting to know what dose of strychnine was given, and whether it was given every four hours night as well as day. The dose which would produce a physiological effect varied in different people. He had known one dose of $\frac{1}{2}$ gr. produce muscular spasms, and in the same patient a week later one dose of $\frac{1}{4}$ gr. produced the same result. As an antidote to the depressing effect of chloroform on the circulation, it was necessary to produce a slight physiological effect to do any good, and for this purpose he generally administered $\frac{1}{4}$ gr. to an adult.

MEDICO PSYCHOLOGICAL ASSOCIATION.—A general meeting (being the first statutory meeting since the incorporation of the Association) was held on November 24th, under the presidency of Dr. NICOLSON. Before beginning the ordinary business the PRESIDENT referred to the death of Dr. Jamieson, of Aberdeen, the oldest superintendent of an asylum in Scotland, who had died at the ripe age of 77. In his day he carried on a great work at Aberdeen, while his writings on insanity were very well worth perusal now in the light of the best work that had been done in recent years.—Dr. GILMORE ELLIS read a paper on "Latah," a disease which affected the natives in the Malay peninsula. It seemed closely allied to the hysterical or hypnotic condition, but was yet essentially different from them. Many of the cases seemed to be markedly of an imitative character. The onset was due to the person being startled by something, or by being suddenly excited; the condition varied in degree, and in his experience it did not incapacitate the person affected from ordinary work. Latah was just as frequent at the present day, when there were British-taught schools throughout the peninsula, as it was forty or sixty years ago. The disease was not of the nature of insanity in any way, for the subjects of latah carried on their work like other people, and were very able as far as Malays go. The histories of some cases were given. A discussion followed, in which the PRESIDENT and Drs. COOKS, MERCIER, NICKLE, SEYMOUR TUCK, RICHARDS, and FLETCHER BEACH took part.—Six candidates, including one lady, were elected ordinary members of the Association.

NOTTINGHAM MEDICO-CHIRURGICAL SOCIETY.—At a meeting on December 4th, Dr. CATTLE in the chair, Mr. ANDERSON read a paper on Nephrectomy for Hydronephrosis. Details of five cases were given, all of which recovered after operation. In two (a boy aged 10 and a woman aged 37) the usual symptoms of hydronephrosis were present. In both the origin of the ureter was reduced to a pin-hole, the kidney substance atrophied, especially in the case of the woman, whose symptoms had lasted twenty years, and the pelvis

dilated to the capacity of a pint or more. In three other cases, one in a man, the hydronephrotic condition was associated with mobility of the organ. The man was successfully treated by suturing the kidney to the loin. The same treatment was pursued in the case of a female, but the kidney subsequently became loose. This was occasioned, it was thought, by the stitches cutting through the attenuated kidney substance. The patient was seized with rigors; high temperature and swelling of the abdomen. On exploration the kidney was found swollen and livid, owing to twisting of the pedicle. The kidney was removed and the patient recovered. In a third case of hydronephrotic and movable kidney extirpation was at once performed. The paper concluded with a review of the various causes of hydronephrosis, the writer remarking that he believed his cases of pinhole ureter were almost unique.—After some remarks by Dr. Watson, Mr. Fryce read notes of a case of Diabetic Neuritis in a man, aged 50, who had drunk freely. He was ataxic, but Romberg's symptom was not well marked. In the left leg no knee-jerk could be obtained; there was an erythematous rash and trophic ulcers on the foot. He had suffered from sciatic pains. The urine contained much sugar. The CHAIRMAN and Mr. Anderson made remarks, and Mr. Fryce replied.—Mr. Anderson showed the following specimens: (1) An Ovarian Tumour weighing 10 lbs.; (2) Tumour involving Right Lobe of Thyroid Gland; (3) Two Hydronephrotic Kidneys with Pinhole Ureters.

TORQUAY MEDICAL SOCIETY.—At a meeting on November 20th, R. POLLARD, M.B., President, brought the case of Dr. Anderson, of Tobago, before the notice of the members present, and the following resolutions were carried unanimously: 1. "That on the grounds set forth in the interim reports of the Civil Rights Defence Committee, the members of the Torquay Medical Society present desire to express their entire concurrence with the Civil Rights Defence Committee in earnestly inviting members of Her Majesty's Government, Members of Parliament, public men and public bodies both medical and lay, to co-operate with the Committee in defence of the chartered and statutory rights of medical men, and of the ancient rights and liberties of British subjects." 2. "That this Society, having considered the case of Dr. Anderson, desires to express its sympathy with him under the wrongs he has sustained, and recommends for approval by the Council that a sum of five guineas be contributed in the name of the Society to the fund being raised in support of Dr. Anderson's appeal." The sum of five guineas was subsequently forwarded to the Civil Rights Defence Committee, with a further sum of ten guineas subscribed by medical men in Torquay, and a memorial signed by most of the medical men in Torquay has been forwarded to their M.P.—Captain Philipotts, R.S., M.P., asking him to afford the Civil Rights Defence Committee his co-operation and support.

REVIEWS.

MANUAL FOR ARMY MEDICAL SERVICES—ADDENDA. By Surgeon Colonel W. E. RICHARDSON, Medical Staff. London: Eyre and Spottiswoode, 1895. (Cr. 8vo, pp. 56. 2s.)

ON May 3rd, 1890, we reviewed this admirable manual, which has proved a very valuable book of study and reference, not alone to the medical but we believe to other branches of the army. The changes—invariably and necessarily—in army organisation and administration, even during the short space of five years, have, in the opinion of the author, called for addenda extending to over fifty pages, which take the form of additions to the various chapters in the *Manual*. The changes in the last edition of the *Manual of Military Law* are not touched on; and it is strange to find that this important official volume is not, as it ought to be, faultless; for instance, "in the definition of a corps, the Army Hospital Corps is still included, instead of the Medical Staff Corps;" of course the former name has been obsolete for more than a dozen years past. Surgeon Colonel RICHARDSON deals

with the extended powers of summary punishment conferred on commanding officers, which, however, are safeguarded by the right of a prisoner to have the option of a district court martial. He mentions the new arrangements by which principal medical officers are relieved of details connected with pay, clothing, and equipment of the Medical Staff Corps, which now devolve on the company officers and quartermasters.

His criticisms seem to us fair and always to the point, while the suggestions he occasionally throws out are well worthy the attention of those in authority. He makes the admirable suggestion, for instance, that when a well-conducted soldier is allowed to re-engage he should start with a clean company sheet, instead of storing up a record of bygone and atoned-for offences against him.

In treating of Boards, he naturally refers to the petty and mischievous exclusion of medical officers from mixed Boards. Although their opinion may be asked, the advantage of their knowledge, consultation, and advice is lost on report, even on such special medical subjects as sanitation and hygiene. He comments on another ridiculous regulation whereby "the judicial principle of inquiry is in many instances set at naught." For example, if there are local sanitary defects of an engineering character to be inquired into, the President of the Board is to be the local commanding Royal Engineer; or, if there be defects in the provisioning of the troops, the President of Inquiry is the local officer commanding the Army Service Corps. By this arrangement these officers probably report on their own acts and shortcomings.

No fewer than twenty out of fifty pages of the addenda are in Chapter V, treating of organisation and administration. The author writes: "The primary object of military organisation is to render the soldier individually and collectively as efficient as possible," and "the ultimate object is, with a minimum sacrifice, to defeat an enemy," an excellent definition, and ideal, no doubt, to be aimed at by our War Office, but the big blot on our system is the "diffusing of authority," an evil which greatly impressed the Hartington Commission, and through which very few heads of departments are allowed to come into direct contact with the military or civil heads of the army. It is to be hoped this defect will be met in a reorganised War Office. Every question, however important or trifling, has to filter through a series of War Office officials. Under this system all direct power or responsibility is diffused or lost. The remedy is concentration at the head and decentralisation at the extremities of an army administration. The latter, though easy enough in such an army as that of Germany, is very difficult for us with our large colonial and Indian garrisons. For much of the delay and mismanagement at headquarters the author very properly holds "financially accountable." Greater devolution must be extended to our units of regiments, batteries, troops, etc. As matters are, regimental officers are so bound by rules and regulations, and "unaccustomed to stir in the matter of providing themselves or their men with anything," that they come to lean helplessly on the departments. The power of initiative is lost or stunted through repression and non-use. This was specially noticeable, he remarks, when medical officers, coming to be regimental, were suddenly thrown on their own resources of administration and command. The system of regimental letters has, it is declared by competent authority, developed in the British officer "an extravagant dread of responsibility in administrative matters," yet no men are more trustworthy and self-reliant when really thrown on their own resources and their faculties allowed free scope.

In discussing the duties and qualifications of an efficient staff officer, the author shows the absolute necessity of cordial and close relations between these officers and those of regiments. It is just here that the present arrangements of the Medical Staff lamentably break down. The medical officer is far more in physical touch with regiments and corps than any other of the general staff, but he is isolated and prevented from coming into mental and moral touch with them to his and their infinite disadvantage. "Continuity of feelings" has become sadly interrupted, and Surgeon Colonel Richardson thinks this can best be remedied by giving medical officers army rank, which would break down distinctions between men who are essential to each other,

The unsold copies of the book with addenda attached will be sold at the original price, 2s.

The medical department exists merely at the War Office; its executive is the Medical Staff, which is not a department but an integral and essential part of every unit and branch of the army.

The author recalls the fact that the Royal Wagon Train organised for medical transport during the Peninsular war was disbanded in 1833; and so for twenty years before the Crimean war we had absolutely no provision for succouring or moving the wounded. Such want of provision seems almost incredible; yet, with the terrible experiences of the Crimea, it took another twenty years to inaugurate our present field medical organisation; at the end of yet another twenty years it is very doubtful if we are now sufficiently prepared.

The addenda on Hygiene are interesting and important, and it is shown that, while a general knowledge of that subject is desirable on the part of all military officers, all "questions of vital importance must ultimately be referred to the medical officer."

Chapter XIII, dealing with the Organisation of an Army Corps, the author shows yet once again the absurdity and futility of a general attempting to keep the principal medical officer of the force at arm's length on the line of communications. His chief and most difficult work will be the "evacuation of the wounded from the fighting line," and therefore his position must be in front.

We have said enough to show the value of this *Manual* and its addenda, which should certainly be in the hands of every medical officer who wishes to get a thorough grasp of his military duties and position.

CLINICAL LECTURES ON THE PREVENTION OF CONSUMPTION.

By WILLIAM MURRELL, M.D., F.R.C.P. London: Baillière, Tindall, and Cox. 1895. (Cr. 8vo, pp. 108. 3s. 6d.)

THESE lectures, delivered by the author at Westminster Hospital, discuss points of great importance in the history of the disease. After drawing attention to the terrible yearly mortality, as well as the physical incapacity caused by it, he enters upon the question of its contagiousness. He deals summarily with the well-known Brompton statistics, and shows by the evidence of experimental pathology and clinical observation that phthisis is a communicable disease. In discussing the relation of tuberculosis in animals to that in man Dr. MURRELL takes the opportunity of showing that tuberculin has not been a failure in the sense of providing a valuable diagnostic agent in tuberculosis in animals. The predisposing causes important in the prevention of phthisis are also dealt with. The very important and practical question as to whether phthisis should be made a notifiable disease is discussed. The author, although acknowledging the propriety of it, does not think that public opinion is yet ripe for it. Finally he draws attention to a number of practical points in preventing the spread of phthisis, especially to those living in the same house or nursing the patient. These lectures contain information based on sound principles, and are also an expression of our greatly increased knowledge of phthisis obtained by the aid of bacteriology.

NOTES ON BOOKS.

DIARIES.

Messrs. JOHN WALKER AND Co., Limited, Farringdon House, Warwick Lane, London, E.C., publish a large number of convenient diaries carefully compiled to meet various wants. Amongst the pocket diaries a very excellent form is the *Graphic Diary* (No. 17), a thin long oblong volume which lies flat in the breast pocket (1s. 6d. to 2s. according to binding). The No. 1 diary is a similar diary, but adapted in shape to the waistcoat pocket (cloth, 6d.; American Russia, 1s. 6d.). The No. 2 diary, rather longer, can also be carried in the waistcoat pocket (6d. to 2s.). Nos. 3 and 4 are flat diaries for the breast pocket, allowing rather more space for each day. All the diaries contain separate almanacs, and pages for cash accounts and for memoranda, and all can be obtained in loose leather cases, into which "refills" can be inserted, the book being thus renewable yearly (No. 4 in this form in American Russia case costs 5s.). The same firm

issue a desk diary with detachable sheets, which can be renewed yearly, convenient for noting casual appointments, etc.

Messrs. Cassell and Co. publish *Letts's Diaries* in many forms, suitable to all sorts of purposes to which a diary can be put. They are strongly bound, and contain a great deal of information. Thus in one before us (No. 8, large post 8vo, one day on page, price 6s. 6d.) we find a Parliamentary directory, as well as the lists of bankers, markets, and postal information usually supplied. No. 1 is a large volume, and affords space for the fullest notes of the most introspective keeper of a diary.

The *British and Colonial Druggist* issues an office diary for the use of chemists. It is interleaved, and shows a week on a page. It contains a large number of advertisements, to which a classified index is provided, and a great deal of miscellaneous information. Amongst this is one list to which we feel disposed to take exception. It is a list of physicians and surgeons in London, Birmingham, Bristol, Dublin, Edinburgh, Glasgow, Liverpool, and Manchester. The names are classified under Cancer, Diseases of the Chest, and so on through the whole gamut of specialities. The list, we are told, has been compiled "by an experienced London practitioner," who has apparently sought to be impartial, but we should judge that to be thus ticketed and classified for the information of the chemist and his customers must be extremely distasteful to many of the eminent physicians and surgeons whose names appear.

MEDICAL DIARIES.

In addition to the medical diaries noticed in the *BRITISH MEDICAL JOURNAL* of December 7th, we have received *Letts's Medical Diary*, published by Messrs. Cassell and Co. (London, Paris, and Melbourne) in various forms. Bound in cloth, with space for fifty-four patients, its price is 2s. 6d.; for 108 patients, 4s.; in French Morocco with tuck, 3s. 6d. and 5s. respectively. It contains notes on infectious diseases and their notification, on disinfectants, on hypodermic medication, on the general treatment of poisoning, on professional fees, and on many other points to which it may be necessary to make reference in haste. It is a convenient and well arranged medical diary.

Atlas of the Diseases of the Skin. In a Series of Illustrations from Original Drawings with Descriptive Letterpress. By H. RADCLIFFE CROCKER, M.D., F.R.C.P. (Edinburgh and London: Young J. Pentland. Fasciculi ix, x, xi, 21s.)—We have three more fasciculi of this excellent *Atlas* before us. In Fasciculus ix we notice three figures in one plate showing the appearances of hydroa herpetiforme, in which groups of bullae are associated with rings of erythema. Psoriasis punctata, dermatitis exfoliativa, ichthyosis hystrix and ichthyosis congenita are all well shown, the various forms of ichthyosis almost profusely. The last plate in this fasciculus, Plate lxxv, is a very interesting one, showing lupus erythematosus in three forms, one a very early form on the cheek with appearances almost like erythema nodosum, a form on the nose, and the characteristic appearances of the disease when it attacks the scalp. Fasciculus x contains Plate xxxix, in which four forms of vaccination eruptions are reproduced. Plate xli shows an example of the gangrenous dermatitis of infants, and one of erythema multiforme occurring after vaccination. Varieties of elephantiasis and ichthyosis are shown in Plate li. Seborrhoeic dermatitis and papular eczema are shown in Plate lxxxli. Two excellent representations of alopecia areata are shown in Plate lxxxix. A well-marked case of tinea versicolor fills the final plate of the fasciculus (Plate xcvi). Fasciculus xi contains an example of acute lichen planus, the eruption covering the thorax and abdomen. Plate lxxxv contains five representations of the interesting and rare disease lymphangiectodes, otherwise known as lymphangioma circumscriptum, lupus lymphaticus, or angioma cysticum. One of the figures shows a condition of the mucous membrane of the lower lip so similar to the affection on the skin as to suggest an identity in the nature of the two affections. Another rare disease, xeroderma pigmentosum, with development of papillomatous growths, is shown in Plate lxxv. Plate lxxxiii shows illustrations of milium, and a well-marked one of the grouped comedones of

childhood. Well-marked examples of acne are shown in Plate LXXXIV, and typical examples of tinea circinata in Plate xciv. The plates in all the three fasciculi are artistically excellent.

Exposures of Quackery. By the Editor of *Health News*. (London: The Savoy Press. 1s.)—This small volume consists of reprints of articles which have appeared in various journals showing the nature and composition of many of the much-advertised quack medicines with which the world abounds. The book is written in popular language, and is primarily addressed to the general public. Nevertheless, we can commend it to the perusal of medical men, who ought to know the ingredients of the strange pills and mixtures with which people dose themselves. The author lays great emphasis on the "gross wrong" done to the community by the fictitious value given to quack remedies by the Government stamp with which they are sealed. He urges that every proprietary medicine should bear upon each bottle, box, or packet in which it is sold a conspicuous label stating its composition, and that licences to sell patent medicines should be withheld from all persons having no knowledge of the real nature and action of what they are selling.

Traité Pratique des Maladies des Yeux. Par Dr. ED. MEYER. Fourth Edition. (Paris: G. Masson. Crown 8vo, pp. 800. 251 illustrations. Fr.12.)—The publication of a fourth edition of this well known treatise, which has already appeared in seven different languages, speaks well for the place which it fills among students of ophthalmology. The author has brought this edition up to date, while several matters which have been found useless have been omitted, so that in spite of the new additions there is no great increase in bulk. The plan of the book is to give an elaborately classified system of diseases with their causes and treatment, each section being preceded by an account of the structure of the part concerned. In the matter of treatment the author is careful to give all the methods in use while indicating what is, in his opinion, the best one. Thus, in the section on cataract extraction, the old flap extraction and the method of couching are described in full, but the operation of extraction with iridectomy is the one which is preferred. Perhaps too much importance is assigned to obsolete operations, however necessary these may be in showing the steps by which the more satisfactory methods now in use have been arrived at. While the book is in every way excellent from the surgical point of view, and in the parts which deal with the purely local affections of the eye, it would be more useful to the general practitioners if the parts dealing with the relation of eye symptoms to general diseases and to affections of the nervous system were more elaborately dealt with. It would be difficult for one author, however, to write a treatise so thoroughly good in every part as this one is in its surgical and operative parts.

The Management and Medical Treatment of Children in India. By EDWARD A. BIRCH, M.D., F.R.C.P. Third Edition. (Calcutta: Thacker, Spink, and Co. London: W. Thacker and Co. 1895. Demy 8vo, pp. 422. 10s. 6d.)—The history of this book is interesting. Dr. Edward Goodeve, while practising in Calcutta, conceived the idea of drawing up for the use of Indian mothers a brief code of instructions regarding the management of infants under the trying circumstances of Indian life. His little work was found very useful, and became popular throughout the whole of our Eastern Empire. Successive editions were called for, and the original manual has grown under the able revision of Drs. J. Ewart and E. A. Birch into a treatise in which everything that a mother or nurse ought to know respecting the dieting, clothing, and general care of an infant is very plainly and fully set out. The more common diseases and accidents of infancy are also described in homely language, and their treatment in the absence of medical advice indicated. This is the third edition of Dr. Birch's version of Goodeve's *Hints*, and he has spared no pains to bring it into line with the most recent views and practices regarding the hygienic and medical treatment of infants and children.

REPORTS AND ANALYSES

AND

DESCRIPTIONS OF NEW INVENTIONS

IN MEDICINE, SURGERY, DENTISTRY, AND THE ALLIED SCIENCES.

INVALID BED.

THE Gorham Invalid bed is the invention of an American physician, Dr. George E. Gorham. By means of it any invalid, no matter how heavy, may be placed in a reclining or sitting position on a comfortable seat with foot rest, turned on the side, lifted and swung in an easy hammock, transferred to a stretcher, or placed sitting at a table for eating or writing, with no more muscular effort on the part of the nurse than a 10-year-old child can easily exert. The bed is made throughout of iron and steel, and is therefore easily rendered aseptic. Instead of the usual four supporting bed legs, the frame of the bed is mounted at its centre on an A shaped supporting frame. Transversely attached to this supporting frame is a right and left steel screw. On this screw work two supporting arms, travelling in opposite directions when moved from the centre. These supporting arms are each at their upper extremity attached to the frame of the bed bottom, where each works in a ball and socket joint. The screw (and by the screw the supporting arms above it) is worked by turning the wheel shown in the illustration. The wheel may be attached to either side of

the bed; thus a patient who can use either hand can himself change his position. Turning the wheel to the left depresses the foot of the bed; turning it to the right depresses the head. The bed plane remains automatically fixed at any angle from the horizontal at which the wheel is stopped.

All the various movements and liftings above described are accomplished by turning the wheel. The bed is useful in cases of typhoid, heart disease, dropsy, rheumatism, and gout, and it is particularly valuable in surgical cases requiring immobilisation. The bed is 30 inches high, a convenient height for operating, and may be changed in five minutes, without disturbing the patient into an operating table. The lift hammock raises a patient suffering from acute rheumatism, flexing his joints and muscles, without noise or jar. It also renders frequent changing and airing linen and mattress possible, and prevents bedsores. By means of it the patient can be raised to a most convenient position for making examinations and dressings. The German bed is now in use at the following London hospitals: St. Thomas's, the London, the Royal Orthopedic, and the Middlesex, and by the Cottage Hospital, Surbiton. The bed may be seen at 11a, Finchbury Square, where inquiries should be addressed.

AN ADDITION TO THE AURAL SPECULUM.

Dr. LENNOR WAINWRIGHT (Folkestone) wishes to call attention to a modification of Seigel's Aural Speculum, which has been suggested by him, and carried out by Messrs. Krohne and Besemann. The improvement consists in having a small receptacle fixed to the mouth piece, in which is placed a small pad of cotton wool, which effectually prevents dimming and fogging the glass, and also acts as a filter, preventing bacilli or offensive odours being sucked in by the operator. The addition is small and light, and does away with the cumbersome diaphragm. Warming the glass of the speculum prevents fogging for a time, but does not act as a filter. This is why he has introduced the wool.

LIST OF AUTHORS AND OTHERS WHO HAVE PRESENTED BOOKS TO THE LIBRARY OF THE BRITISH MEDICAL ASSOCIATION.

THIRTIETH LIST.

Presented by the Authors.

GACHE (R.). *Climatologie Médicale de la République Argentine et des Principales Villes d'Amérique*. 1895.

MULLINS (G. L.). *Epidemic Diseases and their Prevention in the Eastern Hemisphere*. 1895.

PHILIPPO (Z.). *Elemente de Therapeutica et Materie Medica*. Parts 1-4. 1895.

Other Papers.

PINTRA SANTA (Dr. Prosper de). *Chemins de Fer et Santé Publique*. 1891.

Essai de Climatologie. 1895.

6000 PARTS OF THE INDIAN MEDICAL JOURNAL, to complete series.

BOOKS NEEDED TO COMPLETE SERIES.

The Honorary Librarian will be glad to receive any of the following volumes, which are needed to complete series in the Library:

AMERICAN CLIMATOLOGICAL TRANSACTIONS. Vols. 1 to 7.
AMERICAN JOURNAL OF THE MEDICAL SCIENCES. New series, vols. 4, 5,
1894-95; vols. 13, 14, 1897-98; vols. 15-20, 1899; vol. 20, 1897; vol. 21, 1894-95;
vols. 22, 23, January, 1897; vols. 24, 25, 1899-00; vols. 26, 27, or any parts of
these vols.

AMERICAN JOURNAL OF OPHTHALMOLOGY. Vols. 1-9.
AMERICAN OPHTHALMOLOGICAL SOCIETY. Transactions of Meetings 1 to 4, and
vol. 5, part 2, 1893.

ANNALS OF SURGERY. Vols. 1 to 16. Philadelphia.
ARCHIVES GÉNÉRALES DE MÉDECINE. 1831-1839 inclusive; 1846-1855 in-
clusive; 1857-1861 inclusive; 1871.

ARCHIVES OF OPHTHALMOLOGY. Vols. 1, 2, and since vol. 13.
ARCHIVES OF OXOLOGY. Vols. 1, 2, and since 71.

AMERICAN MEDICAL GAZETTE. Before 1890 and 1872-1892.

BAHREIN. Diseases of the Heart.

DELL (J.). Clinical Observations. Vol. 2, 1813.

DELL (J.). Atlas of Medicinal Plants.

DICTIONNAIRE ILLUSTRÉ. Vol. 2, 1891, Paris.

BRITISH GUIANA HOSPITAL REPORTS (formerly Georgetown Hospital
Reports). 1891-1892.

BRITISH JOURNAL OF DERMATOLOGY. Vol. 1, parts 2, 4 to 10; vol. 2, Nos.
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

BRITISH JOURNAL OF DERMATOLOGY. Vol. 1, parts 2, 4 to 10; vol. 2, Nos.
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

BRITISH JOURNAL OF DERMATOLOGY. Vol. 1, parts 2, 4 to 10; vol. 2, Nos.
1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197,

infected districts, for a time it was confined within limits, and only imported cases occurred in Mansourah and the neighbourhood; these were successfully dealt with so far without any extension. On November 6th a village on the Nile midway between Mansourah and Damietta was infected, since which, as was to be expected, there have been dropping cases down the river in villages to the north.

The total number of cases up to date is 893, and the deaths 64. These figures as regards the cases registered are inaccurate, and it is more than probable that over 1,500 cases of the disease have occurred. A population has to be dealt with absolutely opposed to assisting the sanitary authorities, and who do everything in their power to conceal the existence of cholera. They go so far as to hide the cases in the cotton and douira fields.

The position at present is that the disease is well under control in the Bahr-el-Saghir, and it is hoped will soon be stamped out there. Dropping cases are occurring on the Nile between Mansourah and Damietta, and in the villages north of Damietta. These being all centres of infection, are naturally in danger. Mansourah, a town of 60,000 inhabitants, has so far been saved. Three local outbreaks in the Charkieh province to the south of the infected districts have been dealt with successfully.

The danger lies in the future, for if the disease be allowed to amoulder on until next spring, there is the possibility of a serious epidemic. We trust that the Sanitary Department will be given the means to stamp out the disease now, when it is limited to a comparatively small district, and when the number of cases is limited. All suspicious cases have been examined bacteriologically by Dr. Bitter and Dr. Kaufmann, who further verified that the disease was true Asiatic cholera.

THE ASSOCIATION OF FELLOWS OF THE ROYAL COLLEGE OF SURGEONS, ENGLAND, AND THE CASE OF MR. R. B. ANDERSON.

A DEPUTATION from the Civil Rights Defence Committee, introduced by the Earl of Stamford as President, waited upon the Committee of the Association of Fellows of the Royal College of Surgeons, England, on December 4th, Mr. George Pollock, President, in the chair.

Before proceeding to the business of the deputation, Mr. FRANCY DUNN (Honorary Secretary) read a letter from General Graham, conveying the thanks of the Civil Rights Defence Committee to the Committee of the Association for having at the last meeting adopted a resolution expressing appreciation of the action of the Council of the College in co-operating in support of the rights of a Fellow and Member. A letter was also read from Mr. Holmes to the effect that the published reports of Mr. Anderson's case made it quite clear that he had suffered the grossest injustice as well as indignity, the former at the hands of the Trinidad judges and the latter at those of the English; that he ought to be fully and fairly compensated, and that the Association could not be better occupied than in supporting Mr. Anderson in obtaining compensation and the reversal of the illegal sentences and orders against them.

LORD STAMFORD having briefly introduced the deputation, Major-General GRAHAM expressed a hope that the measures adopted would be confirmed by the general meeting of the Association, and that the example would be followed. In such a hope they already had much encouragement, several Branches of the British Medical Association having organised subscriptions, and some having voted amounts from their funds. The Torquay Medical Society had lately done the same, recommending a vote of £5 from its funds, and organising a uniform subscription of 3s. each from the members, amounting in all to £18. Besides this that Society had adopted resolutions calling upon Her Majesty's Ministers, members of Parliament, public men, and public bodies to unite with the Civil Rights Defence Committee in defence of the common rights of all medical men and all British subjects, and had obtained the signatures of its members to a memorial to Commander Philipott, R.N., M.P. for the Torquay Division. Mr. Cohen, M.P., had promised his support to the Committee. The Council of the British Medical Association had been asked to use its great influence with its

Branches throughout the country, and the friends of Mr. Anderson in Lincolnshire, his native county, had taken up the matter warmly. By such means it was hoped to enlist the sympathy and co-operation of other public bodies, especially that of the guilds and corporation of the City of London. They had a special ground to do in this case, since the rights of one of those guilds—the Worshipful Society of Apothecaries—had been violated, Mr. Anderson being a Licentiate; his licence granted by them under charter being rendered valueless. Major-General Graham concluded by asking the Association to appoint a representative on the Civil Rights Defence Committee.

MR. WALTER RIVINGTON supported the proposals of the deputation, and remarked that there had been nothing like the case of Mr. Anderson since the time of James II.

MR. GANT and Dr. ROBERT BARNES also spoke.

MR. ANDERSON answered various questions.

LORD STAMFORD thanked the Committee of the Association for their cordial reception, and on the motion of Mr. GANT a vote of thanks was passed to Lord Stamford and those acting with him for their public-spirited action in taking up the case of Mr. Anderson.

MR. POLLOCK, on behalf of the Committee, undertook to bring Mr. Anderson's case before the Association at its general meeting.

The deputation then withdrew.

LITERARY NOTES.

Die Cholera in Hamburg is the title of a work by Dr. Friedrich Wolter now in course of publication. It embodies the results of an exhaustive inquiry into all the circumstances of the disastrous epidemic of 1892. The work is divided into three sections dealing respectively with the causes and the history of the outbreak and its effects on the domestic life of Hamburg. The second part completing the second section has just been issued by the Verlag der Neue Börsen, Halle. Two further parts, composing the third section, will complete the work.

With the issue for November 1st the *Medical Reporter* changed its title to the *Indian Lancet*. The reason given for the alteration is that the name "Reporter" "does not give that weight and importance which a scientific journal should claim." It is a matter of regret that the change was not postponed until the beginning of a new volume: altering the title of a journal in a running volume gives much trouble in making references to it.

Everyone knows Lord Fletcher of Saltoun's saying, "Let me make a nation's ballads, and let who will make its laws." The honour of making one ballad which has often been a powerful stimulant to the heart of a mighty nation, belongs, it would seem, to a member of the medical profession. The author of "Yankee Doodle" was Dr. Richard Shuckburgh, a medical officer in General Amherst's army in the "good old colony times."

The *Edinburgh Medical Journal* for December contains an article by Dr. W. G. Aitchison Robertson, in which, under the title of "The Therapeutics of the Sixteenth Century," some account of "The Secretes of the Reverend Father Mayster Alexis of Piemont" is given. The work is a translation from the Italian, and was printed in London in 1565. Mayster Alexis's "Secretes" include prescriptions for the following among other purposes: "The manner and secretes to conferre a man's youth and to hold back old age, and to maintaine a man alwaies in health and strength as in the fairest flower of the age"; "to make a woman that is wont to have daughters to bear sonnes also;" "against the difficultie of bringing forth childe and the retention of the skin that the child is wrapped in, called in Latin secundaria," etc. The following is a specimen of antiseptic surgery as practised by our rude forefathers:—

A verie goodlie and present remedy for to heal the pestilence in drawing out the venim from the botch or sore or otherlike accidents:

Take a quicke hen and pluck the feathers from hir arse and from the place whereas she layeth hir ege, and set hir so that the said bare place may be upon the greese, and that she may as it were sit on the botch or sore on the place of the plague, and hold hir so a good while. Then you shall see that the said hen will have drawne all the venim and infection that shoulde after she will die. It shall be good to do this with two or three or more hennes, immediatly one after another.

BRITISH MEDICAL ASSOCIATION.

SUBSCRIPTIONS FOR 1895.

SUBSCRIPTIONS to the Association for 1895 became due on January 1st; and notice is hereby given, in accordance with By-law 5, that Branch Secretaries' subscription accounts close on October 31st, and all unpaid subscriptions must be forwarded after that date to the General Secretary, 429, Strand, London. Post-office orders should be made payable at the General Post Office, London.

British Medical Journal.

SATURDAY, DECEMBER 14TH, 1895.

THE PROPOSED GENERAL HOSPITAL IN CAMBERWELL.

For some time back a considerable amount of correspondence has taken place in our columns and the press regarding the lack of hospital accommodation in those parts of London which are situated south of the Thames. The friends of the two great hospitals, Guy's and St. Thomas's, which have for so long ministered to the wants of that part of London, have not, however, been slow to point out that not only beds, but the whole administrative machinery on which so large a proportion of the income of every hospital is spent, exist within their walls, ready for occupation, at very little more cost than that of food and service, if the public will but provide the money.

Other schemes which have been put forward involve the erection of new buildings either as complete hospitals, or as what have been termed "out-post hospitals" in connection with existing institutions. Of the plans which entail building, that of erecting a new and completely equipped general hospital in Camberwell has obtained considerable prominence in consequence of the support given to it in the report of the House of Lords Committee (1892).

It can hardly be doubted that this Committee was influenced by the enormous preponderance of hospitals on the north side of the Thames, and by a desire to see a greater symmetry of distribution, and not merely by the proved necessities of the southern sides. They say: "It was suggested that certain hospitals might be removed from places where they are not so much required to localities where the accommodation is deficient. The Committee cannot regard this suggestion as practical, but they would strongly advise that more hospital accommodation should be provided south of the Thames, and were it possible to find the site, and were philanthropic endeavours to be made for further accommodation for the sick in London, a large General Hospital, say in the densely-populated district of Camberwell, would no doubt be of extreme value. The Committee do not lose sight of the tendency of individuals to prefer some particular hospital, and many instances were given of patients passing four or five hospitals on their way from their homes to a particular hospital in which they had confidence. Though the Committee cannot doubt that this is a fact, and that possibly this migratory disposition would not be checked by the building of a large general hospital, they are, nevertheless, convinced

that more hospital accommodation is required south of the Thames."

We have given the above in full so that the exact bearing of the report of the Committee may be evident, for it is clear that their recommendation in regard to this Camberwell scheme is not a very strong one, and is hedged round with many "ifs."

The Committee had before them in evidence that at Guy's there were at least 100 beds (on an average 150) unoccupied for want of funds, while one ward was set apart for patients paying £3 3s., and other patients paying smaller amounts were taken into the general wards.

At St. Thomas's also no fewer than five wards were closed, reducing the accommodation from 509 to 435 beds.

It is clear then that, with upwards of 200 beds available and unused south of the Thames, the statement of the Committee regarding the want of accommodation by no means involves the necessity of a new hospital.

As bearing upon much that has been said, it is worth noting that the Committee say, "As regards in-patients (except accidents) it appears that the proximity of the hospital to their homes is not generally a matter of such great importance."

Then they state that "the prevailing though not unanimous opinion, as appearing from the evidence, seems to be that on the whole the hospital accommodation in London is sufficient," thus disposing of another of the provisions made by the Committee with regard to the Camberwell scheme.

It cannot then be said that the recommendation of the Lords Committee is of such a character as to overrule the discussion of the matter on ordinary general principles. Enormous areas of the outer part of London are as far from hospitals as most parts of Camberwell are now. To erect a new hospital there will not alter largely the central preponderance, and there is but small security, or in fact likelihood, that the people in Camberwell will desert the old hospitals for the new.

The common-sense method of dealing with the question is to open the beds now lying idle on the south of the Thames, and then if after that is done philanthropic efforts should still be made for further accommodation for the sick in London, it will be time enough to consider whether Camberwell is the best locality in which to place a new hospital.

HOSPITAL ELECTIONS.

Our Melbourne Correspondent, in a letter published a few weeks ago, related the history of a recent contested election to the staff of the Melbourne Hospital. We cannot but agree with him that the system is urgently in need of reform. It possesses the worst features of the worst system known in this country, with the added disadvantage that the tenure of office is only four years, and that at the end of that short period the whole of the appointments are again thrown open to competition. At the recent election there were thirty-one candidates for eighteen vacancies, and it is a significant fact that all the old members of the staff were re-elected. Our correspondent states, however, that for months beforehand the candidates, or some of them, had been issuing self-adulatory advertisements, and the newspapers had contained paragraphs, more or less inspired, relating to the merits of certain among them. The whole business was conducted

apparently on the lines of a contested parliamentary election, with this difference—that as the candidate could, from the nature of the case, have no policy to set forth and no opinions to express, he was compelled to found his claim on his personal attainments and professional qualifications.

Our correspondent appears to think that some of the candidates never had much chance, but adds that it may be concluded that none "in this scramble," which further on he likens to a football scrimmage, "have been entirely disappointed. Everyone has got something of value to him. They are all happy, although in various degrees. They have not all hit the target in the centre, but they have all hit it somewhere." This is an apt simile. The system, bad in itself, is made worse by the way in which it is seized upon by persons with a rudimentary perception of medical ethics for the purpose of professional advertisement. Such proceedings endanger the ethical standard within the profession, and tend to lower it in the eyes of the public, who cannot be expected to discriminate too nicely between illegitimate and so-called legitimate occasion for advertisement. They will take the broad fact that every now and again the newspapers are deluged with advertisements—direct and indirect—of medical men seeking the most honourable posts open to the profession in the locality, and they will be slow to understand why, if this is esteemed right or permissible, it is wrong for a struggling practitioner starting in a poor locality to distribute handbills setting forth his place of practice, his fees, and so forth.

In this country we are not by any means in a position to hold up our hands in pious horror at the doings of our colonial brethren. It is only within the last few years that we have got rid of this pernicious system in London, if indeed we have altogether got rid of it. Perhaps in this matter the practice of London hospitals is a little better than the theory of their constitution. Direct election by the governors, with all its attendant evils of canvassing and advertisement, is, however, still the rule rather than the exception at most of our provincial hospitals and infirmaries. Happily the scandal is less serious because the elections are not periodical, but an appointment once gained is held for life, or until the incumbent attains 60 or 65 years of age.

Some remedy must be generally applied for the cure of the existing defects, and we would strongly urge on the managing bodies of all hospitals to give early attention to this matter. In Melbourne it would seem that a very drastic remedy may possibly be enforced. It appears that a Bill to establish a council for the election of medical officers of public hospitals and other charitable institutions has been introduced into the Legislative Council of Victoria. This Bill proposes the formation of an electoral council, to consist of ten ordinary members, to be appointed by the Governor in Council, two medical men by the Faculty of Medicine of the University of Melbourne, and four others, who may or may not be medical men, representing the medical practitioners. This seems a very fairly satisfactory body for the purpose, but it is to be understood that no medical man is to be employed in, or appointed to, any subsidised charity unless he has been previously nominated to such office by the council.

A properly constituted elective council of this sort would be found in practice, no doubt, to be an immense improve-

ment upon the bad system of election by the whole mass of the subscribers to each charity. But it may not be inopportune to point out that it strikes at the root of the autonomy and independence of the individual hospitals. Those who advocate Government subsidies as a way out of the financial difficulties of hospitals, must recognise the fact that the control will always lie with those who provide the funds.

THE TITLE OF "DR."

THE discussion as to the title of physician having been closed by the publication in our columns of the opinion of Lord Selborne and Mr. Justice Denman, a number of correspondents have raised the further question as to the right of the physician to style himself "Dr."

In the discussion which arose in the *BRITISH MEDICAL JOURNAL* as to the title of physician, attention was drawn to the fact that the diploma of the Royal College of Physicians of Ireland expressly confers the title of physician on their licentiates, and it is suggested by some of our correspondents that the same College also accords to its licentiates the courtesy title of "Dr.," irrespective of their holding a recognised University degree; but however this may have been formerly, the practice is no longer followed, and an express instruction to that effect was some time since issued to the registrar and the clerk of the College. Again, it is urged by some of our correspondents that the examinations which they have passed to obtain their qualifying diploma give them a far better right to style themselves doctors than some of those who hold a registrable University degree.

Our own views of the matter are much the same as those we expressed on the title of physician. The result of the Acts of 1858 and 1886, and what has occurred in connection with them, has tended to confuse or break down altogether distinctions which existed formerly. Reasons may exist more in one case than another in favour of the moral right to use the title of "Dr.," but we can only deal with the question as a whole, and on broad and general lines. So dealing with it we think that we may safely affirm that no legal proceedings will lie against a qualified medical practitioner who chooses to call himself "Dr.," or even to put that title on his doorplate. On the other hand, it is clear that if he describes himself as a Doctor of Medicine or writes the letters "M.D." after his name, or directly expresses or implies that he holds a university degree, he can be prosecuted under the 40th section of the Medical Act of 1858. It goes without saying that he can equally be prosecuted if he describes himself or appends to his name any higher title than the one which he actually possesses. This solution of the question may not be satisfactory to many of our correspondents, but it seems to be the only possible one under the circumstances.

The modern tendency is evidently to get rid of the academic and restricted meaning of the terms physician and doctor as limited to those only who hold a specific licence or a university degree, and rightly or wrongly to extend the application of those terms to all who are duly licensed to practise medicine. If the Gresham University should ever become an accomplished fact, the title of "M.D." will in all probability be largely sought after, and the legal right to use it increased extensively.

The Royal Commission upon Vaccination is now engaged, under the chairmanship of Lord Herschell, in drawing up their final report, and meetings have been held since November 6th, and are being continued every Wednesday till December 18th, when a short adjournment will be made over Christmas. It is contemplated that the report will be ready by the date of the reassembly of Parliament.

We understand that the injuries inflicted on the boy William Ottell have proved not to be of a very serious character. Besides a superficial wound, two inches long, in the sacral region, and an incised wound of the scrotum, the most serious was a punctured wound below the xiphoid cartilage, penetrating the peritoneal cavity. There was also much bruising of the right side of the face. The child continues to make good progress, and will shortly leave the hospital.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

At a Comitia of the Royal College of Physicians of Edinburgh, on December 3rd, Dr. Batty Tuke was elected President, Dr. A. R. Simpson Vice-President, and the following members of Council: The President, the Vice-President, and Mrs. Wyllie, Affleck, Sibbald, Gibson, and Berry Hart. At a second Comitia on December 10th, the remaining office bearers were elected as follows: Dr. P. A. Young, treasurer; Dr. R. W. Philip, secretary; Dr. George W. Balfour, librarian; Dr. John Sibbald, curator of museum; Dr. J. Batty Tuke, curator of research laboratory.

NEW LABORATORY FOR THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

In consequence of the proposed immediate extension of the Royal Infirmary the buildings now occupied as a laboratory by the Royal College of Physicians are to be demolished. After a hot competition between the Municipality and the College, the latter has secured, at a cost of £7,350, the block of buildings between Forrest Road and Bristo Street, and to the south of the Free New North Church, till recently occupied by one of the Edinburgh Parochial Boards, now superseded by the parish councils. The buildings will be altered under the direction of the College architect, and are expected to be ready for occupation in May next. The new President of the College, Dr. Batty Tuke, has been closely associated with the rise, establishment, and development of the laboratory. His election to the presidential chair (succeeding the late Dr. Brakenridge, who would have had that honour with universal acclamation) is peculiarly appropriate at a time when the Research Laboratory is about to be moved into quarters more suitable for good work.

M. HAFKINE'S LECTURE ON ANTICHOLOERA INOCULATION.

M. HAFKINE, who is at present in London, has consented to deliver an address at the Laboratories of the Royal College of Physicians and Surgeons, on the Embankment, on Wednesday next, December 18th, at 5 p.m. The chair will be taken by Sir Russell Reynolds. M. Hafkine will relate the history of his anticholera inoculations in India. Briefly stated, his plan has been to select a village or small town in a cholera district, the average mortality of which from the disease was known. He inoculated one-half or a large proportion of the inhabitants. In this way it was anticipated that after a year or so two epidemics of cholera would have visited the place, and that it would be possible to make a comparison between the resistance of the inoculated with that of the uninoculated. It was not in all cases possible to follow this plan in its completeness, and in large towns it had to be so far modified that it was applied to bodies of people or to families, one half being inoculated and the other half not inoculated. M. Hafkine visited in all 98 localities, and inoculated

under the test conditions described 12,179 persons. The general results will be stated in the lecture, but we may quote as examples of the bulk the latest information which has reached this country. An outbreak of cholera occurred among a party of coolies on the Assam-Burmah Railway. At the beginning of the outbreak Surgeon-Captain Hare, who is employed by the Assam Government to make the inoculations on M. Hafkine's system, inoculated more than half the coolies. The result has been that only 4 cases, all fatal, occurred among the inoculated majority, while 34 cases with 30 deaths occurred among the uninoculated minority.

IMMORAL ADVERTISEMENTS.

We have frequently protested against the indecent advertisements with which so many managers of newspapers, no doubt greatly to the grief of their editors, persist in disfiguring their pages. Nothing, however, seems to have any effect in checking the flood of obscenity which fathers of families, in strange contradiction to all their professions, allow to be left about in their homes. For years we have been accustomed to the advertisements of "female pills" and other remedies, which are guaranteed to remove "obstructions" and to have the "desired effect" without pain or danger. Most of these are mere swindles, for, although some of them undoubtedly contain injurious and poisonous substances, the majority contain nothing more than a little aperient. They are, however, none the less direct incitements to crime, and it cannot be doubted that the women who buy them do so with the direct intention of producing abortion. The prolonged impunity, however, with which these things have been sold has led their vendors to throw off the mask and drop all periphrasis in their advertisements. Perhaps they fear that young girls may not quite understand what is meant by "female pills" and "obstructions" and the "desired result," so they have lately taken to putting the matter in plain English for the benefit of their readers—and their daughters. From the *Newcastle Evening News* of December 4th we extract the following: "To Married Ladies (gratis).—Write for my secret Remedy for the Prevention of Large Families. Guaranteed infallible." Again: "Marriage and its Consequences.—Advice how to limit your family, and valuable information to ladies." Is it not obvious that a public offer of a means of getting rid of the "consequences" of marriage is a direct incentive, not only to undesirable practices among the married, but to all sorts of immorality among the young, by holding out a promise of relief if difficulties should arise? This is a matter of police. That the police should not take steps to put a stop to what is a public incitement to crime is a cause of unending surprise, which is only exceeded by our astonishment that parents who would be shocked at any suggestion of immorality on the part of their daughters should allow such newspapers to come into their houses.

THE RECENT CHOLERA IN EGYPT.

We have reason for believing that the cholera which has for some time been hanging about the lower part of Egypt, and has culminated in the outbreak at Damietta, described by our Special Correspondent in another column, is the product and result of the deficient arrangements at the so-called quarantine station at Tor. There is reason to believe that the malady was imported from Tor, the quarantine station there serving as a focus for the distribution of cholera to Egypt just as the quarantine station at Camaran had served as a similar focus for its distribution through the Hedjaz. It appears that a considerable number of the pilgrims who returned by way of Yambo, the port for Medina, suffered from an acute fatal choleric form gastroenteritis, a malady which, from the clinical symptoms it presented, would certainly have been considered to be cholera but for the fact that a bacteriologist who was lately sent out failed to discover the cholera bacillus. Nations which love quarantine have adopted many devices for obscuring the evils which

seem always to dog the steps of that most delusive method of obtaining protection against cholera, but of all methods of obscuring truth in regard to such matters, negative bacteriological reports are probably the most dangerous. Positive evidence of the presence of cholera bacilli must, even in the absence of acute disease, lead to the adoption of sanitary precautions, but bacteriology has not yet advanced to such a position as to make it safe to accept negative evidence as showing that precautions may be neglected.

THE CHELSEA HOSPITAL FOR WOMEN AGAIN.

We are informed that a meeting of the Chelsea Hospital for Women will be held on Wednesday next, when a motion will be made "to consider the propriety of the Governors dispensing with the services of a member of the honorary medical staff, and to pass a resolution thereon." According to the manner in which the voting is conducted at the Chelsea Hospital—by cumulative votes in proportion to the amount of money subscribed or collected—this may mean the dismissal of the member of the staff if it should so please a few large givers. We are further informed that the officer in question has offered to submit to a fair arbitration the matter in dispute. It will be the general opinion of the medical profession that this question should be referred to an impartial board of arbitration.

LOCAL ANÆSTHESIA.

Dr. THEOPHILUS PARVIN, at a meeting of the County Medical Society, Philadelphia, on November 13th, read a paper on Schleich's Method of Local Anæsthesia by Subcutaneous and Parenchymatous Injections of Weak Cocaine-Morphine Solutions, and demonstrated the effect in his own person by allowing an incision an inch in length to be made in his forearm, and to be stitched up, under its influence, in the presence of the Society. He declared it to be an absolutely painless procedure, and predicted great future usefulness for this method in surgery, expressing his belief that at least 50 per cent. of the operations now performed under general anæsthesia will ultimately be done by this method, which he declared suitable even for major operations.

MEDICO-CHIRURGICAL DISCUSSIONS.

THE discussion at the Royal Medical and Chirurgical Society on the Latency of Parasitic Germs suffered from two drawbacks—the width of the subject and the length of the introductory speeches. The second was perhaps in part the consequence of the first. Altogether, with the additional half hour granted on the second evening added, and with the time spent in formalities at each meeting deducted, three hours were devoted to the discussion. Out of this very nearly two hours was given to defining the scope and to introducing the subject to be discussed. These lengthy preliminary remarks were able and useful summaries of knowledge, but necessarily they contained, over and above several instructive clinical cases, and with the exception of some of the points in Dr. Washbourn's essay, nothing with which the majority of persons who have taken any interest in these subjects is not familiar—little, indeed, beyond facts and arguments which are to be found in the larger textbooks and in other easily accessible works of reference. This was, of course, inevitable, and is no reproach to these gentlemen, who had evidently been at great pains to prepare their essays. But to hear a reader slowly wading through an essay of which you have a printed copy in your hand is not an exhilarating occupation. It might be well on a future occasion were the scope of the discussion defined in a circular letter from the Council, and if the summaries of the literature of the subject provided by the industry of those who are invited to open the discussion could be limited strictly to ten minutes. II,

as at present printed, they might even be taken as read, instead of the whole of one evening and part of the second being spent in reading them out. The discussion proper when it was at length reached was interesting, though several speakers wandered rather far from the main subject. Perhaps the most suggestive observations were those made by Sir William Broadbent as to the influence of disease or injury, occurring after exposure to infection, in deciding the struggle between the organism and the infection to the disadvantage of the former. The idea is not new, and it has in particular found support as explaining the occurrence of so-called surgical scarlet fever, but Sir William Broadbent's statement that he was convinced that an attack of influenza might in this way determine the outbreak of typhoid fever which the organism might otherwise have been able to avert is valuable. He stated that in some cases the typhoid pyrexia ran on from, and was, as it were, a prolongation of that of influenza; in others a distinct apyrexial interval was recorded. In the latter class at least, the interval between any discoverable exposure to the infection of typhoid fever and the onset of that disease might be prolonged much beyond the usual period.

ULSTER MEDICAL SOCIETY.

THE annual dinner of this Society proved a most successful and enjoyable function. The President of the Society, Professor Sinclair, F.R.C.S., occupied the chair, and fifty-eight gentlemen sat down to dinner. Among the guests were the Lord Mayor of Belfast, Sir William McCammond, and the President of the Queen's College, Dr. Hamilton. After an excellent dinner the Chairman proposed the health of "The Queen, the Prince and the Princess of Wales, and the other Members of the Royal Family," which was duly honoured. Dr. McKeown proposed the toast of "The Lord Lieutenant and Prosperity to Ireland," and spoke in flattering terms of the impression which his Excellency had made upon all classes in the country. Dr. Bingham responded in a very happy speech. Mr. Fagan, F.R.C.S.I., proposed the toast of "The City and Corporation of Belfast," and expressed the satisfaction which was universally felt in Belfast at the conferring of a knighthood upon their guest of the evening, Sir William McCammond. The Lord Mayor, in rising to respond, received an enthusiastic reception. Brigade-Surgeon McFarland, A.M.S., proposed the toast of "The Queen's College, Belfast, and the Belfast Medical School." This was responded to by President Hamilton, Dr. Walton Browne, and Professor Whitla. The remaining toasts were "The North of Ireland Branch of the British Medical Association," proposed by Dr. Kevin and responded to by Dr. Campbell, Secretary of the Branch; and "The Ulster Medical Society," proposed by Dr. Dempsey and responded to by the President (Professor Sinclair) and the Secretary (Dr. McKisack). The proceedings of the evening were agreeably diversified by some excellent songs and glees from Drs. Mackenzie, McCaw, McKisack, Leslie, and McCullagh, and Dr. Morrow recited two of Kipling's ballads very effectively. The proceedings came to an end shortly after midnight.

BLINDNESS IN SCANDINAVIA.

A very valuable series of statistics has been collected by Widmark, which show the variable frequency of blindness in the four northern countries—Sweden, Norway, Denmark, and Finland. Denmark had in 1890 for every 10,000 inhabitants only 5.3 blind, Sweden 8.3, Norway 12.8, Finland 15.5. Compared to other European countries, of which Portugal and Russia stand highest with 20 blind for every 10,000, and Holland lowest with only 4.5, the order is as follows: Portugal, Russia, Finland, Spain, Norway, Hungary, England, Germany (without Prussia), France, Prussia, Sweden, Belgium, Austria, Switzerland, Italy, Denmark, and Holland. The most common cause of blind

ness in Finland is trachoma, which is very common. It is a curious fact, however, that this disease almost exclusively occurs among the Finns proper; the Swedish inhabitants (in Finland) do not suffer from it. Some authors would attribute this to the smoky and unhygienic huts of the Finn, but the infectious nature of the malady doubtless plays a great part. In Norway the most common cause of blindness is cataract, probably because operations for cataract are only rarely performed, owing to the scantily populated country. In Europe blindness is as a rule more common in men than in women, but in Finland and Sweden (there are Finns in the north of Sweden) the opposite holds good, probably because trachoma is more common in women than in men. In all the Scandinavian countries blindness is decreasing. In Stockholm very good results have followed the adoption of Credé's method of preventing ophthalmia neonatorum; from 1884 to 1890 the percentage of this affection has decreased from 1.20 to 0.24.

NURSING IN IRISH WORKHOUSES.

We are glad to notice that among other Boards of Guardians that of New Ross has refused to adopt the resolution which is now being sent over the country in denunciation of the Local Government Board. One member very properly observed that the poor should get the benefit of a trained nurse when they were entitled to it and when the rate-payers paid for it.

THE DUBLIN MEDICAL SCHOOL.

The returns from the Anatomical Committee for this session show that the number of dissectors in the various schools is 480, showing an increase of 50 on last year. Trinity College has 208; the Royal College of Surgeons 154, and the Catholic Medical School 118. There are probably also about 400 in the different stages where dissection is not required.

MEDICAL INSPECTION UNDER THE PILGRIM SHIPS BILL AND CAMARAN.

The prospect of the Pilgrim Ships Bill being shortly considered during the Calcutta session raises a question as to which there has been a good deal of feeling on the part of some of the native population of India. We hope, however, that no opposition will be made to those portions of the Bill which tend to the health and the comfort of pilgrims. Such an attitude will go far to undo all the efforts of the Government to secure an abatement of the quarantine detentions at Camaran. It has been suggested, for example, that medical examination of intending pilgrims before going on board is likely to raise the greatest opposition; even "riot" has been talked of. But surely such a result could only be brought about by making improper appointments, and by bungling methods of procedure. Medical women and adequate privacy can surely be obtained in Bombay, and these would suffice for the purpose. Moreover, no one can contend that pilgrims should start utterly irrespective of their condition in the matter of health and infection. Turkish officials would be the first to take advantage of any hesitation on the part of the Indian Government, and they would retort that British India had no right to ask that Camaran shall be abolished, or that the detentions there shall be shortened, when her Government refuses to take such precautions as to health as nearly all other nations deem to be necessary. This is an aspect of the question that needs to be borne in mind.

HOSPITAL ABUSE AT BRIGHTON.

We have received a report of a paper read before the Brighton Medico-Chirurgical Society by Dr. Francis Waring, from which it would appear that the remarks made recently in our columns on this subject have by no means exaggerated the gravity of the evil. We have already mentioned

the fact that over a third of the confinements taking place at Brighton are attended gratuitously. In regard to this, Dr. Waring brings forward an interesting fact, as showing that many of the recipients of this charity neither need it nor very much care about having it. He says: "A few years ago, when the late midwife was appointed to the Western Branch, the attendance was not so high; but she was a skilled woman, kindly in manner and much liked, and the consequence was the number of cases rapidly rose, and I believe has nearly doubled. . . . This midwife has now started on her own account in the same part of the town, and, strange to say, as she informed me, many of the patients whom she formerly attended for the institution are now engaging her services and paying the fee." This reminds one of the scene in *The Children of the Ghetto*, where, in the midst of the wedding feast in the Jewish quarter, while the table was groaning with good things, the daughter of the house arrived with the jug of soup from the soup kitchen. The good, careful souls knew that soup was being given away, and, even in the midst of the feast, did not neglect to send out the girl to fetch the daily dole. So it would appear that these good, careful Brighton mothers take the good things the gods provide, doubtless without any great exuberance of thankfulness, and, as Dr. Waring suggests, use the club money they receive on the birth of a child for other purposes; for does not money always come in handy? It seems quite clear that those who are scattering such favours in the name of charity, and especially those who, on the plea of charity, are collecting money for the purpose are perpetuating a great abuse.

"THE EYES OF ENGLAND."

UNDER this pretentious title the *Pall Mall Gazette* of December 5th printed what purports to be an interview with an optician. We much regret that our contemporary should lend its columns to the writings of "representatives" who are so little qualified to judge of the fitness of things as the author of this article. No good purpose can be served by the publication of such catchpenny effusions, and we do not for a moment believe that the readers of the *Pall Mall Gazette* are likely to be guided by the opinions of a manufacturing optician upon the use of the ophthalmoscope or the medical care of patients with diseases of the eyes.

JOHN KEATS AND GUY'S HOSPITAL.

A RECENT number of the *Guy's Hospital Gazette* contains an interesting letter from Mr. F. G. Hopkins, in which he suggests that the centenary of John Keats (who was born on October 29th, 1795) would be an appropriate occasion for the erection of a memorial of some kind to him in Guy's Hospital, which the poet once "walked" as a student of medicine. John Keats was entered as a surgeons' pupil at Guy's on October 1st, 1815, under Mr. Lucas. The personality of Astley Cooper was predominant at Guy's in those days, and we know from Dr. Wilks's *Biographical History of Guy's Hospital* that the great coryphaeus of surgery took a special interest in the "cheerful crotchety rhymester," whom, however, he may not have recognised as a beloved son of Apollo. Keats passed the "Hall" on July 16th, 1816, as Dr. Wilks (in the *Guy's Hospital Gazette* of November 9th) shows by an extract from the minute book of the Court of Examiners of the Society of Apothecaries. Some of his medical notebooks are or were till lately to be seen in the Chelsea Free Library. Medicine was not so utterly distasteful to the poet as his purely literary biographers make out. Two years after he had qualified we find him writing to a friend: "Every department of knowledge we see excellent and calculated towards a great whole. I am so convinced of this that I am glad at not having given away my medical books, which I shall again look over to keep alive the little I know thitherwards." Somewhat later he writes: "I have enough knowledge of my gallipots to ensure me an employment and maintenance." For surgery he lacked nerve, but

as late as 1819 he had serious thoughts of going to Edinburgh for a degree, with the view of practising as a physician. His chief objection seems to have been one that does not greatly trouble more prosaic natures, for he says: "I know I could not take the fee!" In this, however, habit might, perhaps, have begotten tolerance. The real reason of his want of enthusiasm for his profession is revealed in the following passage of one of his letters: "The other day during the lecture there came a sunbeam into the room, and with it a whole troop of creatures floating in the ray, and I was off with them to Oberon and fairy-land." Keats's connection with the medical profession is usually passed over very cursorily by his biographers, and we are therefore grateful to Dr. Wilks for having established the fact that the poet was a qualified practitioner. Guy's Hospital would honour itself in honouring so famous a son, and in this case it should not be left to American admirers of the poet to put up a tablet to his memory. If properly appealed to many members of the profession to which he belonged, and many lovers of poetry, would doubtless be glad to subscribe. Keats wished to have as his epitaph "Here lies one whose name was writ in water." If not written in the human body like those of other famous Guy's men, it is written deep in countless human souls, and it shines as a bright particular star in the firmament of fame.

THE LATE SURGEON-MAJOR PARKE.

A HANDSOME memorial brass has been set up in the parish church of Kilmore, Ireland, in memory of that distinguished medical officer, Surgeon-Major Parke, whose premature death called forth such widely expressed sympathy at the time. The following is a copy of the inscription: "In Memory of Thomas Heazle Parke, Surgeon-Major A.M.S.C., second son of Wm. Parke Esq., J.P., of Croghes House, Kilmore. Born November 27th, 1837; died September 11th, 1888. Beloved and honoured by all who knew him. He entered the Army Medical Staff in 1861; served in Egypt with distinction, accompanying the Hazada Desert column of the Nile Expedition for the relief of General Gordon, 1884-1885. From January, 1887, to December, 1889, he served on the expedition for the relief of Emin Pasha as surgeon. It is as a tribute to his constant gentleness and care for the sick and suffering and to the splendid services he rendered alike to Europeans and Africans during the three years' march across Africa that this tablet is erected in grateful and affectionate remembrance by the two surviving officers of the expedition, Henry Morton Stanley, A. J. Mounteney Jephson (Lieutenant)." The brass is mounted on a slab of polished marble.

DEFICIENT CHILDREN UNDER THE LONDON SCHOOL BOARD.

CHILDREN of deficient brain power and mental ability have been the subject of investigation and study by a Committee of the British Medical Association since 1888, and several reports upon their investigations have been issued. A full report on 100,000 children is in the press. Following upon evidence afforded by this Committee, the Royal Commission on Blind and Defective Children in 1890 recommended all public educational bodies to make provision for such children, and in 1891 the London School Board provided experimental centres of special instruction for deficient children who attend school daily. The movement was found successful, and was approved by the Education Department; parents gladly sent their weak children who previously were left untaught, and much improvement in the pupils is reported. Recently a new special training centre was opened by Lord George Hamilton at the Hugh Myddelton School, Clerkenwell, for the instruction of physically and mentally deficient children; there are now twenty such centres, and more are in course of erection. It should be stated that these children are distinct from the classes of blind and deaf, for whom special provision is made under

the Act of 1893. There appear to be over 2,000 of these children mentally and bodily defective who are known to the School Board in London: it is a wise provision that is thus being made for their early training, which may render some of them useful members of society, and save many from those depths of degradation and helplessness into which they sink when uncared-for and untrained. Birmingham, Leicester, and Brighton have already established similar classes. The School Boards in other towns will, it is to be hoped, follow the same lines of action which now receive the direct encouragement, if not pecuniary support, of the Education Department. A special report on the 400 odd "deficient children" now under the care of the London School Board, classifying them and describing their condition, would be valuable. Experts' description is needed as a guide to the efforts of others. It is not at present evident exactly what classes of children are dealt with, and how distinctions are made between those really deficient and the dull, lazy, backward, and neglected or starved children. The great social importance of training from earliest days the children of deficient mental capacity is now more generally understood, and this matter is being pressed forward by many of the Poor law guardians, who confess their want of homes where such children may be boarded. The whole question of the provision necessary for children mentally and physically feeble needs careful consideration as a matter of public policy. All are agreed that early training may prevent much future misfortune, and may check their degradation to the ranks of pauperism, crime, and failure. The census (England and Wales) of 1891 gives the number of blind persons as 23,467, and of deaf and dumb persons, 29,280. An estimate from returns by the Committee of the British Medical Association founded on their observations in schools shows that probably there are between the ages 3 to 13 years 55,000 children of deficient mental capacity, excluding the imbeciles, the deaf, and the epileptic.

M.D.U.S.A.

THE Medical Defence Union is to be congratulated on having carried through so successfully the prosecution, a full report of which appears on p. 1532. This is the most important prosecution under the Medical Acts which has been carried through for many years, as up to the present time it was imagined by the fraternity of quacks that, by adding certain letters to the title M.D. they were safe from conviction under Section 40 of the Medical Act. It would be monstrous if the law permitted any unqualified person to use the title of M.D., and to practise medicine with impunity, merely by the addition to the title of some cabalistic letters.

THE WORK OF THE METROPOLITAN ASYLUMS BOARD.

MR. DUNCOMBE MANN, the able and energetic clerk to the Metropolitan Asylums Board, has addressed a letter to the Chairman of the Board, pointing out that, whatever may be said about the deficiencies in the present accommodation for fever cases, an immense amount of work has been done in the five years during which he has held office. He draws attention to the fact that so long as the work of the Board was confined to its original function as a department of the Poor Law there was every reason to believe that the provision arranged for would be ample for its purpose, and that it was the sudden and overwhelming rush of patients, caused by the simultaneous action of the introduction of notification and the opening of the hospitals to all classes, that led to the immediate demand for a very much larger extension of the hospital system than could possibly be immediately provided. What has been done, however, makes a very good show. Five sites for new hospitals have been purchased, two large hospitals have been built, one more is approaching completion, another is in course of erection, and the plans for

still another have been approved. In addition to this the existing hospitals have in most cases been enlarged, and the process of conversion from "temporary" to permanent buildings has been steadily proceeded with. The ambulance service has also been extended and improved, new ambulance stations having been provided; the accommodation for small-pox has increased, and a site purchased on which to erect a permanent hospital for its treatment; the provision for imbeciles is being increased; and in addition to all this all the daily work of the Board in managing these great hospitals and asylums has had to be carried on without intermission, and often under the greatest strain. While, then, retaining to ourselves the right to criticize to the full the system according to which all these duties are thrown upon the Asylums Board, we must most heartily congratulate Mr. Mann on a splendid record of hard work well done in the short space of five years.

STUFFY CABINS.

THE great extension of the practice of taking holidays by sea is due, no doubt, in great part to the increased attention which the better steamship companies now give to the comfort of passengers. A good deal remains to be done, especially in the matter of ventilation, before these floating palaces are really rendered as comfortable and as health-giving as they might be. A correspondent has sent us an account of the experiences of a lady travelling recently to South Africa. After starting, she found that she was expected to share a cabin with a lady suffering from "asthma and lung disease." "She coughs most dreadfully," the lady wrote to our correspondent, "the cabin gets very hot and close with someone in it all day, and the cigarettes she smokes and the stuff she inhales makes me feel horribly sick," and so on. Eventually the lady had her berth changed into another cabin, but there is nothing, so far as we know, in the statute law, nor in any order in Council yet prescribed, for promoting health on board of passenger ships, that would apply to such cases as this. Nor would it be easy to frame regulations so as to cover all such abuses, unless, indeed, the surgeon's authority could be somewhat extended. The proper course to pursue would be to make a complaint to the purser, and ask for a change of berth, as was probably done in this case; if unsuccessful, then to appeal to the master and obtain the support of the surgeon. In no respectable company would such a request be refused if it could be complied with. In the case of steerage and intermediate or second-class passengers the law requires a certain amount of space to be set apart for use as a hospital, and in the case of cabin passengers ship companies may well be expected to provide a similar space for like use in case of necessity. The law, however, considers that cabin passengers are able in many respects to protect their own interests, and they would probably do this if necessary by bringing an action in a court of equity for return of passage money were they to fall in obtaining redress in the orthodox way.

ADENOID VEGETATIONS.

THE late Dr. Wilhelm Meyer, of Copenhagen, shortly before his death published the result of a painstaking investigation on the extension of adenoid vegetations, and the age at which they occur in different parts of the world and in different races. In Greenland, amongst 60 Esquimaux children between 6 and 14 years of age, Dr. Helms found only 16 free from adenoid vegetations. In North Dakota Dr. Quarry found adenoid vegetations frequently amongst the native tribes of Indians, but the growths were very little developed in adults. Dr. Cantlie, of Hong Kong, reported that the native Chinese of the Mongolian race, as also those belong-

ing to the mixed Chinese-Portuguese race, frequently suffer from them; while in Bangkok, Dr. Demtzer rarely found the disease amongst the native Siamese. Dr. Reinbach, medical superintendent of the Dutch-Indian Colonies, collected evidence on the subject from several military surgeons with the following results: In Singkil, on the north-west coast of Sumatra, 113 natives were examined; of these, 3, that is, 2.6 per cent., had adenoid vegetations; on the island of Amboika, of 336 school children examined, none of the girls and only 2 of the boys (0.6 per cent.) were found to have adenoid vegetations; on the island of Saparoe, none of 100 adults examined had the growths, while 5 out of 717 school children (0.7 per cent.) suffered from them. Dr. Meyer therefore came to the conclusion that adenoid vegetations are to be found in varying degrees of frequency in at least three-parts of the world, namely, Europe, America, and Asia. The Mongolian is almost as much predisposed as the Aryan. A warm climate seems to be less favourable to their development than a cold one. Dr. Meyer, moreover, studied portraits and busts in numerous European collections, with the object of finding evidence of such growths in past generations. As a proof of the existence of adenoid vegetations in the beginning of the present century, the numerous likenesses of the famous sculptor Canova are mentioned. They all show the artist with an open mouth, a narrow nose, and a somewhat dull, stolid look. We have, further, the testimony of one of his pupils that he was somewhat deaf. There is also evidence that the Emperor Charles the Fifth suffered from adenoid vegetations. His portraits show the characteristic physiognomy associated with these growths. It is also known that he was the subject of asthma; that this disease was not produced by nasal polypi is proved by the fact that the portraits taken early in life are much more typical than the later ones. King Francis the Second, the first husband of Mary Queen of Scots, who, according to M. Potiquet, suffered from adenoid vegetation, may perhaps have suffered from these growths; but Dr. Meyer points out that the nose being far from typical, there is some doubt whether he did not suffer from nasal polypi. Amongst specimens of ancient sculpture, Dr. Meyer has not found a single instance which might serve as a proof of the existence of adenoid vegetations in Greece; this may, however, easily be explained by the fact that the ancient Greek artists had a tendency to idealise the human features. On the other hand, several ancient Roman statues and busts show incontrovertible evidence that adenoid vegetations existed as far back as Roman art goes. As the most pronounced examples, Dr. Meyer mentions Nos. 80, 180, and 192 of the Chiaramonte Gallery in the Vatican, of which three busts the two first mentioned represent children. He finally concludes that it is probable that adenoid vegetations have existed from a very remote period of human history.

THE CARE OF PAUPER LUNATICS OR IMBECILES.

THE question of the care of quiet pauper lunatics has been exercising some Boards of Guardians lately. In some cases the patients of this class are spoken of, at the meetings in which their disposal is discussed, as being imbeciles. In one workhouse some of these so-called "imbeciles" were reported to be quiet and well conducted; some of them had been in the union workhouse for over thirty years. To build a large new lunatic asylum for these and for similar cases in other union workhouses would not be likely to add to their comfort and welfare, and would be to accommodate in a very costly way those who would probably be happier and more comfortable under more simple surroundings, and what to them would be a more congenial and homelike method of care and control than the county lunatic asylum. Thus we find that some Boards of Guardians or individual members of them are inclined to prefer making such accommodation as may be required for cases of the kind in the existing union workhouses or in workhouses at present disused. Other Boards

or individual members of them look forward to providing for the quiet chronic lunatics (or often so-called "imbeciles") a county establishment, intermediate between a workhouse and the present ordinary county lunatic asylum. From a report in the daily press of a meeting of the Camberwell Board of Guardians, it appeared that an account had been submitted by a medical man for fees for certifying forty-six inmates of the Constance Road Workhouse during the four weeks he was acting as *locum tenens* for the regular medical officer. Strong comments were made upon it as a grave public scandal, and it was alleged that some of those so certified had been in the workhouse for years, were simply childish, and were now discovered by the *locum tenens*, in the absence of their regular medical attendant, as being, and certified as being, insane. The subject was further complicated by the fact that one particular justice had ordered nearly all the examinations of these persons, and had departed from the usual custom by ordering a fee of one guinea in each case instead of the usual fee of 10s. After a long and heated discussion it was resolved to seek an explanation from the justice, to be referred, when received, to the Finance Committee for consideration and report. Certainly, the certification of so many inmates in so short a time should be carefully regarded by the Board, and we hope the matter will be thoroughly threshed out.

THE TREATMENT OF CARBONIC OXIDE POISONING.

POISONING by carbonic oxide, which is the most lethal constituent of coal gas and of afterdamp, is not very uncommon in this country, though far less often encountered than in France, where a brazier of charcoal, which yields large quantities of carbonic oxide, in a closed room is a favourite means of suicide. Its treatment is unsatisfactory, and the remarks on the subject in a recent paper by Dr. J. Haldane in the *Journal of Physiology*, vol. xviii, p. 458, are well worthy of attention. Carbonic acid appears to endanger life in three ways. Its primary effect is, as is well known, to displace the oxygen of the blood, the presence of which is essential to life, but a subsidiary effect is to cause a fall of temperature owing to diminished heat production. This effect was noticed in mice, and Dr. Haldane states that some of the men still found alive but suffering from the effects of afterdamp after the terrible explosion in South Wales in 1894, got worse and sank when brought to the fresh air at the bottom of the downcast pit. At this point the air would be cooler and drier than in the workings, and there would be a very rapid current of air. As the men in the pit were clothed very lightly, their removal into this cool dry current might have accelerated a fall in temperature. Dr. Stevenson has stated in a case of slow poisoning by carbonic acid the extremities were exceedingly cold. Those who have become cold owing to poisoning in this way are restored by warmth, and Dr. Haldane suggests that in man a hot bath might be found useful in cases of carbonic oxide poisoning in which the surface temperature was low. Artificial respiration and the inhalation of oxygen when obtainable will assist in clearing the blood of carbonic acid, and as the nervous system suffers especially from the deprivation of oxygen, it is thought that it would be advisable to keep the head low and the limbs raised. The most serious aspect of the poisoning of the nervous system is that carbonic oxide causes serious and lasting damage to the central nervous system, which may cause death long after the patient has been restored to pure air. In such cases neither artificial respiration nor the inhalation of oxygen can be expected to do any good, and the former may even do harm by exhausting the patient. It is, therefore, desirable to be able to ascertain whether the patient is suffering from present want of oxygen or from the effects of previous want of it. This may be ascertained by examining a specimen of diluted blood. Normal blood diluted with 100 parts of water

in a small test tube has a yellow colour, while blood containing large quantities of carbonic oxide has a pink colour. A drop of blood from the patient and a drop of blood from a healthy individual should therefore be diluted with about 100 drops of water; if the diluted blood from the patient is distinctly pink when compared with normal blood similarly diluted, it may be concluded that the patient is in want of oxygen, and the inhalation of that gas if available, or the use of artificial respiration should be persevered with. If, on the other hand, the diluted blood is not pink, it will be safe to conclude that the patient is suffering from the after-effects, and special care should be given to keeping him warm and quiet.

IS LEPROSY A TELLURIC DISEASE?

In the Public Health Section of the Australasian Association for the Advancement of Science, at the Brisbane session, 1905, Dr. Ashburton Thompson read a paper bearing this title. Although he grants that leprosy may perhaps be directly communicable through the sick to the healthy, he considers that leprosy in any country is not maintained by direct communication, and that sufficient information has not been given to justify the belief that leprosy has spread in Australia by contagion, and that in the absence of that information the severely strict isolation of lepers in that continent must seem to be "a renaissance in the nineteenth century of the product of mediæval ignorance into mediæval egoism." "The extremely severe laws against the liberty of lepers in force in five colonies amount to the hardship of adding imprisonment for life to the infliction of incurable disease." It is somewhat difficult to appreciate Dr. Thompson's position. If a case of leprosy occurs in a country where there are pre-existing cases, the new case has occurred on an area of recognised "endemicity," so that primary and secondary case alike were under the influence of locality; but it is evident that in a disease for the development of which only a small portion of persons present a suitable soil, if you go outside countries where cases already exist, it must be very difficult to get new cases at all. That is the reason why cases like Dr. Hawtrey Benson's, of which Dr. Thompson is aware, and the remarkable case from Guernsey reported by Dr. Living, to which Dr. Thompson does not refer, are so rare; nor does he refer to the remarkable development of leprosy at Parcent, although as Parcent is in Spain, and as leprosy has long existed in Spain, probably the inferences which most people would draw from the facts would be vitiated in Dr. Thompson's mind by endemicity. The discovery of the bacillus of leprosy, and the proof that leprosy is not hereditary, have placed the opponents of contagion in a very difficult position, and it is interesting to observe to what fanciful hypotheses they will resort to escape accepting the most simple and natural explanation. Dr. Thompson's hypothesis is that "the concurrence of some other sort of organism with the bacillus of leprosy is necessary to the successful implantation of the latter," and that this would explain how of all the people living on a tract of country, freely infested with the cause of leprosy, only a few would become lepers. We would only remind Dr. Thompson that pathology is a practical science, and of the old maxim, "Causæ non sunt multiplicandæ præter necessitatem." The Australians have wisely acted on the well-known fact that where lepers are fresh cases appear, and that the only approach to a condition in which lepers are not is to so isolate them that their existence can threaten their fellow-colonists as little as possible. The existence of a leper is one of the most miserable conditions known to mankind, but if that is a proper reason for alleviating the leper's misery, it is an equally strong reason for adopting every precaution against healthy persons being attacked by the disease. Dr. Thompson is not convinced by the evidence that has accumulated in recent years in favour of the maintenance of leprosy by contagion, but it is we believe not probable.

REPORTS

ON

THE NURSING AND ADMINISTRATION
OF IRISH WORKHOUSES
AND INFIRMARIES.

SPECIAL COMMISSION OF THE "BRITISH MEDICAL JOURNAL."

XI.—SLIGO WORKHOUSE INFIRMARY.

Our visit to this house was made at an inauspicious moment, owing to a recent outbreak of fever. It seems that during a long period of immunity from infectious disease the fever hospital had been used for the female sick, but, on its being required for its original purpose, the hospital patients were removed to the infirm wards of the body of the house. The male patients are nursed in the hospital proper. When we visited the house the fever hospital—cleaned and disinfected—was standing empty. We gathered that there was some difference of opinion among the authorities as to the use of the fever hospital for general patients. We are not able to decide as to the rights of the question, but any unprejudiced observer would be struck by the inadequacy of the present arrangements for the nursing of the sick. There is an average of

140 PATIENTS,

who were thus distributed: the men in the hospital proper, where also we found the female lunatics placed at one end of the block and the male lunatics at the other. In this block there were about 70 beds. The female patients are on two floors of the female infirm block; 50 beds on each floor in one long ward. If our readers will call to mind the plan of an Irish workhouse they will recollect that these blocks are distinct buildings, separated by wide open spaces. At the time of our visit the female patients far outnumbered the males: there were 70 women on the blocks and 38 men.

THE FEMALE WARD.

were crowded; the low-pitched roof and want of cross ventilation and the length and narrowness of these rooms rendered them quite unsuitable for sick wards. The passage between the two rows of beds was levelled up to the height of the platforms. An additional stove, with a flat top, serviceable for keeping food warm, was placed in each ward, and two windows had been opened in the outer long walls. The coloured plaster of the walls had a smooth surface. There were a few armchairs, small tables, and commodes. The bedsteads, which are close to each other down either side, are wire woven, and have blankets laid on them instead of mattresses.

THE MALE HOSPITAL.

was equally crowded. As the wards were so full in the summer we wondered how accommodation of any kind could be found in the winter months for the additional patients, many of whom come in with phthisis in the acute phase. The large wards on the upper floor held twelve beds each; one on the ground floor had 19 beds, and a smaller one 5. We also found the bath room converted into an isolation ward for an offensive case. An inmate was in charge of the unfortunate patient, who looked very ill, dirty, and uncared for. Two beds were in this little room, already half filled by the bath; there was a small window and a stove. We judge from the appearance of things that the bath room was seldom used for its legitimate purpose. Upstairs the roof is pitched and plastered, the walls plastered and colour washed. The wards are ventilated by openings in the roof, and in some cases by perforated panes in the windows. The windows are small, and there is no cross ventilation; the old-fashioned fireplaces, one to each ward, are inadequate for heating purposes and very wasteful of fuel. There are no day rooms.

The patients in this hospital included a *coterie* of 23 years of age, who in size and general appearance resembled a child of 5 or 6. The poor little creature seemed to be a general pet in the ward, or perhaps we should rather say that he furnished some amusement to the inmates, who were many of them confined to bed with chronic ailments. The bedsteads in

this division are "harrow" frames, with straw ticks and pillows; a board let into the wall forms the bed head. The majority of the cases were helplessness, old age and chronic diseases. In an inner room a phthisical patient was dying; he had just been visited by his priest as we came into the ward. There is no night nurse for these 140 patients. The day staff is quite inadequate, and, in the words of Dr. Murray's report, "the night nursing is in the hands of paupers." We saw one nurse in the male hospital and one in the female wards, and we understand that there is a third nurse on the staff, the senior nurse being trained, and the two junior nurses acting as assistants to her. A hospital of 140 beds, as large as some of our county hospitals, with 8 nurses by day and none at night! Among the women was a case of fractured leg; the other patients, of whom about half were in bed, were chronic or helpless cases.

THE LUNATICS

are in charge of paid attendants; the cells are not in use in this workhouse, but the quarters provided for this class, especially for the females, are cramped and unsuitable. As we mentioned above, the women of this class are lodged in two small wards at one end of the male hospital, with the result that they have no yards for air and exercise. The listless, apathetic air of the idiots and epileptics showed that nothing was done in the way of occupation for the lightening of their unhappy lot. Perhaps nothing was possible in their surroundings.

The male lunatics are slightly better off; they have the use of an airing court, such as it is, some of them find occupation about the house, and they are not so overcrowded. As the workhouse is close to the county asylum the more dangerous inmates are removed thither as there is room in the asylum.

THE INFIRM CLASS

on the female side are lodged in the quarters set apart for the able-bodied; they have no dayrooms because the sick are in their wards. We found the men in the ground floor ward of the male wing, and for them there is a dayroom. Men and women alike sleep on harrow beds with straw ticks; there is one basin and one roller towel in each dormitory for the use of 24 to 28 individuals. The women are crowded together in the room which should be the dayroom, where both light and warmth are insufficient. The only outlet is into the large yard, common to both firm and able-bodied, used also as the laundry drying ground.

THE MALE INFIRM ATTENDANT.

known as Peter, a fine tall man, told us that he was working in Glasgow and doing well, when he injured his ankle, and, falling into the hands of the Poor-law authorities, he was sent back under the Act of Settlement to his native place, Sligo, though he professed himself able and willing to resume his work; and there he remains a burden on the rates, though he appears to be able to maintain himself. There is probably another side to the story, but on the face of it it appears to bear out the contention that timely and generous medical relief, coupled with discriminating assistance, would save many a man from becoming a pauper. We noticed

SOME CONCLUSIONS

to the old people which betokened kindly thought on the part of the authorities; the old men have their dinner in their own dayroom, which does not indeed afford much comfort or cheerfulness, but it keeps them apart from the ruder and noisier class. The old women are allowed to wash their own caps, kerchiefs, and other small belongings, and have the use of the laundry on one day in the week for the purpose. This privilege is much appreciated by the more respectable class, and we have heard of the women paying an inmate with tea to do this small service for them, rather than that their personal clothing should pass through the general laundry.

IT IS THE SAME OLD TALK.

almost nauseating in its iteration, of the entire absence of anything like decency or sanitation, when we come to the conveniences provided for the inmates. Outside are privies on the wagon system; indoors, buckets, pails, and commodes are in use in the sick and infirm wards, these vessels

¹ Since this report was written we understand that two paid nurses have been appointed, who are allowed to sleep by day.

remaining unemptied and frequently uncovered the whole night. In considering the cubic capacity and amount of ventilation in a ward, we must remember that it needs to be unimpeachable in these particulars when the atmosphere is poisoned in such a way at night. We have already noted that these wards are crowded and doubtfully ventilated; nor are there any facilities for the cleansing of the inmates or of their surroundings.

A BATH AND A ROUND TOWHEL

are provided for common service among the sick, and a bath or two, without hot water. Every drop of water has to be carried to the wards for use, and carried away when used, and when warm water is required it must be heated in a kettle or fetched from the main kitchen. It is not surprising that we noticed a lack of cleanliness and sweetness in the wards. The town water supply is laid on to the workhouse. Some of the sewage is carried to a large pit at a distance from the house and some drains into the river. The matron kindly showed us

THE LAUNDRY AND CLOTHES STORE.

Both are under the charge of the same officer. The room set apart as a clothes store is anything but suitable; the brick floor and the walls were stained with moisture, and the window was very small. We saw no mangle in the laundry; the drying closets are fair, and are heated by steam from a central boiler. The same steam heats the jacketed boilers in the kitchen—there is no other means of cooking—where the stirabout for that day's meal was being prepared.

THE FEVER HOSPITAL.

then standing empty, is at the back of the hospital block. It stands on a slight hill, and as the building is also raised somewhat above the level of the ground it has quite an imposing appearance. In internal arrangements it is similar to other fever hospitals: four wards on the ground floor, two long wards above, administration block in the middle, cross light and ventilation, kitchen and laundry, all offering excellent accommodation for the unhappy patients now crowded into the infirm wards. We do not wonder that the officials felt aggrieved at the sight of the empty hospital.

THE NURSERIES.

This department is in three sections for purposes of classification; the first division being for unmarried mothers who have had more than one child. Here we found, unhappily, several women with their infants. The second nursery is for unmarried women with their first child; here we saw three women, but are not sure that there were not others of the class in the house. The third nursery is for the use of the married women; this section was empty. An inmate is supposed to be in charge of each section, but as the inmates can have but little control over each other, we found the nurseries wretched, dreary, and bare; the infants dirty and unnursed, and the usual absence of order and method. But the classification whereby the unmarried women of the first class are kept away from the more depraved is a real boon.

RECOMMENDATIONS.

Our visit to the house made it clear to us that the sick department had quite outgrown the limits of the hospital as originally planned. The first necessity, therefore, is a hospital department adequate to the number of patients. The temporary character of the present female wards is so evident, especially to those who have to work them, that we wonder they have been tolerated so long. With the remodelling of the hospital will come, we trust, a sanitary system in accordance with modern requirements. But even before this can be carried out the nursing of the patients should be provided for. It seems to us nothing less than inhuman to leave from 140 to 160 paupers—sick, helpless, and infirm—with no skilled attendance at night, and equally inhuman to expect the day nurses to face the alternative of either breaking their night's rest continually, or leaving their patients to die alone in the night. The nursing staff is lamentably insufficient; we would urge the Board to consider the whole question, with a view to superseding the pauper help by skilled service.

TRAINED VERSUS UNTRAINED NURSES.

THE *Freeman's Journal* is quoting our Special Commissioner against ourselves in a long quotation from the report on the Day-Dispensary Workhouse Infirmary, in which report our Commissioner gives honour to whom honour is due. "Foremost among our assailants—if we except a Tory Lord Justice—was the *BRITISH MEDICAL JOURNAL*," then, with the curious want of discrimination which so often characterises a non-professional writer in dealing with professional matters, mixes up our comments on the general management of a workhouse with those on the skilled nursing of the sick.

Into the merits of this particular dispute with the Athlone Board we do not enter, but on the wider question as to whether the pauper is to be nursed by trained or untrained nurses our opinion is very decided. The reports that we are placing before our readers will disabuse any candid mind that we are prejudiced against the nurse as nurse; our Commissioner always recognizes the excellence of the work done by these religious-minded women in the workhouses, but good intentions cannot take the place of knowledge, nor can "experience" supersede training. Experience gained in a workhouse infirmary will only carry the possessor of that experience as far as the limits of the sphere wherein the experience was acquired will permit. In other words, because the bulk of workhouse patients are of the chronic order the experience being the application of knowledge acquired by one person, and passed on to another as from teacher to taught, it is limited to the amount of knowledge on the part of the teacher. In a workhouse infirmary, unless there is a resident medical officer, the head nurse is the fount of knowledge, and if she is not trained she has no special knowledge to impart. In a hospital the training of the nurses is carried on on varied cases of sickness, and it is guided and supplemented by direct tuition from teachers skilled in the application of the art of nursing; hence, when a pupil has completed the course, she has seen or taken part in the nursing of all forms of disease, she has seen the treatment of disease by professors in medicine and surgery, and she has learnt the management of patients and wards from those who are qualified to teach. Public opinion has distinctly stated that it is its wish that the paupers for whose care it is responsible shall be nursed by nurses trained in the nursing of the sick in properly equipped hospitals, and by professors of the art of nursing; this mandate will have to be obeyed sooner or later. The Local Government Board is only carrying out the mandate of its masters, the public. We are entirely at one with the public on this point: we feel that the sick, wherever they may be found, have a right to treatment by a qualified medical man, and that his prescribed course of treatment shall be carried out by a properly trained nurse. Whether in the particular instance of the Athlone Board it was judicious to insist at once upon a levelling up, for which both guardians and nursing staff was unprepared, is a matter upon which there would be several opinions, but that the principle contended for is a right one we are most fully assured.

IRISH WORKHOUSES.

THE Chairman of the Lisburn Board, in seconding a motion to make an examination of the sewers, said "that a sewer recently opened presented a shocking sight, and the stench from it was horrible. He did not wonder that the representative of the *BRITISH MEDICAL JOURNAL* should aver that the poor creatures who were compelled to sleep over such a receptacle of filth were in a condition of living death."

We welcome this testimony to the value of the crusade that we have entered upon in the interest of the Irish pauper; and if we can only arouse those in authority to look into the sewers and all the dark places of the Poor Law we shall have secured some results for our work.

GREAT YARMOUTH.

It is extraordinary the delusions that cloud the intellect of the guardian when considering the question of the nursing of the sick in the workhouse infirmary. The valiant lady guardian in Yarmouth has again taken up the cudgels on behalf of the paupers, and moves that a trained nurse be advertised for; she again suffers defeat, because "there are fourteen nurses in the house, and they cost £200 a year." This looks well on paper, but the facts are these: Most of these so-called nurses are inmates; the salaries average £50 a year. The head nurse, who is superintendent of the whole house, is now 81 years of age, and her official assistants are two nurses untrained. The patients average about 200, of whom many are acute cases. The guardians argue that because there are a certain number of inmates told off as ward helpers that the nursing staff is adequate; but we maintain that the effectives are three, and the non-effectives as many paupers as the officials like to place in the wards. We trust that Mrs. Leach will return to the charge again, for she will have the sympathy of all humane people with her.

THE "INDEX MEDICUS."

OUR readers will hear with pleasure that it has been definitely decided to resume the publication of the *Index Medicus*. A circular letter has been issued by Dr. Billings and Dr. Fletcher, in which they state that the necessary number of subscribers has been obtained, and that the work will be put in hand at once. The replies to the inquiry made as to the preferred date of commencement of the journal have been overwhelmingly in favour of its continuance from May 1st, 1895, thus making the work continuous. The first current number will appear in January, 1896, and the *Index* will be continued monthly thereafter. The preceding bibliography, from May to December, will be printed in one number as quickly as the large quantity of material will permit.

A list of subscribers is sent out with the notice. This list is more complete than the one recently issued by Messrs. Davis, to which we referred in a previous note. The editors state that "it is understood that some foreign subscriptions are yet to arrive." A glance at the list of those received up to the date of the determination to proceed with the *Index* shows that we have to thank the United States for the resumption of the publication of the *Index*. Three copies are subscribed for in France and only one in Germany; excepting Great Britain, these are the only European countries represented in the list.

The only towns in Great Britain from which subscriptions have been sent are the following: London, represented by the Royal College of Physicians, Royal College of Surgeons (two copies), and the British Medical Association (two copies). Manchester is represented by the Manchester Medical Society, and Bristol by the Bristol Medical Society. Edinburgh sends three subscriptions. The Royal College of Physicians, Sir T. Grainger Stewart and Mr. Young J. Pentland. Oxford, Cambridge, Glasgow, and all our large towns, excepting those mentioned above, are conspicuous by their absence. Ireland does not appear on the list at all.

Mr. MacAlister stated in the *BRITISH MEDICAL JOURNAL* of December 7th that he had sent some dozen names in as subscribers; these, we presume, were not received in time to be included in the list just issued. Even with these twelve added London cuts a sorry figure in comparison with New York or Philadelphia.

THE ASHANTI EXPEDITION.

[FROM OUR SPECIAL CORRESPONDENT.]

AN account of the arrangements on board the hospital ship *Coromandel*, which sailed on Saturday, and will serve as hospital ship with the Ashanti expeditionary force, may be of interest to your readers.

The whole of the outside of the ship is painted white, and the wards inside are coloured pale green; thus the effect of the direct rays of the sun and of the glare from the surface of the sea will be mitigated as much as possible. The wards are on the upper and main decks, the upper deck being reserved for the worst cases and fitted with specially long enclosed swinging cots of iron, which can be fixed or allowed to swing freely at will. If desired also they can be unshipped from their supports, and then stand on folding feet like ordinary bedsteads. They can then be carried into the open air, or into the operating room, which communicates with this ward through folding doors. These bedsteads, as in fact is the case with nearly all the hospital cots, have an arrangement which admits of the use of the bed pan without lifting the patients, and each is fitted with a little table at the patient's head, a punkah, and with a rope and crossbar whereby the patient can raise himself.

The wards are beautifully light and airy, have large square ports on each side fitted with "chicks" or split cane blinds, which keep out flies and glare, while permitting natural ventilation, which is assisted by Dr. Edmond's steam spray extracting apparatus as well as by a steam fan blast for pumping in fresh air.

The smoking room on the hurricane deck has been fitted up as a small ward for officers, and is very cheerful and airy.

A complete laundry is fitted up for washing linen, etc., and is paved with grooved tiles, as are also the latrines and wash-houses, so that all fouling or dampness of the decks is avoided.

The operating room is fitted with a steriliser for instruments, glass irrigators, and every appliance for the carrying out of all operations under strictly antiseptic precautions. There is a drying room fitted with hooks close to the engine, wherein all personal clothing, etc., can be thoroughly dried—a most necessary precaution in the intensely damp climate of West Africa.

The ship is fitted with Pasteur-Chamberland filters supplied by Messrs. Duffin, and a soda water making machine is supplied, whereby any amount of the condensed water, of which almost unlimited quantities will be manufactured on board for drinking and cooking purposes, can be aerated and made as required.

The troop decks for the men going out in the *Coromandel* are unusually light, roomy, and well ventilated, ample room and cubic space being available owing to the small number of men—under 300—to be carried, while the quarters for the warrant and non-commissioned officers are most comfortably fitted up. The ventilation throughout the ship, assisted as it is by the artificial means above described, is most perfect, and no expense appears to have been spared or anything which science or experience could suggest omitted, tending to promote the comfort and well-being of the sick and wounded in the trying climate to which the *Coromandel* is about to proceed. The nursing sisters have been supplied with electric furnaces, in which a plate of platinum foil, when connected with the wires of the electric light, will in a few minutes boil a kettle, or heat up soup, beef-tea, etc. This arrangement is not only extremely convenient, but is also much safer than using spirit lamps or open fires.

THE CASE OF DR. ANDERSON.

At a meeting of the Trinidad and Tobago Branch of the British Medical Association, held on November 6th, the following resolution, moved by Dr. J. A. DE WOLF, President, and seconded by Dr. C. F. KNOX, Vice-President, was passed:

That the Secretary be instructed to acknowledge the receipt of the letter of General Graham of August 18th, 1895, with accompanying papers setting forth the efforts of Dr. Anderson to secure a hearing of the appeal against the decision of the Court of Appeal in the case of Anderson v. Gorrie, Cook, and Lamb, and to inform General Graham that those documents have been laid before this Branch (at a general meeting held this day, November 6th), and that the Branch desires to express its continued sympathy with Dr. Anderson in his efforts to secure justice to himself and thereby to uphold the dignity and rights of the profession.

A similar resolution was recently passed by the Torquay Medical Society (see p. 1501).

THE BATTLE OF THE CLUBS.

THE NORWICH MEDICO-CHIRURGICAL SOCIETY.

WE are informed that at a meeting of this Society, held at the Norfolk and Norwich Hospital on December 3rd, the report of the Council in reply to Mr. Belding's question, Are the medical officers of the Liverpool Victoria Friendly Society included in the strictures passed by the Norfolk and Norwich Medico-Chirurgical Society on medical men holding medical aid appointments? was received and adopted. The *modus operandi* of this Society had been fully investigated by the Council, and the members were unanimously of opinion that the Liverpool Victoria Legal Friendly Society comes within the meaning of Law VI "as unbecoming and unprofessional for any member of the profession to lend his name or to associate himself in any way with such a Society;" and it was resolved that the decision of the members should be made known at an early date to each member of the Society by circular. Law VI reads as follows:

VI.—Any registered medical practitioner who shall be adjudged guilty of and persist in unprofessional conduct, as defined by the code of rules adopted by this Society, shall be ineligible to be a member of this Society.

The rules adopted by the Society are those formulated by Dr. Storrup, with clauses appended with regard to medical and associated duties, defined as associations formed as trade organizations, carried on by lay proprietors for the purpose of deriving pecuniary profits from the earnings of members of the profession, and punished by means of advertisement, or by the employment of paid canvassers who tout and collect the patients of other practitioners; and that it be declared unbecoming and unprofessional for any member of the profession to lend his name or to associate himself in any way with such societies or clubs.

FERRANAGH MEDICO-ETHICAL ASSOCIATION.

The Ferranagh Medico-Ethical Association has been formed with the object, among others, of promoting professional intercourse, mutual protection and co-operation, and providing opportunities to members for obtaining the advice and united support of the profession in the locality. This Association proposes to arbitrate in disputes between members; to consider and take action upon the relation of medical officers with all kinds of club practice, and with regard to Poor law and other appointments; to circulate a code of ethics (founded on that of the Manchester Medico-Ethical

Association), as well as a tariff of fees: to establish, maintain, and circulate among members a "patients' black list;" and, in particular with regard to club practice, (1) to enforce a wage limit, (2) to insist on a medical examination for all new members and an examining fee, (3) to raise the usual rate of subscriptions for females and juveniles, (4) to safeguard the tenure of office by a three months' notice on either side. Further, the Association will seek to obtain "increased and more efficient representation for general practitioners on the General Medical Council, and of medical men in Parliament." These are all very laudable objects, but we cannot help regretting that it has not been at least attempted to attain them through the local organisation of the British Medical Association. "United we stand, divided we fall," is as true of organisation as of individuals, and while we rejoice to see an awakening of local interest in these matters and a greater disposition to deal with them by local effort, we cannot doubt that local action would be far more effective if it were organically a part of a combined effort throughout the United Kingdom.

THE HISTORY OF SYMPHYSIOTOMY.

In a recent number of the *Quarterly Medical Journal* Dr. P. Dymock Turner has an interesting article entitled *Symphysiotomy, its Introduction, Decline, and Revival*, in which the history of the operation is told in great detail. A work published in 1897 by Severinus Pinus, a surgeon of Paris, paved the way for the introduction of symphysiotomy, though it was nearly two centuries before it was actually performed. He describes the *post-mortem* examination of a woman hanged ten days after delivery. The examination was made in the presence of most of the eminent doctors of Paris, including Ambroise Paré. The pubic bones were clearly seen to be freely movable, and Pinus suggests that more room for the passage of the foetus might be made by aiding the separation of the symphysis, which was believed to take place in labour, if necessary, by cutting.

In 1655 J. O. de la Courville divided the symphysis with a knife to save the child in the case of a woman who had died in labour, and the same thing was done by Menck in 1766. In 1788 Jean René Sigault presented a communication to the Académie Royale de Chirurgie in which he called attention to the bad results of Cæsarean section, and proposed to substitute for it division of the symphysis in certain cases. Sigault asked that the Académie should procure for him a condemned criminal on whom he might try the operation. This request was refused by the Académie, which also emphatically rejected the proposed operation.

It was not till 1777 that Sigault had an opportunity of performing the operation. On October 1st in that year he operated on a rickety dwarf, aged 30, who in her four previous confinements had been delivered by version. The operation was done, with the assistance of Alphonse Leroy, in the night by the light of a candle held by a woman. The patient sat up in bed on the forty-first day, and on the forty-sixth she was able to walk a few steps. On December 3rd, nine weeks after the operation, the woman appeared before the Faculty of Medicine, and the result of the operation was so satisfactory that the Academy decided that Sigault's two memoirs, with the Commissioners' report and the proceedings of the meeting, should be printed in Latin and French, and sent to the civil authorities and to the medical profession; also that a moderate sum should be given to the woman, and that she should be recommended in the proper quarter for a pension. It was also decided that the following inscription should be engraved on the reverse of the Dean's silver medal, and that 100 specimens should be given to Sigault and fifty to Leroy:

Rectio
symphysis, oes. pub.
La-isa Nova.

1788

Invenit Proposuit

1777

Fecit Felicitator

J. R. Sigault, D.M.P.,

Juvit

Alph. Leroy,

P.M.P.

Sigault's triumphant success with the physicians may have

been partly due to the fact that the surgeons had previously pronounced against him, and the surgeons were not slow to find fault with the operation after its performance. The controversy reached the public, and the *Journal de Paris* published a large number of letters on both sides, one enthusiastic lady proposing that a statue should be erected to Sigault in the form of the God of Health. The second operation was performed at Würzburg by Gaspar von Siebold on February 4th, 1778; the child was killed in the delivery, but the mother recovered. Sigault himself operated five times in 1778, in four of them the mothers recovered, but in none was the life of the child preserved. Leroy, Sigault's assistant, operated four times up to 1785, losing one mother but saving all the children. In the hands of others, however, the operation had disastrous results, due either to septic mischief or to its being undertaken in extreme degrees of pelvic contraction, for which it was unsuitable. The publication of Baudelocque's treatise (1781, 2nd ed., 1789) led to the abandonment of symphysiotomy in France. In England it never met with much favour, being opposed by William Hunter and other authorities. In Germany it was very little practised, perhaps on account of the lamentable results of the operation in that country. In Belgium, Holland and Italy it took firmer root, and in the last-named country it never died out of practice altogether. After the introduction of the antiseptic method, the results, especially at Naples, showed an extraordinary improvement in the hands of Morisani, Novi, Mancusi, and Mangiagalli. So little was their work known to the profession in other countries, however, that Morisani astonished the London International Medical Congress in 1881 by the recital of his statistics from 1863 to 1880. In that period he had operated 50 times on 48 women (two having undergone the operation twice), with the result that he had saved 40 women and 41 children. The operation, however, showed no sign of coming into favour with the profession outside Italy until 1891, when Morisani's assistant, Spinelli, visited Paris and induced Professor Pinard to try the operation. He did so with very encouraging results, and up to the end of 1894 49 symphysiotomies had been performed at the Clinique Baudelocque, with the loss of 4 women and 5 children.

It is a curious irony of fate that the hospital named after the man whose teaching caused the operation to be rejected in France should have been the scene of its successful revival.

Since 1892 symphysiotomy has been practised pretty extensively throughout Europe and in America, and the operation has been highly successful in skilled hands. Widely varying opinions, however, are still held as to the position which it ought to take among the resources of the obstetrician. The whole question is discussed in a judicial spirit by Dr. Turner.

RESOLUTIONS OF THE INDIAN GOVERNMENT; A NEW EPOCH IN INDIAN SANITATION.

THE Government of India has now issued its important resolution on the subject of sanitary administration. This State paper, which promises to inaugurate a new era in Indian sanitation, is a response to the representations made by the Indian Medical Congress on this subject in Mr. Ernest Hart's address, and in a paper read at the Congress by Dr. W. J. Simpson, Health Officer of Calcutta, where suggestions were set out as to the organisation of a sanitary executive for the purpose of promoting reforms in Indian towns and villages tending to the betterment of public health. These suggestions, which were cordially supported and endorsed by the Congress, were devised for the purpose of adapting the administrative arrangements existing in India, more especially those founded on the principle of local self-government, to the end of applying local resources to meet the cardinal sanitary needs of the country, namely, the provision of a pure water supply, and of proper arrangements for scavenging and drainage. Mr. Hart and Dr. Simpson's main proposals were (1) the separation of civil and military health; (2) the education and training of a suitable sanitary executive in medical, veterinary, and engineering schools; (3) the appointment by the larger municipalities and by groups of smaller municipalities and local bodies of health officers;

(4) the formation of special sanitary committees to consider the sanitary needs of localities; (5) the appointment of district sanitary inspectors in cases where the civil surgeon is unable, from pressure of medical work, efficiently to supervise the sanitary executive; (6) the retention of provincial and imperial sanitary commissioners as heads of sanitary administration; and (7) the special investigation of disease causes by means of properly equipped chemical and bacteriological laboratories.

The Government resolution now issued is practically a reply to these proposals. It is pointed out that the sanitation of the army and of military cantonments, which is entrusted to cantonment committees working under the order of the Government of India, has already been completely separated from that of the civil population. As regards the latter, the Government virtually accepts Mr. Hart's proposals in his Indian address, and in his address to the British Medical Association at Newcastle in 1893; which it will take time fully to realise. As a commencement it has been resolved to create a strong chemical department in Calcutta for the whole of the Bengal Presidency, for purposes of medical and sanitary analysis, and for training men in practical sanitary work. A bacteriological laboratory is to be organised at Agra under Professor Hankin, who has already done such excellent work, for purposes of investigation and education. Medical and engineering colleges are to be utilised more largely and specially for sanitary teaching, and it is proposed to grant diplomas in public health to men who have undergone a course of study in hygiene. A sanitary executive is to be gradually provided in this way, and it is hoped that by the beginning of the next century a sufficient supply of trained men will become available to justify local bodies being required to appoint health officers. The other items of the programme are accepted as objects to be realised in the early future. Meantime young men specially qualified and selected are to be appointed for a limited term of years as sanitary commissioners, whose main duty will be sanitary inspection. The separation of sanitary from medical work is not a feature of the policy of Government, and it is fully recognised that men who have had a regular medical training are best fitted for devising and executing measures having for their object the prevention of disease, which ought to proceed hand-in-hand with measures designed for the cure of disease.

The question of additional expense is one which confronts the Government on the threshold of this undertaking, and it has been found necessary, in order to provide for the cost of the new laboratories, to abolish the post of Deputy Sanitary Commissioner of the Punjab and close the small bacteriological laboratory in Calcutta, hitherto conducted by Professor D. D. Cunningham. It will probably be possible eventually to throw the burden of these new arrangements on local bodies.

Meantime we hope that on the principle of *salus populi suprema lex* the new sanitary movement will not be stifled by misplaced economy. The sanitary needs of Indian towns and villages are easily discovered, and it does not require high scientific training to recognise and remedy them. They are, as was recently pointed out in a letter to the *Calcutta Englishman* by a native gentleman, by name D. C. Roy, pure drinking water, conservancy, and drainage. These are the simple changes which have to be pealed out all over India, and it remains for the new sanitary executive to ring them in the ears of Indian peoples so loudly and persistently that cleanly ways will in time become national habits.

THE DOCTOR'S WARS.

THE fact that the success of the Ashanti expedition must depend very largely upon the efficiency of medical arrangements is generally recognised, and in consequence the number of army medical officers employed is large. They include, in addition to Surgeon-Colonel Taylor, Principal Medical Officer, Brigade-Surgeon-Lieutenant-Colonel Townsend, Surgeon-Lieutenant-Colonel Bienerhassett, 8 officers of the rank of Surgeon-Major, 10 Surgeon-Captains, and one Surgeon-Lieutenant—23 in all. As the European force sent from this country is only 300, to which a battalion

from Gibraltar is to be added, the staff of army surgeons is large in proportion. In 1874 the expedition included 2,400 Europeans, and there were altogether 80 medical officers detailed for service, of whom about 60 accompanied the force to Kumasi. In addition, Sir Garnet Wolseley could command the services of nearly 80 surgeons R.N.

ASSOCIATION INTELLIGENCE.

BRANCH MEETINGS TO BE HELD.

METROPOLITAN COUNTY DISTRICT.—A meeting of this District will be held on Tuesday, December 17th, at 8 P.M., at the County Infirmary, Northampton Park Hill, N. The business will be: Mr. J. A. Power will read a paper upon the Differential Diagnosis and the Treatment of Cerebral Lesions in Children (specimens and a case will be shown). Interesting clinical cases will be shown by Dr. Chilcott, Medical Superintendent of the Infirmary. Dr. J. H. W. Honorary Secretary.

ABERDEEN, HANTS, AND KINCARDINE BRANCH.—An ordinary general meeting will be held in Aberdeen on Wednesday, December 18th, at 7 P.M. —C. THORNTON BRIDGMAN, J. SCOTT BROWN, Joint Honorary Secretaries.

SOUTHERN BRANCH: SOUTH-WEST DISTRICT.—A meeting of this District will be held at the County Infirmary, on Wednesday, December 18th, at 8 P.M. The business will be as follows: 1. Statement of Accounts. 2. Election of Officers. 3. Consideration of the report of the Committee of the British Medical Association on Medical Charities. 4. Mr. Hosking: (1) Notes of a Case of carcinoma of the Scapula; (2) Multiple Growths of Lower Eyelid, with specimen. 5. Mr. Manning: The Use of the Tintometer in Water Analysis. 6. Mr. Manning: A Case of Orchiectomy for the Relief of Enlarged Prostate. 7. Dr. Manning: Lecture will be provided at 1 o'clock, at 2s. 6d. a head, not to include wine or ale. —H. J. MANNING, Honorary Secretary.

SOUTHERN BRANCH: SOUTH-EAST HANTS DISTRICT.—An ordinary meeting of this District will be held on Tuesday, December 17th, at 8 P.M., at the Medical Library, 5, Pembroke Road, Avenue, Southampton. —C. C. CLAREMONT, Honorary Secretary, 62, Elm Grove, Bournemouth.

GLOUCESTERSHIRE BRANCH.—The 10th ordinary meeting of this Branch will be held at the General Hospital, Gloucester, on Tuesday, December 17th, at 7 P.M., under the presidency of Dr. Oscar Clarke. A paper will be read by Dr. Mackinnon, of Gloucester, on Puerperal Eclampsia, and one by Dr. Herbert Bransford, of Cheltenham, on Puerperal Disease. —S. T. PRUEN, Honorary Secretary.

LANCASHIRE AND CHESHIRE BRANCH.—The adjourned meeting of this Branch will be held in the Medical Institution, Liverpool, on Wednesday, January 23rd, 1896. All notices of business to be sent to the Secretary, JAMES HARR, M.D., 73, Rodney Street, Liverpool, at once.

GLOUCESTERSHIRE BRANCH.

THE first general meeting of the season was held at the General Infirmary, Gloucester, on November 19th. Dr. OSCAR CLARKE, President, in the chair. Thirty-one members were present.

Confirmation of Minutes.—The minutes of the previous meeting were read and confirmed.

President's Address.—Dr. OSCAR CLARKE delivered the opening address upon Prognosis. After the address a vote of thanks to the President for his address was proposed by Dr. EYNER BATTEN, seconded by Dr. E. T. WILSON, and carried unanimously. The President acknowledged the vote in graceful terms.

Communication.—Mr. G. A. CARDWELL showed a Cast of the Foot of a child having six toes.

Supper.—After the meeting the members adjourned to the New Inn Hotel, where twenty-six sat down to supper. At the supper a vote of thanks to Mr. O. H. Fowler, the retiring President, for his able and energetic year of office, was proposed by Dr. OSCAR CLARKE, seconded by Mr. G. A. CARDWELL, and carried unanimously.

SOUTH-EASTERN BRANCH: EAST SUSSEX DISTRICT.—An ordinary meeting was held at Hastings on November 20th; Dr. ALLEN, the President of the Branch, in the chair.

Confirmation of Minutes.—The minutes of the East Grinstead meeting were read and confirmed.

Place of March Meeting.—It was resolved to hold the March meeting at Brighton, conjointly, if possible, with West Sussex District.

Communications.—Professor W. H. CORFIELD delivered an address on the Water Supply of Towns.—Mr. CLELAND LAMMIE related several cases which tended to establish some connection between Disease of, or Operations upon, the Female Pelvic Viscera and Serous Effusion into the Pleural Cavity.

Dinner.—Eighteen members dined together at the Grand Hotel after the meeting.

SOUTH-WESTERN BRANCH.

An intermediate meeting of this Branch was held at the Barnstaple and North Devon Infirmary, Barnstaple, on November 30th. Dr. HARPER, Vice-President, in the chair.

New Member.—Dr. HALLETT, of Bradninch, was elected a member of the Association and Branch.

Communications.—Mr. SWAIN, of Plymouth, read a paper on the "Technique of Abdominal Surgery." At the conclusion of the discussion, a vote of thanks to Mr. Swain for his paper was moved by Dr. DAVY (Exeter) and carried unanimously.—Mr. PENNY (Barnstaple) showed a case of Acute Exfoliative Dermatitis or Pityriasis Rubra.—Dr. SOLLY (Exeter) read a case of Colitis.—Mr. COOK (Barnstaple) read notes of a case of Caesarean Section—deformity from rickets—with recovery, the child being also alive. Also of a case of Tumours in Both Breasts, simultaneous removal, and recovery.—Mr. JACKSON (Barnstaple) showed a patient in whom he had cured Anthrax by the local application of Pure Carbolic Acid.

HALIFAX, NOVA SCOTIA, BRANCH.

A VERY largely attended meeting was held in November 1st, at the Queen's Hotel, Halifax; the PRESIDENT (Dr. TRENAMAN) in the chair.

New Member.—Dr. Thomas Walsh was elected a member of the Branch and Association.

Communications.—Dr. KIRKPATRICK showed a patient with Primary Tuberculosis of the Larynx.—Dr. CAMPBELL showed a case of Lupus.—Dr. FARRELL reported three cases of Abdominal Section and one of Ventral Fixation.—Dr. BLACK reported a case of Hysterectomy, showing specimen.—Dr. N. E. McKAY showed a patient, for whom he had Wired the Olecranon for Fracture.

Treasurer's Report.—The Treasurer's report was received, and referred to an auditing committee consisting of Drs. Kirkpatrick and Hattie.

A REGULAR meeting was held on November 15th; the PRESIDENT (Dr. Trenaman) in the chair.

New Member.—Dr. W. F. Smith was elected a member of the Branch and of the Association.

Communications.—Dr. WALSH reported a case of Poisoning from Belladonna and Aconite.—Dr. CARLETON JONES reported a case of Spontaneous Fracture of the Femur of a child 2 years of age.—The discussion on the Management of Abortion was introduced by Dr. FARRELL, and continued by Drs. MILLER, MILSON, REID, CAMPBELL, WALSH, SMITH, CARLETON JONES, and others.

SYDNEY AND NEW SOUTH WALES BRANCH.

THE usual monthly meeting of this Branch was held at Sydney on October 25th; Dr. JENKINS (President) in the chair. Thirty-two members were present.

Confirmation of Minutes.—The minutes of the previous meeting were read and confirmed.

New Members.—The PRESIDENT announced the election of Dr. Woods, of Albury, and Dr. Woodford, of Glen Innes, as members.

Communications.—The HONORARY SECRETARY read a letter from the Brisbane Branch of the British Medical Association with reference to the case of leprosy. Resolved that the question be referred to the Council to be dealt with.—Dr. BENNETT exhibited a case of Lichen Planus.—Letter from the Registrar of the University was read.

Midwifery Nurses Bill.—The PRESIDENT stated that Dr. Graham could not be present at the meeting, but as the question of the Midwifery Nurses Bill was an urgent one the discussion might go on. He would therefore ask the Hono-

rary Secretary to read the Bill through.—A discussion ensued in which Drs. THIRING, MULLINS, WERRALL, McCULLOCH, CRAGO, NEILL, WILKINSON took part. Dr. WILKINSON moved that the debate be adjourned for one week. Carried.

MALAYA BRANCH.

An ordinary meeting of this Branch was held in the Raffles Library, Singapore, on August 3rd. The members present were Surgeon-Captain Greig, A.M.S.; Drs. Middleton, Lim Bom Keng, Croucher, Fowle, Jansz, and the Honorary Secretary, Dr. H. Campbell Highet. Mr. H. N. Ridley, F.L.S., was present as a visitor.

Election of Chairman.—In the absence of the President and Vice-President Dr. W. R. C. MIDDLETON was called to the chair.

The Potentialities of the Branch.—Dr. JANSZ read a paper with this title. He said the Malaya Branch might in a sense be said to be barely out of its swaddling clothes, but it was really the late Straits Medical Association in a new garb, with an accession of new members, and with a mighty organisation at its back. This was the youngest of the many and widely-spread branches of the parent tree, having been fully acknowledged by the central governing body only early this year, though in the latter part of the previous year they were tentatively recognised as a Branch. Dr. Jansz gave an account of the organisation of the Association and its Council, and the influence which through it the profession could bring to bear on the Government. He dwelt on the importance of this and such matters in relation to the proposed new ordinance as to the registration of deaths, which was being considered by the Government, and the question of the notification of infectious diseases. Linked with these subjects, and moreover forming the only basis upon which any legislation would be of real benefit to the community, to science, or to themselves was the suppression of unqualified practice (which was so rampant there), and the due regulation and registration of qualified medical practitioners. The question regarding the payment of a fee for the notification of infectious diseases had been in a measure practically settled. The Municipal Commissioners had admitted the reasonableness and justice of the claim for a fee for such notification, but pleaded their inability to comply with the demand, owing to the present state of the municipal ordinance, and they had, through their President, assured the profession that it would be dealt with and remedied in the proposed amending municipal ordinance in course of preparation. Their thanks were due to the Subcommittee of this Branch entrusted with the conduct of the question for the favourable and satisfactory result of their labours. The consideration of the subject of death registration was now in the hands of another subcommittee of the Branch. With regard to the suppression of unqualified practice, they should take this opportunity of asking the Government to pass an ordinance by which the public and the profession would be protected against a class of men who did untold harm by being allowed, without restraint, to practise and to employ European drugs, medicaments, and methods. What was required was a short, simple, and straightforward Bill by which those who had duly qualified themselves to practise medicine according to Western methods—in contradistinction to those native doctors, who had their own methods and drugs—should be regulated and registered, and such only should be permitted to practise who hold degrees or diplomas or licenses from European or other universities or colleges, and are also registered in the Medical Register of the United Kingdom or in the Colonial Register. Should the local government fail to give such redress, they could then bring to bear on the subject on their behalf "the great influence of the powerful British Medical Association" by appealing to them and their Parliamentary Bills Committee, and to invoke their aid. Dr. Jansz then proceeded to refer to the extensive field of study offered by tropical diseases, and urged on members of the Branch to be "up and doing," and to use their advantages as members of a vast Association. In the discussion which followed, Drs. CROUCHER, FOWLE, HIGHET, MIDDLETON, and LIM BOM KENG took part.

Vote of Thanks.—Dr. H. CAMPBELL HIGHET proposed that a hearty vote of thanks be accorded to Dr. Jansz for his very able and stimulating paper. Dr. MIDDLETON seconded the proposal, which was carried by acclamation.

SPECIAL CORRESPONDENCE.

PARIS.

Hernia in France.—The Library of the Faculty of Medicine.—The Opening of the Medical School.—Military Hygiene.—General News.

M. BERTILLOU, in a paper recently read before the Academy of Medicine on the frequency of hernia, stated that this was independent of race, but appeared to be in relation to easy circumstances or the reverse. The recruits coming from the Paris districts inhabited by a well-to-do population are freer from hernia than the recruits from poor districts. The occupations which induce the occurrence of hernia are the following: Zinc workers, bakers, pastrycooks, millers, hat makers, bleachers, those who prepare tissues, dyers, iron-founders, and locksmiths. On the other hand, tanners, bootmakers, wood turners, clockmakers, goldsmiths, and those whose calling permits them to be seated are comparatively free from hernia. Among members of the literary profession hernia is rare. Between the ages of 5 and 15 the condition is uncommon. After 40 years of age the proportion rapidly increases.

The French medical student of the present time is easily roused to wrath when suffering from a real or an imaginary injustice, but in some matters he is a long-suffering creature. The bad management of the library of the Medical Faculty is quoted as a proof of his meekness and endurance. During the year which is now passing away 169,180 students have consulted 270,000 volumes in the said library, these statistics giving a flattering idea of the library which is not supported by fact. The library is so overweighed by debt that not only new books are not bought, but sixty subscriptions to publications have been discontinued. Five thousand volumes and pamphlets have been bequeathed to the library by deceased medical men. Among these thousands of volumes there were one hundred new works. Books that the library does not possess are constantly and repeatedly asked for. The medical press, with justice, considers this state of things to be hard on the medical students, who pay something towards the expenses of the library. The position of the library is a difficult one. The allowance for the new spacious library and reading room is the same as that granted to the old one, which was much smaller, and therefore comparatively inexpensive. The staff is larger, and binding is a costly item, and for want of funds books remain ragged. More books than ever on medical and scientific subjects are produced, and yet fewer are bought by the Medical Faculty library. Last year this state of things was commented on by the medical press. The remedy is easy. Without spending either public or private funds, the library could be provided with a good supply of books by simply decreeing that the copy of all published medical books which must according to law be deposited at the St. Genevieve library should find its way to the Medical Faculty library as its natural home.

The Quartier Latin has now resumed its wonted aspect. The Boulevard St. Michel is again peopled by its usual inhabitants. The startling difference between the Boulevard St. Michel at the present time and what it was during the summer holidays is a more convincing proof that the lecture theatres of the medical faculty are opened than the blue and green bills posted on all public buildings, furnishing the details of the lectures to be given during the winter season. On December 10th the opening lectures were given. Thousands of students assembled to applaud MM. Mathias Ival, Farabouf, and Dieulafoy, the most popular among the lecturing professors of the medical faculty. Three thousand tried to find room in a lecture theatre capable of containing 1,500. M. Farabouf, who is always listened to attentively by the students, gave much useful advice concerning not only how to study anatomy but how to teach it. There is a belief that medical instruction requires reform here, and that it is better organised in England and Germany. Professor Farabouf is dissatisfied with the examination of the "Second Doctorate," which he does not consider sufficiently difficult. He read a list of questions set in certain written and *visu* voce examinations in England. M. Farabouf considers that the Paris Medical Faculty has too many

students to be able to give them practical instruction. As to the examinations, he very truly declares that it is impossible to judge of the knowledge of a candidate by questioning him during five minutes. Written examinations would be a much better test, and the candidate would not be handicapped by timidity, which causes hesitation and frequently failure.

M. Viry has published a book entitled *Précis d'Hygiène Militaire*, which is a valuable collection of sanitary measures to be applied to human agglomerations on the vast scale modern warfare demands in standing armies. This volume is positively a sanitary codex. The weak points in French military sanitation are conscientiously and ably exposed, and the improvements due to the reorganisation of the military health service are duly enumerated. Barrack sanitation is fully treated, the mode of their construction, etc. The food, clothing, and equipment of the soldier are treated in detail with the same knowledge and care. Precise and minute directions are given for examining all articles of food, in order to prevent intoxication from unhealthy or deteriorated provisions.

Le Conseil d'Hygiène et de Salubrité de la Seine has elected M. Moissan to take the place of M. Pasteur, and M. Albert Josias, Chef at the Trousseau Hospital, to replace Baron Larrey.

Mme. Guérant has bequeathed to the Assistance Publique £6,730 to be used to build a consumption hospital for chest patients between the ages of 15 and 30.

The Prefect of the Seine has organised a departmental commission for the purpose of overlooking in a sanitary point of view the agricultural sewage system of the Seine Department.

At the Conseil Académique de Paris M. Darboux, Dean of the Faculty of Sciences, stated that a bacteriological laboratory is attached to the Faculty. M. Heurtot, Mayor of Rheims, likewise announced the existence of a bacteriological laboratory at Rheims accessible to all doctors.

M. Monod, the well-known surgeon, has been elected member of the Academy of Medicine.

The Budget of the Interior for 1896 accords a State grant voted by the Chamber of Deputies to the Public Assistance amounting to £58,000. M. Lechevallier said this sum would probably have to be increased each successive year.

BERLIN.

Retirement of Professor Krause.—A Professorship for Dr. Ehrlich.—The Berlin University.—Industrial Exhibition.—The Police and Secret Remedies.

In consequence of the disapproval with Professor Krause's conduct expressed by the Medical Faculty of the Berlin University, Dr. Krause has retired from the teaching body of the University. Dr. Krause is the *Privatdocent* who refused to explain, when officially summoned to do so, how his name had come to be placed below the puffing advertisements of a new soap.

Dr. Paul Ehrlich, an assistant of Koch, has been appointed to a Professorship of Special Pathology and Therapeutics in the Berlin University, and will therefore give up his position at the Koch Institute.

The Berlin University numbers 5,368 students this half-year, of whom 1,288 are medical students. For the first time women have been admitted officially to University courses; they are, however, not called students, but visitors or listeners. Their number this half-year is forty.

In the Berlin Industrial exhibition of next summer a prominent place is to be given to the Berlin ambulances. A fully organised and fitted ambulance station, with a clinic containing a certain number of beds, and a surgical station, will not be for exhibition merely, but for practical use in case of accidents or sudden seizures in the exhibition grounds.

A Berlin chemist some time ago advertised a preparation of iron in a Berlin newspaper, and was ordered by the sheriff (*Schöffengericht*) to pay a fine as punishment. The chemist brought the case before a judge, and obtained a favourable verdict, the judge being of opinion that the iron preparation was not a secret remedy. But the judicature court (*Kammergericht*) annulled the verdict on the ground that the prepara-

tion must be considered a *Geheimmittel*, as it was recommended, not only as a general tonic, but for the cure of special diseases. Thus the case was carried back to the common court and the sheriff's fine upheld. Once again the unfortunate chemist appealed, and maintained that his preparation ought not to be considered a *Geheimmittel* for that he had, before advertising it, submitted the formula of the preparation to the police committee, and had received from it the permission to recommend it publicly. The Senate of the Court, however, has not admitted the appeal. Its decision—the final one—is that *Geheimmittel* means a remedy recommended for the cure of diseases the components of which are not made known to the public at the time of purchase, and that in this case, though the police committee was told what the preparation in question was made of, the public was not. All this uncertainty and "going to law" would be avoided if a properly established definition of a *Geheimmittel* existed in the German law.

VIENNA.

Thyreo-Antikotin.—The Admission of Women to Medical Study.—A Theory of Gout.

At one of the last meetings of the Vienna Medical Club Dr. Fraenkel gave a preliminary report of investigations as to the active principle the thyroid gland. He succeeded in extracting from the gland of sheep a well-characterised crystalline substance in powder, called by himself "Thyreo-antikotin." The details of the chemical processes by which it is obtained will be described in a special paper. To this antitoxin Dr. Fraenkel ascribes all the well-known effects produced by the gland itself or its preparations. By taking it himself for six successive days, he found a daily diminution of 600 grammes of his body weight. Experiments on animals have also been successful, but are few in number, and are to be continued.

The question of women's medical education brought before the public by Professor Albert's essay some time ago, has now become of new and more actual importance, since the Emperor has shown his favourable opinion of the subject. By a late decision of the Emperor in Hungary, women will be allowed to frequent universities as ordinary students, and take degrees of the philosophical and medical faculties. Next day the same question arose in the Austrian Parliament, and found much sympathy. The Minister of Public Education gave a startling picture of the very precarious position of the marriageable girls in Austria—473,395 (or 11 per cent.) of whom cannot marry at all according to statistical reports. But though he felt keenly the necessity of opening new callings to these girls, he could not recommend as such medicine or the other higher studies of men. A resolution has been accepted, which recommends to the Government the admission of women to university studies.

A very original theory of gout and the "uratic diathesis," based wholly on chemical principles, has been suggested by Kolisch in a paper lately read before the Society of Physicians. The uratic diathesis is, according to Kolisch, a typical form of auto-intoxication, consisting in some disturbance of the physiological process of nucleic decomposition, whose last products are uric acid and the substances of the xanthin group. Increased decomposition of nucleins and increased production of the bodies form the disturbance, which appears clinically as "uratic diathesis." Kolisch succeeded in producing, by injections into the circulation of animals of the bases referred, lesions of the kidney similar to those found in gout. At the beginning of the gouty diathesis, also, an excess of uric acid is formed in the kidney, and at the same time the amount of bases increased. Early diagnosis can be made by examination of the blood, which shows Neusser's perinuclear granulations. Later the substance of the kidneys is injured by the prolonged passing of poisonous substances, the uric acid therefore diminished in favour of the bases mentioned, and thus the *circulus vitiosus* is closed. Not without success Kolisch tries to explain by his theory the various symptoms and phases of the gouty disposition.

Some of the newspapers caused general excitement by stating that, according to the monthly reports published by the Board of Health, the prevalence of enteric fever is increasing in

Vienna. There have been, indeed, sixty-two cases reported in the last month, which is more than we have had for a long time. As it has been generally believed that since, more than twenty years ago, an abundant supply of excellent water was obtained, enteric fever had almost entirely ceased in Vienna, and it would have been a great shock to the population if this belief had now been shaken. Happily the Board of Health was able to prove not only that the frequency of enteric fever, though exceedingly high in the last month, is this year still below the yearly average, but also that a large number of the cases were not genuine Viennese, but had occurred in strangers or in people just come back from a long sojourn in the country.

ROME.

The Italian Red Cross Society in Africa.—Maragliano's Serum and Parliament.—The Roman Doctors and the Income-tax Outbreak of Typhoid Fever at Cremona.—The Opening of the New Institute of Clinical Medicine at Pisa.

THE Italian Red Cross Society, with the consent of the Minister of War and General Baratini, the Commander of the Italian troops in Africa, sent some months ago a fully equipped mountain hospital to Eritrea. It appears from the report lately presented to the Central Committee in Rome that the hospital has already done excellent work. It was opened at Asmara in May, and it has a branch, including a dispensary, at Adi Ugry. The treatment of the troops in the neighbourhood of the hospital has been entrusted to it. The mountain ambulance has been removed from Asmara to Adigrat, where it is at present stationed. The wounded at Macallè have been received there, and several of the patients have been discharged cured. In the six months the hospital has been working 294 white and 428 native soldiers, as well as some white and native civilians, have been received. Twenty-nine surgical operations have been performed in the hospital. To the dispensaries situated at Asmara and Adi Ugry in the six months over 10,000 visits have been paid by the soldiers and the non-combatants. The total expenses of the Society in Africa exceed 5,000 lire (£200) a month.

At the meeting of the Italian Parliament on December 3rd Professor Celli, Director of the Institute of Experimental Hygiene, asked the Minister of the Interior why the Government permitted the sale of Professor Maragliano's anti-tuberculous serum in Italy. Signor Galli, in the absence of Signor Crispi, in his reply, stated that the Public Health Act of 1886 could not make provisions for a treatment which was then unknown. When, however, Behring and Roux's anti-diphtherial serum had given positive experimental results, the Minister permitted its sale in Italy under certain conditions. Dr. Maragliano's serum having been discovered for the treatment of tuberculosis, the Minister—for reasons of equality of treatment—had also permitted its sale. At the present time the Superior Council of Health were deeply studying the question in order to enable them to make definite regulations. Professor Celli not being satisfied with Signor Galli's reply, observed that the regulations, as far as concerned the sale being under the responsibility of the inventor who prepared it, were not well defined. It appeared to him also that the sale of this serum at high prices was a pure speculation, and he therefore desired that the Superior Council of Health be consulted in the matter. This was agreed to by Signor Galli.

The Consiglio dell' Ordine dei Medici of Rome has sent a petition to the Prefect as to the increase of income-tax demanded this year of medical men. Up to the present the income-tax amounted to about 14 per cent. of the estimated income, but this year it has been increased to 18 per cent. Some few years ago the average annual income of medical practitioners in Italy was estimated officially as under 600 lire (£24), which was certainly not an excessive estimate, although the average earnings of the profession in Italy are very small in comparison with that of their colleagues in England. The present condition of the population, however, especially of those who wish to pay their medical attendants, is urged, not such as to justify this increase of taxation on a hard worked and very much underpaid profession.

About the middle of last month a severe outbreak of

typhoid fever was reported at Cremona, caused, it is believed, by the impure water of the aqueduct, which has been for a long time in a bad state of repair. Within a very short time more than 300 cases were reported, chiefly amongst young persons between 10 and 18 years of age. The municipal authorities have taken precautions to prevent the further spread of the epidemic.

The New Institute of Clinical Medicine was opened lately at Pisa. The building, a very fine one, is of a severe type of architecture. Representatives from most of the Italian universities, as well as the municipal, political, and military authorities, were present at the opening ceremony.

DUBLIN.

The Conjoint Scheme of the Irish College of Surgeons and the Apothecaries' Hall.

I AM not satisfied that the General Medical Council appears to the best advantage in its conflict with the Conjoint Board of the College of Surgeons in Ireland and the Apothecaries' Hall. It is true that, having considered the letter of the former to the Privy Council, it still adhered last week to the opinion that the examination in medicine was insufficient. I do not quarrel with that, although the inspector and visitor comment upon the candidate's failure to diagnose an affection which it seems did not exist. But I think there is very reasonable ground for complaint by the Irish College of Surgeons that the report upon which the examination was condemned was not submitted to that body before the trial and verdict, and that sentence was passed without their having seen the document or even known its character. This charge was plainly made, and it was not contradicted by any member of the Council.

The important fact is that, as the General Medical Council informs us, the final decision rested upon this report. Its judgment regarding the part of the examination conducted by the Irish College was quite satisfactory; indeed, it was in part distinctly flattering, because it declared the examination in ophthalmic surgery to be a model for others. The fault was that a candidate was passed in clinical medicine who, in the opinion of the inspector and visitor, ought not to have been passed. The Irish College points out that the examiners were most competent; that the disease which was supposed to be empyema was not empyema; and that in any case the candidate was of necessity rejected in this subject because he had failed in other parts of the group.

At this stage, when the case was before the Council in June, a most unfortunate thing happened. Mr. Wheelhouse, who was the visitor of the examination, having pointed out the candidate's serious shortcomings, declared to the Council that not only was he passed in medicine, but that he was "now a qualified man." This statement the Irish College of Surgeons, in its letter to the Privy Council, repudiated in very emphatic terms, for the simple reason that it was not true.

It now appears that the College is quite right, for Mr. Wheelhouse withdrew the allegation, and apologised for it at the meeting of the General Medical Council last week. The Irish College complains that such an announcement from the visitor, who was necessarily regarded as an authority, must have had considerable weight in determining the decision to refer the case to the Privy Council. It was sought to get out of the difficulty by stating that the representation depended upon the three preceding reports as well. But it must not be lost sight of that the last report was certainly the one upon which the final action of the Council depended. If that report had been favourable—and Mr. Wheelhouse declared that it would have been but for the averring of this candidate—the General Medical Council could have taken no steps to bring the Conjoint Board before the Privy Council.

The proceeding was in my view bad *ab initio*. Admitting that everything in the report is accurate, that document ought to have been sent to the bodies interested in sufficient time. The meeting of the Council at which sentence was pronounced was on June 6th. The report did not reach the Secretary of the Conjoint Board in Dublin until June 2d; no formal meeting could be held in the intervening time, and

certainly no reply could have been prepared. The Irish College of Surgeons protests, and I think justly, against this form of doing business. It is, like other bodies, jealous of its own reputation, and not unreasonably resenting being pilloried in this fashion.

The whole thing is most regrettable. It has excited a good deal of bitterness, and it has not helped to dignify the proceedings of the General Medical Council. I am sorry that body did not recognise its mistake, and leave a practically dead scheme alone. It was already dying when the dispute arose, and I do not see that any real advantage has been gained by referring its shortcomings to the Privy Council. Perhaps, however, the public attention which has been attracted to the Council may make it careful in future to follow the ordinary usage of allowing defendants to know what the charges against them are, and of giving them the fullest opportunity for explanation.

BRISTOL.

Small-pox.—Medical Officer of Workhouse.—Divided Authority and River Pollution.—Faculty of Medicine University College.

THREE cases of small-pox have occurred in the Barton Regis Union, the infection probably having been introduced from outside, as the city proper is free from the disease. Some cases have arisen in Stapleton, a district to all intents and purposes, except sanitary ones, a part of Bristol. If the recent Boundary Bill had been passed it would have been included, but the determined opposition of the inhabitants of the better residential parts just outside Clifton succeeded in obtaining the rejection of the Bill by the House of Lords. The consequence is that much difficulty arises in notifying and isolating cases of small-pox which occur just outside the parliamentary boundary. At present the Stapleton authorities do not appear fully to appreciate the necessity of providing means for the proper isolation of small-pox and scarlet fever, and have to apply for assistance to the sanitary authority of Bristol for help.

The report of the Stapleton Visiting Committee as to the appointment of a medical officer for the workhouse was read at the meeting of the Bristol Board of Guardians on November 20th. The recommendations were that the medical man appointed should live within half a mile of the house, that he should pay two visits daily, dispense all medicines, attend urgent calls at any time of day or night, visit every ward once a week, and fulfil certain other specified regulations. On the adoption of the report being proposed, an amendment was moved that a resident medical officer should be appointed, and was carried by nearly two to one. The question of salary was referred back to the committee.

The inspector of nuisances reported on November 20th that the Stapleton Urban District Council were cleaning out a sewer which runs parallel with the river Frome, and that in a field near Eastfield Park had diverted the sewage into the river whereby the water, which passes by an open and in places covered way to the floating harbour in Bristol, was being polluted. In response to a letter, the clerk to the Stapleton Urban District Council stated that the sewer having become blocked, men were sent to see to what the obstruction to the flow was due. It was found to be caused by an accumulation of rags, some bearing the stamp B. L. A. (Bristol Lunatic Asylum), scrubbing brushes, washing apparel marked with a number, felt hats of a pattern worn at the asylum, stockings, and a large quantity of rags and dusts. To remove them the drain had to be opened, and the sewage was diverted into the river, then nearly in flood. The clerk added that the council have repeatedly expressed surprise that such articles are allowed to get into the drains, and that they will consider what legal steps can be taken to prevent its recurrence in the future.

The Bishop of Hereford, as President of the College, presided at the annual distribution of prizes and certificates to the students of the Faculty of Medicine of University College, and was supported by Mr. Albert Fry, Mr. P. J. Warley, the Master of Balliol, Professor Lloyd Morgan, and all the professors and lecturers of the Faculty. Mr. N. O. Dobson, F.R.C.S., Honorary Professor of Surgery, distributed the prizes and addressed the students.

CORRESPONDENCE.

BATTLE OF THE CLUBS.

SIR,—I have watched with great satisfaction the victories at Portsmouth, Inverness, etc., where medical men have united to ameliorate their condition, and also the small number of those poor creatures who applied for posts, vacant only on disputed conditions.

Here in Leicester it seems a wonder that no advance towards redress is made, especially as the pittances are much smaller than those paid in the above places. The secretary or rather mainspring of the "Provident Dispensary," a powerful institution claiming 40,000 members, and from 20 to 30 chosen medical officers, assigns that these worthy gentlemen shall attend each member for less than 1s. 10d. per annum (families being admitted for 1s. per month).

As a result of this underselling, some who are not medical officers to this commendable institution have been literally forced to associate themselves with clubs, medical aid societies, etc., and thus enter into unhealthy competition, however degrading the conditions. It should be for the medical officers of this provident dispensary to take the initiative, when I feel certain all holding clubs, etc., would amalgamate for the common good.

I might add, that upon approaching one or two of the medical officers aforesaid, they seemed in great fear of the secretary, and appeared to prefer to drudge on this state of sweating slavery than to risk a fall in their annual receipts. —I am, etc.,

ERNEST W. HAYDON, M.B.

Leicester, Dec. 14th.

MILK FOR DIABETIC PATIENTS.

SIR,—Will you kindly allow me to state that I have received a communication from Dr. A. E. Wright, in which I learn that in an interesting lecture delivered by him as Grocers Research Scholar at London University, he recommended a preparation of desaccharated milk very similar to that I described in the BRITISH MEDICAL JOURNAL of December 7th. We both precipitate caseinogen with acetic acid, wash, and filter; we differ only in the solution employed to dissolve the precipitated caseinogen. Dr. Wright recommends the following—a 1 per cent. solution of the following admixture of salts:

Sodium chloride	11.5 parts	Magnesium citrate	4.4 parts
Potassium chloride	9.6 "	Bicadium phosphate	5.0 "
Monopotassium phosphate	13.4 "	Tricadium phosphate	9.6 "
Impotassium phosphate	100 "	Calcium citrate	25.5 "
Crystalline potassium	5.5 "	Calcium oxide	5.5 "
Magnesium phosphate	4.0 "	Sodium carbonate	40.0 "

May I also draw attention to another and similar plan which no doubt has occurred likewise to many others—the separation of sugar by dialysis? Milk is first heated in a hot water bath and then poured into tubular parchment dialysing paper, and the whole placed in a vessel filled with tap water, the water being kept running by means of a tube connected with a tap, the tube ending in a piece of glass tubing long enough to reach the bottom of the vessel, so that it is supplied from the bottom. In about three days Mr. Martindale and Mr. Lee found that the sugar is reduced to one-sixth. If the milk be again heated to destroy germs and the dialysis proceeded with all the sugar can be withdrawn. —I am, etc.,

Camden Place, W., Dec. 9th.

SYDNEY RINGER.

THE NEW ERA IN INDIAN SANITATION.

SIR,—With reference to the article with the above heading, which appeared in the BRITISH MEDICAL JOURNAL of December 7th, I write to say that so far back as in 1891 I wrote a pamphlet entitled *The Hygienic Conditions of Indian Cantonments, and the Necessity for Sanitary Legislation*, in which I advocated the separation of the sanitation of the army and of military cantonments from that of the civil population, also

many of the other sanitary reforms which were so strongly urged by Mr. Ernest Hart, D.O.I., in his address to the Medical Congress held at Calcutta in December, 1894.

My pamphlet was submitted to the Government of India for legislative action, but a more powerful voice was required to obtain official action. "One man sows and another reaps" is a matter of everyday experience, and I do not complain.

May I ask the favour of the insertion of this letter in the next issue of the JOURNAL as a subject of some historical interest in the progress of Indian sanitation? I rejoice to know that the action of Mr. Ernest Hart, backed up by our powerful Association, has been so successful for improving the health of our army in India, and of the teeming native population of that country, has thereby become a question of "practical politics."—I am, etc.,

W. HILL CLIMO, M.D.,
Brigade Surgeon Lieutenant-Colonel,
Army Medical Staff (Retired).

Aldeburgh, Dec. 9th.

* * Our correspondent has omitted to notice the important part taken by Dr. Simpson, of Calcutta, in bringing about this reform.

THE COUNCIL OF THE ASSOCIATION AND THE GENERAL MEDICAL COUNCIL.

SIR,—As your report of the recent proceedings of the General Medical Council is necessarily somewhat condensed, I should be glad of an opportunity of stating somewhat more fully the circumstances attending the Council's action concerning certain resolutions of the annual general meeting of the Association. It is important that the documents in which these resolutions were communicated should be set forth at length. I give them here as they appear in the minutes of the Executive Committee:

S. Read: The following communications from the British Medical Association:

(a)
"British Medical Association,
"General Secretary's Office,
"499, Strand, London, W.C.,
"November 4th, 1895."

"Sir,—I forward to you subjoined herewith copy of resolution passed by the Council on the 23rd ultimo, together with copy of resolution passed at the annual meeting on July 31st referred to:

"I am, yours obediently,
"FRANCIS FOWLER, General Secretary."

"The PRESIDENT of the General Medical Council."
"Resolved: That the General Medical Council be informed that the annual meeting has passed this resolution, and that the Council of the Association has under consideration the means for giving effect to the recommendation."

"(Passed at the annual meeting, July 31st.)

"That as Sections 7 and 8 of the Medical Act, 1886, provide for the election of only five direct representatives to the General Medical Council by the registered medical practitioners resident in the United Kingdom; and as Section 10, subsection 1, paragraph C of this Act provides that the General Medical Council may represent to the Privy Council that it is expedient to confer upon the registered medical practitioners resident in any part of the United Kingdom the power of returning an additional number of direct representatives to the General Medical Council; and as the General Medical Council has in November, 1892, in November, 1891, and in November, 1892, refused absolutely to make such representation; and as the number of registered medical practitioners has increased from 22,713 in 1870, to 32,634 in 1894; and as we medical practitioners were not given our due and proper number of direct representatives in 1888; and as the registered practitioners contribute all the income of the General Medical Council by which the Medical Acts are administered, while the twenty universities and colleges represented on the General Medical Council do not contribute any income to it; and as the representatives of the universities and colleges are elected to the General Medical Council by their small conventions, senates, and councils, and not by open vote of all their medical graduates only, and as other important councils, having similar but larger duties to the General Medical Council (such as the Councils of the Incorporated Law Societies of England and of Ireland, the Councils of the Pharmaceutical Societies of Great Britain and of Ireland, and the Council of Veterinary Surgeons), consist of direct representatives only, this Association instructs its Council to take immediate steps to have a Bill introduced into Parliament providing that the registered medical practitioners in England and Wales be empowered to elect five additional direct representatives, the practitioners resident in Scotland one additional direct representative, and the practitioners resident in Ireland one additional direct representative to the General Medical Council."

(b)
"British Medical Association,
"General Secretary's Office,
"499, Strand, London, W.C.,
"November 4th, 1895."

"Sir,—I am directed by the Council of the 23rd ultimo to forward to you copies of resolutions passed at the annual meeting of the Association held in London on July 28th and 31st; the first on the subject of the registration of medical, surgical, and midwifery nurses, and the

second resolution upon the question of the admission of students to their Final Examination after being present at a certain number of conferences.

"I have the honour to be, Sir,
Your obedient servant,
"FRANCIS FOWER."

"The President of the General Medical Council."

"That we, the members of the British Medical Association, while anxious to improve the training and supervision, and, if need be, to support a practical scheme for the registration of medical, surgical, and midwifery nurses, unhesitatingly condemn any proposal which has for its object the formation of a class of medical or surgical or midwifery practitioners other than those recognised under the Medical Act, 1858, as now existing."

"That we view with deep concern and regret the recommendation of the General Medical Council to the medical examining bodies that they should admit students to their Final Examination who present a certificate stating that they have 'conducted personally' only three, and 'been present at' only three conferences, and as the General Medical Council has refused in November, 1895, to alter this recommendation, we instruct our Council to present to the General Medical Council to recommend that no student be admitted to his Final Examination until he presents a certificate showing that he has personally conducted at least thirty conferences under the direct supervision of a registered medical practitioner."

Received. That these communications be received and entered in the Minutes.

The first resolution of the annual meeting (July 31st) is a long statement ending with an instruction to the Council of the Association "to take immediate steps" to procure by Parliamentary action certain changes in the constitution of the General Medical Council, on the ground, among others, that that body had on various occasions "refused absolutely" to make such changes by their own action. It does not ask the General Medical Council to reconsider their refusal; it "appeals to Caesar." The Council of the Association, by their resolution, simply agree to give certain information to the General Medical Council by way, presumably, of courteous notice. They express no opinion as to the soundness of the views of the annual meeting, but they so far accept the "instruction" that they take into consideration "the means for giving effect" to the annual meeting's wishes.

On November 26th, Sir Walter Foster moved in the General Medical Council, Mr. Whitehouse seconding:

That a committee be appointed to consider the resolution of the British Medical Association, and to report thereon to the Council at his session.

I ventured to point out that it was practically impossible for the Council "to consider the resolution" as it stood. The annual meeting represented those members only who happened to be present in person. The Council of the Association alone were entitled, by virtue of their representative character, to speak in the name of the Association, and the Council had not spoken. Moreover, the resolution was in effect a menace to the General Medical Council; it was not an ultimatum, but a declaration of war. No place was left for repentance, should the Council hitherto recalcitrant be now inclined to relent. Parliament was to be moved to overrule the Council; the Council could do nothing but abide the event. There was nothing for a committee to consider. Had the Council of the Association informed the General Medical Council that, before taking steps to introduce a Bill, they desired the latter body once more to go into the question at issue, I am sure that their wish would have been courteously considered. But there was no evidence of such a desire in the documents submitted. The General Medical Council adopted the attitude I have indicated, and by 21 votes to 7 said in effect, "The persons present at the annual meeting have appealed to Parliament, to Parliament they must go."

The second communication, dated November 5th, was in a different case. The annual meeting here "instruct" the Council of the Association to present a petition to the General Medical Council, praying for certain changes in the recommendations in respect of training in midwifery. The Council of the Association sent up, not a petition, but a copy of their "instructions," without a word of comment! The natural inference was that the Council did not approve of the "instruction." They did not endorse it, they did not obey it. When, therefore, Dr. Glover proposed that the "petition of the British Medical Association" should be granted off-hand, it became necessary to point out that no such petition appeared to be in existence. To take action on the mere resolution of the fortuitous concourse present at a particular time during the annual meeting, unsupported by the Council of the Association, was in effect to offer a slight to the repre-

sentative body at the instance of the non-representative gathering. The inevitable result was that Dr. Glover had, with pardonable reluctance, to withdraw his motion.

Between Tuesday and Saturday the Council of the Association apparently considered the question again and did decide to endorse the resolution of the meeting. The result was that a "petition" in their name, duly attested by the President and the General Secretary, was presented and printed in the agenda of the General Medical Council. It was at length possible to feel that we had something of tangible authority to deal with, and I had great pleasure in seconding Dr. Glover's proposal that the petition should be considered and reported on by the Education Committee.

I have trespassed too much on your valuable space; but I think it of importance to remove misapprehensions on a question affecting the relations of two important bodies each in their way representing the profession—the Council of the British Medical Association and the General Medical Council. The formalities of communication usually observed between such bodies are not idle: they are necessary for smooth working and mutual respect. Nothing was gained, much was in danger of being lost, by their relaxation in the present instance.—I am, etc.,

Cambridge, Dec. 4th.

DONALD MACALISTER.

THE BRITISH MEDICAL BENEVOLENT FUND.

SIR,—May I ask you kindly to allow me to acknowledge the following additional donations to the British Medical Benevolent Fund through your columns?

	£	s.	d.		£	s.	d.

Mr. Herbert Allingham	...	3	2	0	Carlsruhe	...	100 0 0
Dr. Gervis	...	10	10	0			

I am, etc.,

Brook Street, W., Dec. 11th.

W. H. BROADBENT.

ST. LUKE'S HOSTEL.

SIR,—On being requested to assist in starting the Hostel of St. Luke, I hesitated at first, as I feared that this might be another attempt to exploit the medical profession for the benefit of those who could well afford to pay the ordinary fees for attendance. When, however, I became acquainted with the principles on which it was proposed to conduct the hostel, I at once gave in my adhesion. Herewith I am sending to you the rules and the certificates required to be filled in by the applicants. From these you will see that three classes of patients are received: Class A, absolutely free; Class B, those who pay towards their board, but receive free medical and surgical attendance; Class C, those who pay both for board and also for attendance. No case is admitted without a statement from some independent person as to the pecuniary position of the applicant, and a certificate from his medical attendant that in his opinion the case is a suitable one. These certificates have to be passed by the House Committee, which consists of two clergymen, one layman, Dr. Champneys, and myself. I should like to take this opportunity of saying how anxious my non-medical colleagues on the House Committee have been to see that medical attendance is paid for whenever the position of the applicant permits. Paying patients are quite at liberty to select any member of the profession to attend them, so that the hostel is in no sense to be regarded as being run for the benefit of the staff; as a matter of fact, most of the paying patients have called in outside help. The visiting medical officer receives an honorarium. I therefore maintain that by the establishment of this hostel fees which would otherwise go into the pockets of the profession are not diverted, but that many patients have been kept out of the wards of general hospitals.

I have only to add that I have been painfully struck by the extreme poverty of many of the patients who have been admitted, and the uncomplaining way in which they have battled against illness until quite broken down.

The Committee will be very glad if any members of the profession will pay the hostel a visit; the address is 13, Nottingham Place, W.—I am, etc.,

Wimpole Street, Dec. 11th.

F. DE HAVILLAND HALL.

THE SCHOTT TREATMENT OF HEART DISEASE.

SIR.—No one has read with greater interest than I the correspondence which has been evoked by Dr. Sandby's important paper on the Schott treatment of heart disease, and I feel sure that many of your readers share with me a sense of obligation to Dr. Poore for the mathematical formula which he offers for the approximative estimation of the actual shrinking of a dilated heart which is represented by the remarkable and rapidly induced diminutions of area of dulness which have been attested by so many observers that their reality has been placed beyond the range of reasonable question. That such shrinkage may be actually less than the diminished area of dulness would at first sight suggest Dr. Richard Greene's acute anatomical reasoning makes sufficiently clear; but, as he well remarks, clinical facts far outweigh both explanations and objections. Indeed, the restoration to health, in the course of a few weeks, of sufferers who have been treated for months or years with little or no success by the methods which have hitherto held the first place among therapeutic resources is one of those facts which is too stubborn to admit of cavil, however wide the field which it may offer for discussion and explanation.

It must, however, be said that Dr. Poore's reasoning on the subject of lung expansion seems to be based on a misconception of the views which have been advanced by Dr. Schott and his followers. Unless I misunderstand Dr. Poore, he is under the impression that it is contended that "the lungs undergo no extra expansion." Such is not the case. What is contended is that the migration of the apex beat towards the mesial line is not the result of an overlapping of the pulmonary margin induced by more complete inflation of the lung.

The argument which I adduced in a communication to the *BRITISH MEDICAL JOURNAL* in March last appears to me to be conclusive on that point; for the interposition of an air cushion of inflated lung tissue, however thin, between the apex and the chest, would of necessity diminish the force of the blow communicated to the thoracic wall, whereas the opposite is the case. If the apex beat be modified, as it often is, it increases in force. Moreover, it appears to me that the argument deduced from the greater weight which would be incumbent on the lower lobes in consequence of the inclination of the body of the bather is not consistent with the results of clinical observation. The apex beat is never verily depressed as the result of the baths or the exercises, but it may be frequently noted to rise obliquely in the direction of the sternum.

The inference, therefore, is that the lungs, by inflation, advance passively to occupy the vacuum which would otherwise be created by the shrinking heart. As a matter of fact, it is not uncommon for the patient to volunteer the remark that he can breathe more deeply, and in such cases the respirations are found to have diminished in frequency. On the other hand, Dr. Schott would be the last to contend that deeper inspirations do not, in their turn, assist a burdened heart to expel the contents of its distended chambers.—I am, etc.,

W. BEZLY THORNE,

Upper Brook Street, Dec. 2nd.

CHITRAL RELIEF FORCE.

SIR.—In the *BRITISH MEDICAL JOURNAL* of October 19th a letter appears under the above heading, signed by Staff-Surgeon Kirker, R.N., in which he refers to an article of mine published on August 10th, entitled "Waterborne Typhoid." In that contribution I tried to draw attention to the common fly as a probable carrier and disseminator of morbid products.

Your comments at the end of Staff-Surgeon Kirker's letter are I think apt to be misunderstood, hence I take this earliest opportunity of asking you to kindly elucidate them. You state that "Dr. Battersby's observations are of course theoretical, and based on the hypothesis of *omne ignotum*." I do not think this expression is quite correct, as I am as much a believer in the waterborne theory of enteric fever and cholera (under certain circumstances) as you are, but as the result of practical experience and personal observation, I am strongly impressed with the belief that in certain outbreaks their primary causes have to be looked for. With reference

to the common fly, my theory is based upon the argument by analogy. Having witnessed the marvellous manner in which the cholera bacillus is capable of multiplying on agar jelly within a few hours of inoculation, I say it is probable that the typhoid organism may do likewise when implanted by flies on suitable pabulum. Since my letter of August 10th, I have read an account in which some of our Continental friends have actually demonstrated the existence of typhoid bacilli in the defects of flies previously fed on typhoid excreta. So after all my observation may not be so theoretical, nor based upon the hypothesis of "*omne ignotum*."—I am, etc.,

Rawal Pindi, Punjab, Nov. 11th.

J. BATTERSBY, M.B., D.P.H.,
Surgeon-Major, A.M.S.

THE SECRET OF CENTENARIANISM.

SIR.—In your criticism of Sir B. W. Richardson's recommendation of total abstinence as one of the conditions for longevity, you state that "a strictly temperate use of alcohol tends to prolong life," and you cite Sir George Humphry's statistics of centenarians and octogenarians as showing that abstainers have "only a slight advantage in point of longevity over the non-abstainers." I wish to point out that these statistics are overwhelmingly in support of the advantage of total abstinence. Thus, of 45 centenarians, 12 were abstainers and 33 were moderate drinkers. These numbers must not be compared together, but with the number of the class from which each was taken. The number of abstainers 100 years ago must have been very small, probably not 1 per cent. of the population, yet these furnish more than 26 per cent. of the centenarians. The same reasoning applies to the 689 persons between 80 and 100. The abstainers supplied 12 per cent., while it is noted that a considerable percentage besides took very little and not regularly. It is perfectly clear that if the whole population had been abstainers for the last 100 years, the number of centenarians would have been enormously greater than it is, and with the spread of total abstinence we may reckon on an increase in their number and of the average age at death. This can only operate gradually, but every one who abstains from intoxicating liquors is surely helping to increase his own longevity and that of his posterity who walk in his steps. I need hardly say that the statistics of life insurance societies entirely support Sir Benjamin's dictum.—I am, etc.,

J. JAMES RIDGE,

Honorary Secretary British Medical Temperance Association.

SIR.—In the annotation on "The Secret of Centenarianism" in the *BRITISH MEDICAL JOURNAL* of November 30th, I read: "The most trustworthy statistics on this subject are those of Sir George Humphry. Of 45 cases of centenarians collected by him only 12 were total abstainers, while 33 were moderate drinkers, and 3 were heavy drinkers," going on to say, "the abstainers would appear from these figures to have only a slight advantage in point of longevity over the non-abstainers."

Sir George Humphry found that between 80 and 100 of the abstainers were a fraction over 12 per cent., whilst the percentage of abstainers amongst the centenarians had risen to 26 per cent., rather more than "a slight advantage." If we knew the proportion of abstainers between 50 and 60, 60 and 70, 70 and 80, 80 and 90, and 90 and 100 we would have material which would show whether it is or is not the case that the proportion of deaths amongst non-abstainers are in all periods higher, and that therefore the percentage of abstainers would steadily increase with age. The statistics of Sir George Humphry, as far as they go, support the affirmative.

Your annotator also says that "what evidence is available on the subject seems to show that a strictly temperate use of alcohol tends to prolong life, for the excellent reason that it assists digestion and therefore promotes health." I am deeply interested in the subject but do not know any evidence to the above effect.

Finally, may I recommend your readers to a leading article dealing with this matter in the *BRITISH MEDICAL JOURNAL* of October 19th?—I am, etc.,

Dublin, Nov. 30th.

E. MACDOWEL COSGRAVE, M.D.

REGISTRARS AND DEATH CERTIFICATES.

SIR.—The Registrar-General approves of the conduct of the Holloway Registrar in refusing to accept as reliable or sufficient evidence of the cause of death my certificate given in the case already recorded in your columns. Now, sir, I think I am justified in supposing that the registrar reported the case to the coroner on the usual form, a copy of which is in my possession. If he did so, then I say emphatically that if this document had been published so as not to be protected by "privilege," I should at once have brought an action for libel against the author. This being so, I can only say that when inquiry showed that there were no grounds for refusing my certificate, there was no honourable course open to the Registrar-General's department but to apologise to me.

The Registrar-General contends that the registrar acted according to his instructions in reporting to the coroner a case of "death after operation." If so, then a registrar who fails to report such a case should be censured. Will the Registrar-General do this? If so, I will at once supply him with the requisite information. He knows he will not.

No reasonable man believes for a moment that the registrar reported the case to the coroner on any other ground than the suspicion of an "illegal operation." Many people have told me that they understood this to be the ground for refusing my certificate. The relatives of the girl told me they believed this.

The law would enable me to punish such an imputation if it originated without the protection of "privilege." I should have a remedy if a charge of the kind were made in a police court, as it would have to be sworn to, and so on. It would seem, however, that under the present involved system of registering and inquiring into causes of death there is nothing to prevent registrars from finding "mares' nests," to the detriment of medical men, except the fear of "horse-whipping."

I do not for a moment believe that my character will suffer from what I and others regard as the highly improper action of the Holloway registrar; but it is more than likely that some even of your readers may think that there may have been some reasonable grounds for suspicion, or the Registrar-General would hardly try to justify the action of his subordinate as he has done. I therefore publicly challenge the Registrar-General to prove that the Holloway registrar had any reasonable grounds for refusing my certificate (outside his own ignorance). If the Registrar-General cannot do this, I call upon him to say so publicly. If he does not respond to this challenge, his department must stand convicted of having unnecessarily and recklessly brought upon a respectable medical practitioner a false imputation of the worst kind; and the medical profession will have to face the fact that the certificates they are compelled to give without payment place their characters at the mercy of any registrar who is suffering from detective aspirations.—I am, etc.,

Hilgiate, Nov. 25th.

IRON WOODS.

DR. CALMETTE AND PROFESSOR FRASER ON SNAKE POISON.

SIR.—In reference to the statements contained in Professor Ray Lankester's letter in the *BRITISH MEDICAL JOURNAL* of December 7th, I have to point out that no claim of priority has ever been advanced by me. Hitherto my communications have been of the nature of preliminary statements, and in such communications it is neither possible to enter into details of the work done by others on the same subject, nor usual to attempt to do so. On each occasion in which I have described the results of my experiments, I have briefly referred to all previous workers on the subject in so far as they were known to me, and in particular I have definitely mentioned or otherwise drawn attention to the fact that before I had done so, Dr. Calmette had published evidence showing that animals could be immunised against snake venom, and that the blood serum of these animals possessed antidotal properties. At the same time the work done by me was absolutely independent in its conception. It was originated several years ago, and has been carried out on a plan and with aims which were formed independently of the work of any other experimenter. That part of it which has as yet been described in the published abstracts had for the

most part been completed before Dr. Calmette's first paper announcing successful immunisation had come to my knowledge. I need scarcely add that I entertain a high opinion of his work.—I am, etc.,

Edinburgh, Dec. 6th.

THOMAS R. FRASER.

SIR JOSEPH FAYRER AND ZENANA WORK IN INDIA.

SIR.—Will you kindly give me space to ask the following questions and make the following statements with regard to the assertions made by Sir Joseph Fayrer in his speech at the Royal College of Physicians to the effect that, "so far as his experience went, there was no difficulty in the way of medical men entering the most jealously guarded haem when there was need for their services." And again: "There is scope for educated women to instruct native women in the principles of prevention of disease but no need of them as doctors." If these statements are correct, how is it that the Countess of Dufferin Fund has grown to its present proportions, and why is the scheme bearing that name so warmly supported by the Indian gentry? They, at least, seem to want women doctors for their women.

I presume that Sir Joseph Fayrer bases his beliefs on a few exceptional cases where, under circumstances of great urgency, family affection has won the day, and, contrary to tradition and usage, a European surgeon has been called in to see a zenana inmate, and has even operated on her, but these are rare occurrences. How many civil surgeons have actually seen the ladies for whom they have prescribed, and what percentage would such cases be of the entire number of the secluded?

When a civil surgeon has a patient who needs special examination, he calls in the aid of the female hospital assistant, and on her report the advice is based. In the course of six and a-half years of work in connection with the medical mission at Lucknow I have myself been frequently called in consultation by the civil surgeon when he had a case that needed more skilled investigation than the hospital assistant was capable of making, and generally on these occasions the conduct of the case was handed over to me.

If the zenana system were to be abolished at one stroke, it would be quite impossible for the medical men at present in the country to attend more than a mere fraction of the liberated population, for the women who are secluded in zenanas number many millions. But we must face facts as they are. For all practical purposes the zenanas of India are still closed to male surgeons and physicians, and the attendance the ladies receive at the hands of the native *dais* is worse than useless and often cruel.

The women of India have appealed to their British sisters to bring them help in their times of sickness and dire need, and it only remains for the women of Britain to rise and answer the call. To do so efficiently they must fully equip themselves as physicians and surgeons, and be ready to practise as well as to instruct.—I am, etc.,

Adolph Terrace, Dec. 10th.

JANE L. J. HASKEW, M.D. BRUX.

THE LEPROSTATION ON ROBBER ISLAND.

SIR.—In consequence of our having seen the paragraph in the *BRITISH MEDICAL JOURNAL* of October 25th relating to Dr. Impey and the alleged cure of leprosy, we consider that you should be made aware of the following circumstances, which you are at liberty to publish.

1. That since February 15th, 1895, Dr. Impey has had absolutely nothing whatsoever to do with the Leprosy Institution on Robber Island, and in proof thereof we forward you a copy of an official letter received from the chief official of the island at that time, Dr. Impey having been dismissed in January, 1895.

2. For nearly two years previously to February, 1895, Dr. Impey has visited the leper wards solely in an administrative and not in a medical capacity, and then only at very rare intervals.

3. For further information as to why Dr. Impey was deprived of the sole administration of this institution which exists entirely for medical reasons and the control vested in a layman, and as to why, in the second place, he was deprived of any supervision, medical or otherwise, of the Leprosy Institution.

tion in particular, we beg to refer you to the reports of the Cape Leprosy Commission, which are no doubt already in your hands, after the perusal of which you will doubtless arrive at a fitting conclusion.—We are, etc.,

ARTHUR J. H. THORNTON, M.B. Dubl. Univ.
P. EVERARD TODD, M.B., C.M. Edin.

Robben Island, Nov. 16th.

[CONT.]

Acting Commissioner's Office,
Robben Island,
February 18th, 1896.

REARRANGEMENT OF DUTIES OF MEDICAL OFFICERS ON ROBBER ISLAND.

SIR,—I have the honour to inform you that the Under Colonial Secretary, by letter No. 3183H of the 14th inst., approves of the following changes in the Medical Staff:

Dr. Impoy to be Medical Superintendent in charge of the Male and Female Lunatic Asylums. Dr. Todd to be Medical Officer in charge of the Male and Female Loper Wards and Convict Station, having Dr. Thornton as an assistant. These changes will therefore take place from the morning of February 18th.

I have the honour to be, Sir, your obedient servant,

H. A. JENNER, Acting Commissioner.

Dr. P. E. TODD, M.B., Robben Island.

WATERBORNE TYPHOID AT DUNBAR.

SIR,—It may interest you to know that at the inception of the Spott water scheme for this town more than twenty years ago, I protested against the burn water being used, and I advised that the springs about the farm of "Kalls" should be impounded instead.

The analysis of the burn water was by no means a bad one, but being an open stream with several communities dwelling close upon its banks, it would, I argued, always be open to contamination, and therefore unsafe as a supply source. What I feared has happened, although the Dunbar community may be thankful that they have had so long a period of immunity.—I am, etc.,

Bedford Park, W., Dec. 8th.

DAVID JAMES, M.D.

P.S.—I had frequent opportunities, on my professional rounds, of observing the filth thrown upon the banks of the stream, which filth was certain to be washed down to the reservoir as soon as heavy rain fell.—D. J.

RE THE DEBATE ON A POSTURE IN ANÆSTHESIA.

SIR,—In all cases of anæsthesia experience has led me to consider the orthodox mode of raising the trunk and legs a mistaken one, as adding embarrassment to the dilated heart by not only increasing thoracic blood pressure, but by allowing the abdominal viscera to roll against the diaphragm. Indeed in cases of impending syncope in other instances even quiet walking about often relieves more than resting still or lying down.

The indication, it seems to me, is to lower the head and thorax only, not the head alone, so as to avoid tracheal constriction. This can be done by means of an inclined plane, and by a table I have made myself.

I wonder why so called "mixed narcosis" is not now used in nervous cases as a means of deadening reflexes—I allude to the hypodermic injection of morphine and atropine or the plethoric glass of brandy or two given before anæsthesia, which were once used.

There is a curious condition of irregularity met with generally in the dog's heart, which I presume others have noticed likewise, which may have some interest in connection with these experiments.—I am, etc.,

Finsbury Pavement, Nov. 14th.

JAMES MACMUNN.

THE CHILDREN'S INCUBATOR.

SIR,—Having seen in the BRITISH MEDICAL JOURNAL of November 16th (page 1260) a paragraph on the contemplated provision of an incubator at the Liverpool Workhouse, with your comments on Hearnson's and Auvard's systems, I should suggest to you the latest type devised by Mr. Lion, which has met with general approval at Marseilles, Lyons, and Paris. I have had the opportunity of examining it here in this town, where in a large room eight or ten incubators are kept for the general public. The expenses are met by small fees, voluntary contributions aided by the Town Council, as a set-off to the destitute parents who are unable to give pecuniary help.

The main features of this incubator are:

1. The incubator is entirely composed of galvanised sheet iron, which therefore can be easily disinfected should this be necessary. Its dimensions are: height, 0.70 cm.; length and breadth, 0.55 cm.

2. The ventilation is effected by a row of holes at the lower part of the apparatus and another row at the top; besides, there is a ventilating shaft (0.10 cm. diameter) fixed in the roof, which can be connected with the exterior of the room or house.

3. The temperature is kept up by a Bunsen burner beneath a reservoir containing 12 litres of water, from which metal coils pass into the apparatus to heat the air; the feeding required is insignificant and obviates the inconvenient changing of hot water bottles or larger reservoirs as in Auvard's invention. The regulation of the temperature is automatic, by a simple expedient depending upon the variation in volume of a column of air altering the position of a column of mercury, which in its turn allows more or less gas to reach the Bunsen burner.

4. For further security there is a detachable small arrangement consisting of a dry battery connected with a thermometer and an electric bell; the variation in temperature is transmitted by a movable needle placed between two commutators; should the mercury depart from the mean range of temperature the needle comes into contact with one of the commutators and the bell rings.

To this summary of advantages I may add that the apparatus is easy to put into working order, and has been very favourably reported on at the Paris Academy of Medicine by Professor Pinard. The price of the incubator in galvanised sheet iron is about £18, in wood about £9; these figures I have obtained second hand, as Mr. Lion is away at present and I have not been able to make his acquaintance. No doubt for hospitals the price would be materially modified.—I am, etc.,

Nice, Nov. 18th.

J. EGERTON BRANDT, M.D.

A FIXED RATE OF PAY FOR EXAMINING CANDIDATES FOR LIFE ASSURANCE.

SIR,—After Dr. de Havilland Hall's statement that a discussion on this subject was ruled out of order at a recent meeting of the Life Assurance Medical Officers' Association, there can be little doubt that the time has now arrived when the question should be considered by the members of the British Medical Association.

The difficulty seems to be to fix a minimum fee for policies of small amount. I wrote to some of the principal companies in Great Britain—about 30. A few refused the information I asked for; the remainder may for convenience be classed in three groups:

A. Offices which pay a minimum fee of £1 ls. on all proposals of £100 and upwards. They were 12 in number, and their names deserve to be known:

The Western Life	The National Provident Institution
The Prudential (ordinary policy)	The Scottish Widows
The Eagle	The London Assurance Corporation
The University	The Equity and Law Life
The Metropolitan Life	The New York Mutual
The Legal and General Life	The London Life Association.

B. Offices—7 in number—which pay a fee of 10s. 6d. on proposals under £250, and £1 ls. on sums above this.

C. Offices—6 in number—which pay a fee of 10s. 6d. on sums under £500, and £1 ls. on sums above £500.

So that, out of 31 offices, 12 pay a minimum fee of £1 ls. on £100 proposals, and 13 pay a fee of 10s. 6d.

The nature of the information required from the examiner varies. Some companies go very carefully into the question of family history and trivial ailments, others leaving this almost entirely to the discretion of the examiner; others, again, ask for full information as to personal habits, consumption of tea, tobacco, etc.; all require a careful examination of the urine for sugar albumen. Is 10s. 6d. an adequate fee for such an examination and report? A professional brother of some forty years' experience tells me that in his younger days the lowest fee offered was £1 ls. An authoritative statement that the minimum for which a member of the Association would conduct an examination was £1 ls. would soon lead to a levelling up movement amongst the more important societies. The examination for industrial

policies is somewhat different; the same amount of information is not required, and rarely is an examination of the urine asked for.

I make it a practice to decline examination where the fee is not £1 1s. In country practice advice is usually sought from the medical attendant as to the status, etc., of various offices by intending assurers.—I am, etc.,

J. DICKINSON LEIGH, M.B., L.R.C.P., L.R.C.S.E.

Bristol, Nov. 9th.

MEDICAL "ENGLISH AS SHE IS WROTE."

SIR.—As chief medical officer to two assurance companies it falls to my lot to see a good many specimens of the "English" of my professional brethren whose "reports" on proposers I supervise. Seldom has anything richer in the way of orthography fallen under my notice than the following misspellings, all of which appeared in a single "report" perused by me this morning. Anemia is spelt "anemia," erythema is turned into "erethyma," and phthisis blossoms out in "phythisis." The only other strictly technical term in the whole report is the word "paralysis," and that happens to be spelt correctly. The medical examiner who perpetrates these orthographical jokes appends M.D.Lond. to his name. Surely the "schoolmaster" must be very much "abroad" at Burlington House.—I am, etc.,

London, Dec. 8th.

VERBUM.

JOHN HUNTER'S FAMILY.

SIR.—I have compared the dates given in Mr. D'Arcy Power's interesting letter in the BRITISH MEDICAL JOURNAL of December 7th with those in the Hunter Family Bible, which is now in the possession of the Royal College of Surgeons. The only difference in the dates is that Agnes is said by Mr. Power to have been born in 1716, whereas the Bible gives the year as 1717; John's birthday is February 7th according to the document published last week, and February 8th according to the Bible. This still further complicates the disputed point as to the day on which John Hunter was born. Sir Everard Home gives it as July 14th; this is explained by his having misread Hunter's handwriting. "Feby." in John's writing is not unlike "July," and it was thus read by Home. Otley says: "The parish register states February 13th to have been his birthday, but he himself used to date it on the day following, and it is on the 14th consequently that his anniversary is celebrated at the College of Surgeons." The entry in the register of births and baptisms for the parish of East Kilbride was as follows: "John a lawfull son procreat betwixt John Hunter and Paul, born Feby. 13th and baptised March 30th 1728."

It is quite plain that the valuable document printed by Mr. Power was written before 1783, as the date of William Hunter's death is not filled in; this date is given in the Bible, as is also the year of Dorothy's death, 1807. The Bible also contains the following record which is not without interest:

James Baillie and Dorothea Hunter.

Married 1756.

Their children.

	Born.	Died.
William	1757	1780
Agnes	October 24th, 1760	
Matthew	October 20th, 1761	1768
Joanna	September 14th, 1769	

On the same day with Joanna a female infant who lived only a few hours.

In the *Dictionary of National Biography* it is stated that Joanna's birth was premature. I do not know whether the fact that she had a twin sister has been recorded before.—I am, etc.,

Royal College of Surgeons, Dec. 6th.

JAMES BLAKE BAILEY.

THE GENERAL MEDICAL COUNCIL.

SIR.—On reading in the BRITISH MEDICAL JOURNAL the remarks of Sir Richard Quain as to the disabilities of the legal profession, I could not see that there was any reason for our being content with the present constitution of our Council. Some of us from Lancashire and Cheshire who

were present at its session in May last certainly were not favourable impressed with what we witnessed.

We certainly hope that those members of our profession who can visit the Council chamber during any session will avail themselves of the opportunity, for the public have free access, as they will then see how and by whom the business of the government of our profession in these realms is conducted.

As to Sir Richard's remarks about the number of direct representatives, many of us in this part of the country are of opinion that if we had had more we should have had a far more practical outcome of the investigation in reference to medical aid associations than we can find in their report on that question.

One effectual means of bringing the medical officers of such trading institutions into line would be to have an annual registration as in the legal profession that the president referred to. If the amount of the fee were 5s. the Council would have an additional income of about £8,000. This would provide us with ten additional direct representatives, and leave a large balance to be applied to some other useful purpose for the benefit of the profession at large.

It is not necessary to state at length the advantages that would be derived from an annual registration, but this one might be stated, that such men that I have mentioned would at once begin seriously to reflect that it would be absolutely necessary to put their houses in order. For the first year or two there might have to be a prolonged session of the Council or its executive to inquire into the reasons why certain men should not be again licensed to practise, or whether their licences should be endorsed both as a record and a warning, as is done by the magistrate in certain other licences. But as time went on and better discipline resulted, the extra sessions would become small matters, for members would always feel that they were under direct control and supervision of the General Medical Council.—I am, etc.,

Manchester, Dec. 7th.

G. H. BROADBENT.

SUPERFICIAL AFFECTIONS OF THE RED PORTION OF THE LIPS.

SIR.—After reading the interesting paper of Dr. Jamieson on Some Superficial Affections of the Red Portion of the Lips, I am sending you a short account of a case that occurred in my practice.

In the spring a young girl, aged 17, was under me suffering from anemia. During her illness she developed a soreness of the lower lip, which became dry, and a thick crust formed which on being removed left a red moist-looking surface, which was very tender. Several applications were tried both by the hospital (where she attended later on) and myself without any benefit. As one crust was removed another began to collect, and if not removed got very thick. The condition only affected the red portion of the lower lip. She is now attending the St. John's Skin Hospital, and is under Dr. Milton, who, I think, looks upon the condition as akin to eczema and lepra.—I am, etc.,

W. H. PAYNE, M.R.C.S., L.R.C.P.Lond.

Brockley, S.E., Dec. 10th.

SUPERSTITIONS AND CUSTOMS AS TO DEATH AND BURIAL.

SIR.—I am endeavouring to obtain for scientific purposes trustworthy evidence concerning customs and superstitions connected with death and burial, and it has been suggested to me that there are many medical men in villages and country places all over the United Kingdom who often come across odd old-world customs, sayings, and superstitions, especially among the peasantry and labouring classes, and who, if they knew that they were of value, would be glad to forward a note of them. You will be conferring a favour on me if you will allow me to make known through your columns that I shall be most grateful for any such information, and that I shall be happy to acknowledge the kindness of my correspondents in any use I may make of their communications.—I am, etc.,

E. SIDNEY MARTLAND, F.S.A.,

Hon. Sec. of the Ethnographical Survey Committee of the British Association, Editor of *Antiquary*.

Highgarth, Gloucester, Dec. 6th.

¹ Blank in the original.

PROPOSED HOSPITAL FOR CAMBERWELL.

SIR,—I learn from our local press that you have opened your columns to a correspondence upon the proposed general hospital for Camberwell. The philanthropic intentions of the proposers of this scheme have all my sympathy, but I fear that the scheme, if launched, would end in disaster. "More hospital accommodation should be provided for South London" we are told.

In Mr. Gladstone's letter, which lies before me, it is stated that there are 100 beds unemployed in Guy's Hospital from want of pecuniary means to keep them open, and that unless a considerable sum can be obtained a further closing of a portion of the hospital will have to be made. I learn that St. Thomas's Hospital is in a like crippled condition from want of means, having about 150 beds vacant.

Have the proposers of a general hospital for Camberwell any funds at their disposal? If so, is it not their obvious duty, and would it not be praiseworthy on their part, to utilise those funds in making once more available the accommodation already existing, but in painful idleness at Guy's and St. Thomas's? A new hospital would necessitate the acquisition of a site, erection of buildings, provision of beds, equipment and staff, involving a very large outlay, before a patient could be admitted.

Do the promoters of the scheme rely upon diverting subscriptions from already starving charities to effect their purpose? Where is their justification?

We have in our midst, in Havil Street, an up-to-date infirmary, with 450 beds under the care of an efficient medical and nursing staff directed by a resident medical superintendent. On the other side, in Constance Road, we have a sister institution with 808 beds, also having an experienced medical and nursing staff. We have two dispensaries—apart from the provident dispensary, which has been so deservedly commended in your columns—and we have eight district medical officers. In the face of these facts the general hospital scheme savours of an unmerited reflection upon the large-hearted and broad-minded local authorities. We are told that the institution is to benefit surrounding parishes. We do not need an institution here which would attract into Camberwell the *lazzaroni* of neighbouring parishes. Our own poor are groaning under a rate of 6s. 10d., and we do not wish to see their burdens augmented or the scanty beneficence which now reaches them diverted into another channel.

Mr. Jephson has sent you a copy of a resolution which was carried at a so-called public meeting in our Vestry Hall. The meeting was, in my opinion, a failure so far as local representation went.

I regret, for his own sake, that Mr. Jephson did not send you the vestry's own resolution upon the subject. I use the freedom of supplying his omission. I take it from the minutes of the vestry of August 14th, two months after the very public meeting.

"Report of the Finance Committee.—Your Committee has considered the reference to it from the vestry of a letter from Mr. Waugh, secretary to the Committee for the proposed General Hospital for South London, enclosing resolution asking the vestry to call a public meeting for the discussion of this subject. A letter has also been received from the London County Council stating that an offer has been received by the Council to take on lease the remainder of the surplus land in the Coldharbour Lane improvement with a view to erecting such hospital thereon, and asking the views of the vestry upon such proposal; recommending that the Council be informed this vestry is of opinion that the site is not a suitable one, and that pending the decision as to the same no farther steps be taken as to the vestry calling a meeting."

This recommendation was carried *nem. con.*, not in a thin public meeting, but in full vestry.

I fear that Mr. Jephson is not too well acquainted with this locality. I write as a resident in it of some years' standing, and whose membership of its Board of Guardians and vestry should tell him something of its requirements and resources.—I am, etc.,

Denmark Hill, S.E., Dec. 6th.

WHITWORTH ST. CKDD.

[See p. 684 Minutes.]

PRURITUS.

SIR,—Your valuable report on pruritus, with remarks of the distinguished dermatologists who took part in the discussion are not only interesting but an important contribution to cutaneous medicine. However, what has struck me as singular is the fact that not one of the speakers mentions the advantages of linen to be worn next the skin in itching or other irritable conditions of skin. The ordinary Irish linen probably is rather "cold" for winter wear. However, for years I have recommended Balbriggan "Flaxonia," especially the most porous kind. This linen is made from pure flax, is knitted in place of being woven, and improves with washing. It is far over silk or any cotton garment for comfort.—I am, etc.,

Belfast, Dec. 7th.

H. S. PURDON, M.D.

A NOVEL APPLICATION OF TENDON GRAFTING.

SIR,—Under the above heading in the *EPIGRAM* of November 30th, you describe as a new operation the grafting of part of the tendon of a healthy muscle into the distal end of the tendon of a paralysed muscle. I beg to refer you to a case of a similar nature which I showed at a meeting of the Lancashire and Cheshire Branch of the British Medical Association in June last, which was operated on in February, 1894, and fully reported in the July number of the *Liverpool Medico-Chirurgical Journal*.—I am, etc.,

Liverpool, Dec. 8th.

F. T. PAUL.

VENESECTION IN CHLOROFORM POISONING.

SIR,—In reading the constantly recurring accounts of death from chloroform, I have never noticed that bleeding the patient has been tried. As a rule, in these reports there is no account of a *post-mortem* examination, but in some of those reported I have noticed that the left ventricle is stated to be empty and the right full.

Now, it strikes me if the engorgement of the right side could be relieved there would be a much greater chance of the patient's recovery. The bleeding might be supplemented by galvanism to stimulate the heart's action. No harm, at any rate, would be done in bleeding, as none of the usual remedies have any beneficial effect, the patient always dying if the pulse ceases before the respiration. I should recommend opening the jugular vein as more directly relieving the heart.

Many years ago, when I was house-surgeon at the Children's Hospital, Shadwell, I noticed that at the *post-mortem* examinations of children dying from morbus cordis, the right side of the heart was engorged and the left empty, although just before death the child had been pale and not at all cyanotic. I determined to bleed in the next case of impending death in morbus cordis. A few nights later I was called to a child with morbus cordis—I forget the particular form—and found him pale, pulseless, and apparently in *extremis*. I opened the jugular vein, and with difficulty got the blood to flow, but after a very little blood had come the child roused up and seemed much relieved; by the next morning he was quite himself again.—I am, etc.,

Clapton, N.E., Dec. 2nd.

FRED. H. SPOONER, M.D.

OBITUARY.

ROBERT GORDON TATHAM, M.R.C.S., L.S.A.

WE regret to have to record the death on December 3rd, at the age of 66, of Mr. R. G. Tatham, of East India Road, an old and well-known practitioner of Poplar, where his family have practised for hard on a century. Mr. Tatham received his medical education at the London Hospital, and obtained the diploma of L.S.A. in 1851, in which year he joined his father, the late Mr. Christopher Tatham. He took the diploma of M.R.C.S. in 1856, and eventually succeeded his father as Surgeon to the Trinity House and to the East and West India Dock Companies. Mr. Tatham took a warm interest in all social and philanthropic work in the district in which he resided, and where he was much respected. He will be missed also by many friends at the Hunterian Society, of which he was at one time Vice-President. He was a Surgeon-

Lieutenant-Colonel to the Tower Hamlets (15th Middlesex) Rifle Volunteers, and received the Volunteer Decoration. Mr. Tatham had long suffered from mitral regurgitant disease, and the immediate cause of his death was dropsy. He was buried at Nunhead Cemetery on December 6th. He leaves a son, settled in Australia, and two daughters.

Dr. ANTONIO VERGA, of Milan, who died on November 21st, was one of the leading authorities on mental diseases in Italy. He was born at Freviglio in 1811, and studied medicine at the University of Pavia, where in due course he took his doctor's degree. After acting as assistant to the professor of anatomy (Panzani) he became physician to a private lunatic asylum. His subsequent professional career was passed in the practice of this department of medicine. He was director of various large asylums till 1885, when, visiting the Asylum of Siena for the purpose of lecturing, he received a blow from a patient which destroyed his left eye; he had lost his right eye as the result of a similar assault many years before. He contributed largely to the literature of his speciality; his writings include a monograph on the skull, and papers on *de-a-lia*, the relation of epilepsy to insanity, widowhood and insanity, the distinction between hallucinations and illusions, etc. Verga was at different times President of the Reale Istituto Lombardo di Scienze e Lettere, and of the Society of Temperance. He was a Senator of Italy, a Knight of the Legion of Honour, a Commander of the Brazilian Order of the Rose, and of those of the Crown of Italy and Saint's Maurice and Lazarus. In him Italy has lost a genuine philanthropist as well as an eminent physician.

Dr. J. DUNCAN MENZIES, R.N., who died on November 12th at the Royal Hospital, Portland, was only 34 years of age, but was a distinguished surgeon of the Royal Navy. For his services on board H.M.S. *Mappin* in 1890-91, during the expedition to the West Coast of Africa, he was awarded the Gilbert Elphinstone medal. He also served on board H.M.S. *Sanspareil*, *Starhunter*, *Swallow*, and others. He had recently been appointed one of the surgeons at the Royal Hospital, Portland. Dr. Menzies was the son of Surgeon-General Duncan Menzies, who so ably commanded the Medical Staff during the Crimean war, the British hospitals at Scutari being under his direction, where the wounded from the battles of Alma, Balaclava, Inkerman, and those daily from the field were treated by him with a care that has made his name to be remembered by the wounded.

Dr. RICHARD HODGES died on November 28th in Camden Road in his 75th year. He was admitted L.S.A. in 1844, and a Fellow of the Royal College of Surgeons in 1849 by examination after studying at St. Thomas's Hospital. He took the degree of M.D. King's College, Aberdeen, in 1853. He was awarded the Fothergill gold medal in 1861 for an essay on *Alumina* by the Medical Society of London.

Dr. Bruce A. Bannan died in Edinburgh on November 20th, at the ripe age of 78. His father was Acting-Governor in the West Indies, when, in 1817 Bruce A. Bremner was born at Dominica. He came to Scotland at an early age, went to school, and subsequently to the University at Aberdeen, where he graduated A.M. in 1857. He then went to Edinburgh for his medical education, and in 1860 he took the degree of M.D. and also the diploma of L.R.C.P.E., and was engaged in practice in Bombay for thirteen years. In 1863 he came home, living in Perthshire for a time. More than thirty years ago he settled in Edinburgh, where he has been a director of the National Savings Bank; and a vice-president of the Indigent Old Men's Society. He originated or helped to originate the Association for Improving the Condition of the Poor; and was a director of the Royal Edinburgh Hospital for Sick Children, and of the Edinburgh Medical Missionary Society. He devoted a large part of his life and energies to philanthropic work, and few men will be so much missed by so large a number of friends. He was a man of boundless sympathy and endless energy.

The death is announced of Dr. HENRY LAWRENCE, of 14, Berkeley Square, Clifton. He was a M.R.C.S. Eng. and L.R.C.P. Edin. In addition to other appointments he was public vaccinator and medical officer to several institutions.

Dr. A. J. WOLTOFF, Professor of Bacteriology in the University of Moscow, recently fell a victim to his devotion to scientific research. He infected himself with a virulent culture while experimenting in his laboratory, and died soon afterwards of the effect of the accident.

DEATHS IN THE PROFESSION ABROAD.—Among the members of the medical profession in foreign countries who have recently died are Dr. Ludwig Teichmann-Slawatski, formerly Professor of Anatomy in the University of Krakow, well known by his researches on the lymphatic system, aged 72; Dr. Almeida Couto, Professor of Clinical Medicine in the Medical Faculty of Bahia; Dr. Antonio de Carguiera Pinto, sometime Professor of Organic Chemistry in the same school; Dr. Ludwig Klemmeyer, Professor of Comparative Anatomy in the University of Basel; Dr. Adolph Morawski, President of the Medico-Philanthropic Committee of Moscow; Dr. Bourienne, Professor of Clinical Obstetrics in the Medical School of Caen; Dr. Julio Arthur da Silva Gomes, Surgeon to the San José Hospital of Lisbon; Dr. Tepljassin, of Kazan, a distinguished ophthalmologist well known by his writings; Dr. Francis Peyre Porcher, some time Professor of Materia Medica and Therapeutics in the South Carolina Medical College, and author of *Resources of the Southern Fields and Forests, Medical, Economic, and Agricultural*, aged 70; and Dr. Paulin Silbert, Chief Physician to the Aix (Provence) Hospital.

NAVAL AND MILITARY MEDICAL SERVICES.

ARMY MEDICAL STAFF EXCHANGE.

The charge for forwarding notices respecting *Bullbumps* in the Army Medical Department is 25 cts., which should be forwarded in stamps or post office order with the notice. The last post on Wednesday is the latest by which these arrangements can be completed.

A BENTON SURGEON-CAPTAIN A. M. S., at present stationed in Rangoon, wishes to exchange with an officer whose position on the roster would enable him three years at home. Advertiser arrived in India on December 2nd, 1904. State terms—Apply, Surgeon Captain Davis, c/o Messrs. A. Scott and Co., Rangoon.

THE NAVY

THE following appointments have been made at the Anniversary, November 1935: W. ANDERSON, Staff Surgeon to the General, December 65; WILLIAM BRYT, Surgeon, to the General, December 1935.

Staff Surgeon THOMAS ROBERT FORTNUM died at Marston, Natal, on December 3rd, aged 37. He was appointed Surgeon February 1904, 1905, and Staff Surgeon April 10th, 1908.

ARMY MEDICAL STAFF

The services of Surgeon-Captain H. N. Dukes have been placed at the disposal of the Army for employment in the European Army.

[illegible]

ARMY MEDICAL RESERVE

HUDSON CAPTAIN J. W. HUDSON, M. D., is promoted to the Surgeon Major, December 1894.

Sergeant Lieutenant James TAYLOR, M. D., 2nd Volunteer Battalion The Gordon Highlanders, is appointed Surgeon Lieutenant, 1st Oct. 1916.

INDIAN MEDICAL SERVICE.

The retirement of Nicholas S. ... Colonel P. A. Murray, ... Major ... and ... which was announced in the ... at ... of ... to ...

THE VOLUNTEER

Honorable Captain T. H. ...
Western Division,
December 11th.

Surgeon-Lieutenant W. B. MACKAY, M.B., 1st Volunteer Battalion the Northumberland Fusiliers, is promoted to be Surgeon-Captain, December 11th.

Surgeon-Captain R. G. GIBB, M.B., and Surgeon-Lieutenant J. T. WILSON, M.B., and (Berwickshire) Volunteer Battalion the King's Own Scottish Borderers, are promoted, the former to be Surgeon-Major, the latter to be Surgeon-Captain, December 11th.

Surgeon-Major W. HAMMOND, 2nd Volunteer Battalion the Duke of Cornwall's Light Infantry, has resigned his commission, with permission to retain his rank and honours, December 11th.

Mr. WILLIAM H. H. HANBURY, M.B., is appointed Surgeon-Lieutenant in the 1st Volunteer Battalion the King's Own Yorkshire Light Infantry, December 11th.

SURGEON COLONEL GROSS, Principal Medical Officer of the Scottish military district, died on Friday night, December 6th, in Edinburgh very suddenly. He was accompanying his son, a Lieutenant in the Derbyshire Regiment, stationed in Ireland, to the Waverley Railway Station. Becoming ill on the way, he was at once placed in a cab, where he expired almost instantly. He had had thirty years' service, most of which was passed in India.

PROMOTION IN THE A.M.S.

THE position of some of the Surgeon-Colonels as regards promotion at the beginning of the next financial year gives some food for reflection. After the retirement of Surgeon-Major-General CARAHAN, now P.M.O. in Ireland, on March 30th, 1895, and the promotion in his succession, some medical officers in surgeon-colonel's rank will not only have passed 60 years of age, but some will be very near the completion of that age. It is now generally understood that an officer of surgeon-colonel's grade who has completed 60 will not be likely, except under the conditions of "special ability and merit," to obtain promotion, seeing that he would not be able to complete three full years in surgeon-major-general's rank. It is futile to say that all the officers in surgeon-colonel's grade can claim promotion on these grounds. What then is to become of those who, through the circumstances of the recent numerous extensions in service granted, will have become debarred by age from attaining higher rank? Three officers of surgeon-colonel's rank will, on April 1st next have exceeded 60 years of age, and two will be within measurable distance of it. On looking over the *Army List*, there are four surgeon-major-generals to retire next year: one of these, for obvious reasons, may be excluded as being the best fitted, and likely, we hope, to be selected to succeed to the director-general's chair when the vacancy occurs on May 7th next. There is no reason why the tenure of the director-general's chair should exceed five years, and the appointment should be for the same period as other staff billets.

THE MEDICAL STAFF CORPS.

THERE is a rumour current at Aldershot that the Medical Staff Corps will only be employed at large stations where complete units can be kept together, and that in the smaller stations there will practically be a return to the regimental system in hospitals. It is said that the resources afforded examples of the non-cohesion of the units. Some of each unit were from Chatham, Woolwich, Netley, etc., and as a result confusion regarding rationing occurred.

THE RECRUIT AND HIS TRAINING.

THE current number of the *United Service Magazine* has an article by Brigade Surgeon-Lieutenant-Colonel CLIMO, who finds much in the recruit and his training that might be improved. He suggests verification of the ages of recruits, and the need of elementary drill and physical training being enforced in all Government grant-aided schools. If their inferiority of physique should continue, the writer recommends that the age of enlistment should be raised, the system of training altered, and the subjects of ration and clothing investigated. The clothing and equipment of the recruit are discussed. Brigade Surgeon CLIMO considers the most ration not nearly enough for a growing lad, much more so in a lad suffering from defective nutrition. The rations are not sufficiently varied in cooking.

THE GERMAN ARMY MEDICAL COLLEGE.

THE centenary of the foundation of training establishments for army surgeons was celebrated in the hall of the Berlin University on December 2nd in the presence of representatives of the civil and military authorities, the professors of the Medical Faculty, and more than one hundred army surgeons from all parts of Germany.

Dr. von Cöler, Chief of the Medical Department of the Prussian Army, delivered an address, in which he alluded to the achievements of German surgery, and the extension of the Army training system. The Minister of Ecclesiastical, Educational, and Medical Affairs addressed the meeting in the name of the Government, and the Rector spoke for the University. The Emperor sent a telegram to Dr. von Cöler expressing his regret at being unable to be present, and bearing grateful testimony to the unselfish and beneficent work of all the medical officers of the army, especially in the late war. He has issued a Cabinet Order directing that the Frederick William Medical and Surgical Institute and the Military Medical and Surgical Academy shall be united under the name of "The Emperor William's Academy for the Training of Army Surgeons." The order also recognises the great services of the establishments in question to the army and navy.

The Empress Frederick has presented a portrait of her late consort to the Academy.

THE VOLUNTEER AMBULANCE SCHOOL OF INSTRUCTION.

LIEUTENANT-GENERAL MONCRIEFF made the sixteenth annual distribution of prizes of the Volunteer Ambulance School of Instruction recently at Crosby Hall. The principal award was Surgeon-General Hamilton's Challenge Bowl, held by the London Rifle Brigade for the year. A team of the Civil Service, headed by Corporal A. B. King, which scored 222

points out of the possible 340; a team of the London Rifle Brigade, led by Private Fuller, 213 points; and a second team of the Civil Service, led by Lance Corporal Douglas, won the other prizes.

VOLUNTEER BRIGADE COMPANIES.

CRITIC writes: 1. Let surgeon-Captain Turtin consult the *Army List*, p. 35e, for brigades that have no bearer company. 2. The brigadier decides from what regiments the bearer company is to be formed. It would, perhaps, be best to form it from one regiment only, so that the men could drill together. 3. The personnel of the company remain part of their corps for discipline and otherwise; but it would be better to have them under the medical officer and the direct orders of the brigadier. 4. The sergeants have the same rank as other sergeants of their corps, which perhaps might exclude them as combatants from coming under the Geneva Cross. They are not supernumerary in their regiments, but ought to be.

THE ARMY MEDICAL SERVICE.

ANOTHER A.M.S. (Burmah) writes: I feel I cannot allow the letter of "A.M.S.," in the *British Medical Journal* of September 21st, to pass without saying a word or two. You may, indeed, ask him what his lot would have been without the advocacy of the *Journal* and the Parliamentary Bills Committee. Our position without your aid would have been intolerable.

Mr. Ernest Hart, in an after-dinner speech last winter in India, referred to a matter which I think deserves more attention, namely, the establishment of messes, for which a grant should be obtained. Medical officers are sometimes not made honorary members of the regiments or batteries of which they are in medical charge. No notice whatever is taken of their call on the mess. I think, too, the establishment of messes would go far to removing that "social boycotting and ostracism" of which you speak, and which undoubtedly exists. As for "A.M.S.'s" contention about your "injurious criticism," I often think you are not strong enough in your remarks. Surely it is only fair to let candidates know what they may expect before they enter the service.

That a surgeon-lieutenant and surgeon-captain up to five years' service should draw Rs.317 6d a month is a crying shame. A veterinary-lieutenant comes out to India on Rs.400, and a Staff Corps subaltern (aged, perhaps, 30 or 21) draws Rs.325, while you see surgeon-captains of 30 years of age and over drawing Rs.317 6d. After five years there is a paltry increase of about Rs.17. Even after six years the surgeon-captain draws less pay than captains of the line, who get the smallest pay of all captains in the army. For example, the surgeon-captain after six years gets Rs.434 10s 2d; the infantry captain gets Rs.415 plus Rs.30 company allowance. Total Rs.445. I have no personal interest now in advocating an increase of pay to junior medical officers, but I drew Rs.317 6d myself, and know its inadequacy.

In conclusion, I will venture to mention a few reforms which would, I think, tend to bring about a better state of things in the Army Medical Staff:

1. Formation of a corps with proper titles, the present hybrid titles being a failure.
 2. Establishment of messes where practicable with a Government grant.
 3. Increase of pay for junior medical officers and for brigade-surgeons in India. For juniors I would suggest: Surgeon-lieutenant, Rs.375, for three years; surgeon-captain, Rs.450, after three years; surgeon-captain, Rs.500, after ten years.
 4. Reduction of the foreign tour to five years.
- Approx. of (4), engineers now serve for five years only in India and draw better pay. They formerly served seven years. Why should medical officers serve six years if it is considered too long for engineers?

MEDICO-LEGAL AND MEDICO-ETHICAL.

M.D.U.S.A.

ON December 8th a summons was heard before Mr. Sheil, at the Westminster Police-court, taken out against a Mr. John Ferdinand, of 201, King's Road, Chelsea, on an information laid by Mr. Thomas William Tyrrell on behalf of the Medical Defence Union.

Mr. Muir Mackenzie, who appeared to support the summons, said the charge was that the defendant "falsely and wilfully took and used the title of M.D., thereby implying that he was recognised by law as a physician." The summons was taken out under the 40th section of the Medical Act, which had been construed by the Courts to apply to a case in which a person without registrable qualification practised medicine, and in doing so assumed a title leading persons to believe that he had a qualification. In the present case the defendant had described himself in newspaper advertisements as a "physician" and as "fully qualified"; he also signed certificates as "M.D.," sometimes adding "U.S.A."

Mr. Thomas William Tyrrell, the informant, said that he saw the defendant lecturing from a cart outside Battersea Park on a Saturday evening in October. He went up to him and asked him to prescribe for a cold. Defendant gave him a bottle of medicine, and he paid it. He called on defendant at Chelsea on the following Tuesday, and told him he had pains in his back. Defendant said he had a nasty cold and should rest. He signed a certificate as "Dr. Ferdinand, M.D.U.S.A." He gave witness another bottle of medicine, for which he charged 4s. 6d. He spoke of wonderful cures which the doctors dare not refuse, and also said that if witness went to the chemist's to have the medicine made up he would be charged three guineas. He gave witness a local newspaper containing a long advertisement occupying nearly the whole page, in which it was stated "Dr. Ferdinand, 201, King's Road, Chelsea, has no connection with any of these good men or their qualifications, as he graduated in the Eclectic Schools of America, and is now the first physician in the world, the only authority in rupture, cancer, consumption

etc. Advise free every Tuesday 9 A.M. till 3 P.M., Sunday 10 to 1. No connection with any English practitioner. No canvassers for advertisements ever admitted. Letters only. Ferrianti, 25, rd. and co. only, no redaction. Ferrianti applied to write and come night and morning and taken internally destroy them. He also claimed to be "a duly qualified Doctor of Medicine from the Eclectic Schools of America, holding over 5000 testimonials." On visiting defendant again he said his medicines were purely vegetable, and that "Ferrianti" could not be purchased anywhere for twenty cents. He gave witness a further certificate for his employers, again signing himself as "M.D. U.S.A." Witness told him he had heard that he was a quack. He said, "I am fully qualified, and those," pointing to the "M.D. U.S.A." "are my qualifications."

In cross-examination by Mr. Turrell, who appeared for the defendant, witness said he was a clerk in the employ of the solicitors for the prosecution.

Other witnesses were called, who had also consulted the defendant and received certificates from him, in which he signed himself as "M.D. U.S.A." In one case he signed a receipt "Ph.D., LL.D., B.A."

A copy of the *Medical Register* was put in to show that the defendant's name did not appear.

Mr. Turrell submitted that no proof had been shown that the defendant had assumed the name of M.D., "wisdom and faculty" in accordance with Section 4. He did not claim to be an English medical man, and no man who added to the words "M.D." the words "U.S.A." or "qualification of a foreign university" could be convicted under that section.

Mr. Shell said the "M.D." assumed his being a doctor of medicine according to English law. Defendant said he took that title because he was a Doctor of the Eclectic Schools of America. It was for him to show that.

Mr. Turrell said he had no evidence on that point.

Mr. Shell said it was laid down by Mr. Justice Coleridge that the "M.D." implied in English law that the man was a qualified medical man.

Mr. Turrell admitted that if the defendant had simply styled himself "M.D." it would have been incumbent upon him to show that he was qualified. But in these certificates he had added "U.S.A."

Mr. Shell said he should utterly disregard that. The addition of all the letters of the alphabet after the "M.D." would not prevent the assumption that he was a qualified medical man according to the English law.

For the defence a Mrs. Maria Blumer, of Lavender Hill, was called, and said she consulted the defendant because she heard that he was an American doctor. She had a large cancer of the liver, and Dr. Ferdinand cured her.

In cross-examination she admitted that she had sometimes testified with the defendant as to this "remarkable cure."

Mr. Shell said he was quite satisfied that the defendant had violated the law. This was a most proper prosecution, seeing that the people who were imposed upon by his kind of practices were generally those who were poor and ignorant, and unable to protect themselves from such quackery. Rich people might be able to look after themselves, but it was the poor who were victims in such cases. He should fine the defendant £20, with 20s. costs, or two months in default of distress. Pending the return of the distress warrant, the defendant must be detained, or find surety for the penalty and costs. The defendant said he could find surety.

"SALISBURY MEDICAL CLUB."

A.C.S.M.—The issuing of such cards, as the one sent us by your correspondent is contrary to all rules of medical etiquette. It would certainly seem to amount to personal advertising, and whoever is responsible for them can have little regard for professional ethics. Few offenders in this way have shown such disregard for the opinion of their professional brethren as to affix their names to a club of this description.

CIRCULARS TO PATIENTS.

E. J. W.—In view of the fact that the partnership in question has *de facto* existed for eleven months or more, the suggested notification would be inexpedient, and could not fail to give rise to the supposition that it was especially intended to make known to the patients, and through them to others, what would be regarded by the profession as an ill-judged flourish of academic titles and degrees. If such had been introduced by the senior partner in the autograph or other announcement of the impending or effected partnership, with the view to emphasizing the prospective advantages to be derived from a highly educated junior, it would have been admissible and legitimate, but not so under existing circumstances.

CALLING FOR ORDERS.

ALIAS derogatory to himself and to the medical profession as is the alleged trade-like action of B. in daily calling at the chemist's for messages, or, in other words, orders, and that, moreover, in the immediate neighbourhood of a resident practitioner, we would counsel A. in his own true interest and that of the profession, to abstain from any unfriendly step towards a medical brother, inasmuch as though his conduct may be, but rather seek to devise means by which he may be induced to review and amend his ill-considered procedure.

FAIRNESS.—The principle enunciated in the rule appended relates to, and should govern the case referred to: "When a practitioner is called to an urgent case, either of sudden or other illness, accident, or injury in a family usually attended by another, he should (unless he is further attendance in consultation be desired, when the emergency is provided for, or on the arrival of the attendant-in-ordinary, resign the case to the latter, but he is entitled to charge the family for his services."

SALE OF POISONS.

2.B. writes as follows: A. is M.R.C.S., L.A.S., and keeps a retail shop managed by an assistant, who holds the assistant certificate of Apothecaries' Hall. Can the assistant legally sell poisons? The Phar-

macy Act, Section 14, says: "Nothing hereinbefore contained shall extend to or interfere with the business of any legally qualified apothecary." Let's contention is in above section.

* The special regulations as to the sale of poisons are contained in Section 17 of the Pharmacy Act, 1858. The section quoted by "Lex" is the 16th. We think it doubtful that such assistant can sell the poisons in Schedule A to the Act, except in the presence of, and to persons known to, the employer. We mean when such poisons do not form part of the ingredients of any medicine supplied to a patient. To provide for such a case there are certain special provisions in Section 17 to be complied with.

SALE OF PRACTICES.

RECENT writes: Your correspondent from the North of England has just cause of complaint against the man who, having made himself acquainted with the particulars of the practice, canvassed for a club, took a house, and settled down in the neighbourhood. There is no excuse for so dishonourable an action. I could give you particulars of the conduct under similar circumstances on the part of a qualified man in London whose action was more grossly dishonourable and outrageous.

A HANDBILL.

A MEMBER has sent us the whole of a chemist's handbill, part of which was referred to in a note under the head "Medical Irregularities" published in the *BRITISH MEDICAL JOURNAL* of November 10th. At the foot of the handbill, which we are informed is distributed broadcast, is the following announcement:

DR. MORRIS JENKINS, M.R.C.S. Eng., L.R.C.P. Lond.,

Attends daily.

Hours of consultation—morning, 12 to 1; evening, 6 to 9.

Midwifery attended.

The handbill is one which might with advantage be brought to the notice of the Royal College of Physicians of London.

ABSENT FRIENDS.

J. K. C.—THE course of action which B. should have pursued is clearly laid down in the appended rule: M. E. Code, 4th edition, Chap. II, Sec. 6, Rules 6 and 7. "(6) When a practitioner is ill or absent from home, and the patient wishes to have a medical man of his own choice rather than the officiating friend, partner, or house agent, the practitioner so elected should act in accordance with the following rule: "(7) When a practitioner is called to an urgent case, either of sudden or other illness, accident, or injury in a family usually attended by another, he should (unless he further attendance in consultation be desired, when the emergency is provided for, or on the arrival of the attendant-in-ordinary, resign the case to the latter, but he is entitled to charge the family for his services;" to which we may add that B's invitation to C. to administer the chloroform under such exceptional circumstances is, to say the least, remarkable and indicative.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF CAMBRIDGE.

GEOLOGICAL MUSEUM.—The late Mr. James Carter, F.R.C.S., of Cambridge, has bequeathed to the Woodwardian Museum his very valuable collection of fossil crustacea, on which he was an acknowledged authority, together with the M.A. of a work on the group, which he was preparing at the time of his death.

WALSINGHAM MEDAL.—The medal annually given by the Lord High Steward for biology (including physiology) has this year been awarded to Mr. L. L. Tuckett, Fellow of Trinity College.

THE DEGREE OF MASTER OF SURGERY.—The Special Board for Medicine have published an important report in which new regulations for the M.C. degree are proposed. The report states that: "The Board have had under consideration the conditions on which the degree of Master of Surgery is at present conferred, with a view to their possible improvement. They find that under the existing regulations only seven candidates have presented themselves for examination during the last ten years, and of these only two were admitted to the degree. The degree of Bachelor of Surgery is now taken by the great majority of those who graduate in medicine, and serves as primary qualification in surgery. The mastership of surgery cannot be taken except by Masters of Arts until after three years from inauguration as B.A., and it is accordingly regarded as a distinction rather than a qualification. Those surgeons who might be expected to aspire to it are in general men of some standing in their profession, and they naturally feel some reluctance to submit themselves to an examination of the ordinary kind, in view of the practical failure of the present arrangements. The Board have thought it expedient to propose as an alternative to the present plan, which may still be maintained as suitable for the requirements of certain students, a procedure in some respects analogous to that for the degrees of B.Sc. and Litt.B. They think it probable that such an alternative would lead to an appreciable increase in the number of candidates for the degree, both directly by enabling it to be obtained by surgeons of standing and distinction who have passed the one for ordinary examination tests, and indirectly by encouraging the dignity of the degree, and so raising its value to younger men of ability, for whom the present examination is well adapted. The Board further think it expedient that the present regulations, which prescribe that two years shall have elapsed between the time of passing the last examination required for Bachelor of Surgery, and the time of admission to the examination for Master of Surgery, should be altered in so far as it affects Masters of Arts." The proposed regulations will allow a candidate

either (1) to present himself for the ordinary examinations, or (2) to apply for permission to be exempted from the degrees without examinations. In the latter case the candidate must have passed the examination for the Bachelor of Surgery at least three years before. He must submit to the Special Board of Medicine the printed or written contributions to the advancement of the Science or Art of Surgery on which he bases his claim to the degree. Before he will be admitted to report on his contributions, and on their reports the degree cannot be of the Board will decide whether the degree should or should not be granted. A fee of five guineas will be required when the application is made. The proposal is to form a new department, but it might have been included in the procedure recently approved for "Advanced Students" in Arts and Law.

MEDICAL DEGREE.—At the Congregation on Thursday, December 8th, the following degrees were conferred:

M.B. and B.Sc.—D. V. Warthington, M.A., Pembroke
M.D.—W. H. West, M.A., M.B., B.Sc., St. John's, G. T. Birdwood, B.A., M.B., B.Sc., St. Peter's.

EXAMINATION IN SURGERY.—As there are over 50 candidates for Part I (Surgery and Midwifery) of the Third M.B. Examination, the Deputy Vice-Chancellor has approved the appointment of Dr. Joseph Griffiths, M.A., F.R.C.S., of King's College, to be an additional Examiner in Surgery.

PROFESSORSHIP OF PHYSIOLOGY.—Professor J. G. McKendrick, M.D., F.R.S., of Glasgow, has been appointed an elector to the chair of Physiology in the room of the late Professor Huxley.

EXAMINERS IN NATURAL MEDICINE.—Dr. A. Ransome, Dr. Lazarus Barlow, Dr. J. L. Norton, Dr. T. Stevenson, and Dr. R. Thorne Thorne have been appointed Examiners for the Diploma in Public Health during the coming year.

UNIVERSITY OF LONDON. EXAMINATION FOR HONOURS.

Medicine.—First Class: F. G. Crookshank (Scholarship and Gold Medal), University College; A. Salter (Silver Medal), Guy's Hospital; B. L. Abrahams, F.R.C.S., University College; S. G. Cook, St. Bartholomew's Hospital; J. H. Cook, University College; Second Class: H. B. Shaw, University College; A. R. Cook, B.Sc., Cambridge University and St. Bartholomew's Hospital; W. S. Handley, Guy's Hospital; A. Dimsey, University College; C. J. Harriott, Guy's Hospital; G. H. Hunt, St. Bartholomew's Hospital; W. T. G. Pugh, Middlesex Hospital; H. J. Walton, St. Bartholomew's Hospital. Third Class: L. E. Eastes, B.Sc., Guy's Hospital; L. E. V. Every-Clayton, Guy's and London Fever Hospitals; A. J. Rodenhausen, B.Sc., University College; T. M. Thomas, Guy's Hospital; H. Singer, Mason College; Rosina Clara Despard, London School of Medicine for Women; Charlotte Elizabeth Hall, London School of Medicine for Women and Royal Free Hospital; S. W. Brook, Owens College and Manchester Royal Infirmary; J. H. Rodman, University College, Bristol and St. Bartholomew's Hospital; Margaret Marston Traill Christie, London School of Medicine for Women and Royal Free Hospital.

Obstetric Medicine.—First Class: S. Gillies (Scholarship and Gold Medal), St. Bartholomew's Hospital; W. S. Handley (Gold Medal), Guy's Hospital; R. Hunter, Yorkshire College; A. R. Cook, Cambridge University and St. Bartholomew's Hospital; L. E. V. Every-Clayton, Guy's and London Fever Hospitals; A. Salter, Guy's Hospital. Second Class: J. H. Cook, University College; W. T. G. Pugh, Middlesex Hospital; A. J. Rodenhausen, University College; J. H. Rodman, University College Bristol, and St. Bartholomew's Hospital; W. H. Jewell, Guy's Hospital; G. H. Sewry, St. Bartholomew's Hospital. Third Class: J. J. Coleman, Guy's Hospital; A. Dimsey, University College; H. B. Shaw, University College; P. N. Vellacott, Guy's Hospital; Rosina Clara Despard, London School of Medicine for Women.

Forensic Medicine.—First Class: C. J. Harriott (Scholarship and Gold Medal), Guy's Hospital; S. Gillies (Gold Medal), St. Bartholomew's Hospital; B. L. Abrahams, University College; A. Salter, Guy's Hospital; H. Singer, Mason College; T. G. Nicholson, B.Sc., St. Thomas's Hospital; H. B. Shaw, University College; R. G. Kirton, London Hospital. Second Class: W. S. Handley, Guy's Hospital; G. H. Hunt, Guy's Hospital; E. F. H. Hardenberg, Guy's Hospital; T. H. Hunt, Owens and Yorkshire Colleges; M. G. Pearson, B.Sc., St. Bartholomew's Hospital; P. N. Vellacott, Guy's Hospital. Third Class: Rosina Clara Despard, London School of Medicine for Women; F. G. Crookshank, University College; A. R. Cook, Cambridge University and St. Bartholomew's Hospital; S. W. Brook, Owens College and Manchester Royal Infirmary; P. J. Edmunds, B.Sc., University College.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

Are Comitia of the College held on Tuesday, December 10th, the following gentlemen were appointed examiners for the ensuing year:

I. For the Licence.—First Board.—Drs. Dawson Turner and Daniell, Physic. Drs. Allan Gray and John Gibson, Chemistry. Dr. Lovell Gailand and Mr. J. Arthur Thomson, M.A., Biology. Second Board.—Sir James A. Russell and Dr. Whitaker, Anatomy. Drs. Noel Paton and J. G. Dunlop, Physiology. Third Board.—Drs. A. Bruce, R. Muir, and R. F. C. Little, Pathology. Drs. Murdoch Brown, Buchanan, and Gillespie, Materia Medica. Drs. R. Peel Ritchie, Andrew, P. A. Young, and Campbell, Medical Jurisprudence. Final Board.—Drs. Smart, Muirhead, Wilson, Abbott, Jamieson, James, Bramwell, Gibson, Philip, Graham Brown, and William Russell, Medicine. Drs. Cream, Berry Hart, Milne Murray, and Harbour, Midwifery. Drs. Batty Tuke and Clouston, Insanity.

II. For the Membership.—Dr. G. W. Balfour, Dr. R. Peel Ritchie, Sir T. Graham Stewart, Dr. Benjamin MacLagan, Dr. Simpson, Dr. Crum Brown, Dr. Stewart, Dr. Muirhead, Dr. T. R. Fraser, Dr. Wilson, Dr. Batty Tuke, Dr. Campbell, Dr. J. Carmichael, Dr. Adam, Dr. J. Playfair, Dr. Sibbald, Dr. Underhill, Dr. Jamieson, Dr. James, Dr. McEldrie, Dr. Croome, Dr. Berry Hart, Dr. James A. Russell, Dr. Greenfield, Dr. Harbour, Dr. A. Bruce, Dr. James Ritchie, Dr. W. Russell, Dr. Melville Dunlop, Dr. Brewis, Dr. Hamilton, Dr. J. W. Ballantyne, Dr. John Thomson, Dr. Haig Ferguson.

III. For Diploma in Public Health.—First Examination.—Dr. Charles Hunter Stewart, Practical Work in Laboratory; Dr. Crum Brown, Chemistry; Dr. Dawson Turner, Physics. Special Examination.—Dr. Muirhead, Epidemiology and Endemiology; Sir Benjamin MacLagan, Practical Sanitation; Sir James A. Russell and Dr. J. Allan Gray, Sanitary Law, Vital Statistics, and Statistical Methods; Dr. R. W. Thump, Registrar of Applicants for the Licence; Dr. Noel Paton, Superintendent of Laboratory.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At the monthly meeting on Friday, December 6th, the President admitted to the Laureates in Medicine and Midwifery the following candidates who had been successful at the Final Examination held in November, 1885, under the Conjoint Scheme with the Royal College of Surgeons in Ireland:

J. F. O'Malley (passed with honours), J. W. Benson, G. Corcoran, T. J. Green, M. J. Cuffe, R. Glynn, C. E. Hodgson, J. Lynch, J. M. Morrissey, J. J. O'G. McDonagh, J. A. M'Munn, J. R. O'Brien, J. J. O'Reilly, R. W. Sealy, J. N. Snee, J. E. P. Shera, and F. C. Wright.

ROYAL COLLEGES OF PHYSICIANS AND SURGEONS, IRELAND.

First Professional Conjoint Examination.—Honours (in order of merit):

M. Garin, G. G. L. Kerans. Pass (alphabetically)—Completed the examination: E. Bennett, W. A. Cooke, A. D. C. Cummins, A. L. Dunwoody, R. J. Franklin, P. A. Fraxer, R. Hughes, J. L. Jones, J. N. B. Martin, E. R. Townsend, A. A. Woods. Passed in Anatomy: A. J. Connolly, P. Heffernan. Passed in Biology: A. G. Bennett, H. E. Hayes, P. Heffernan, J. L. McCarthy, P. J. M'Donnell, J. G. Young. Passed in Pharmacy: A. J. Connolly, H. E. Hayes, P. Heffernan, P. J. M'Donnell.

Second Professional Examination.—Completed the Examination: D. B. Bradlaw, J. A. Browne, W. E. Brunsell, J. M. H. Cooney, P. C. Fowler, D. Hadden, N. J. Keller, W. O'Connor, B. A. O'Donovan, G. J. Powell, T. W. Rodgers.

Passed in Anatomy: W. J. P. Ayde Curran, W. H. May, J. F. Treaston, T. A. J. White.

Passed in Physiology: G. Kennedy, W. H. May, R. H. Moffat, J. F. Treaston.

Passed in Materia Medica: G. Carroll, C. W. Crowe.

Passed in Histology: W. J. P. Ayde Curran, J. A. Byrne, V. F. Connor, J. Conway, W. H. May, J. M. McCarthy, W. H. Spaight.

Passed in Hospital Practice: J. L. Allen, J. M. McCarthy.

Third Professional Conjoint Examination.—Candidates have passed this examination as undernoted.—Completed the Examination: Honours Division, None.

Pass Division: W. J. Beveridge, H. V. Blake, H. S. Wardley, S. C. Elgee, L. R. Fannin, T. Fitzgerald, J. G. Gill, M. Mitchell, G. G. H. Muirhead, B. M'Caul, J. G. G. Pigott, Miss L. F. Strangman, V. B. Taylor.

Passed in Anatomy: J. J. Foley, W. C. W. Glenney, C. J. D. Odevaline, B. R. Phillipson, De C. S. Potterton.

Passed in Physiology: T. E. Coten, W. C. W. Glenney, W. H. Odium, B. R. Phillipson, De C. S. Potterton, J. F. Short.

Passed in Medicine: J. J. Foley, J. O'M. Irwin, C. A. Kenny, C. J. D. Odevaline, J. F. Short, De C. S. Potterton.

Passed in Surgery: J. J. Foley, W. C. W. Glenney, J. O'M. Irwin, C. J. D. Odevaline, A. N. Sampay.

The following candidates have passed the Final Conjoint Examination:—Honours Division: T. F. O'Malley. Pass (completed the examination): J. W. Benson, G. Corcoran, T. J. Green, M. J. Cuffe, R. Glynn, C. E. Hodgson, J. Lynch, J. M. Morrissey, J. J. M'Donagh, J. A. M'Munn, J. R. O'Brien, J. J. O'Reilly, R. W. Sealy, J. N. Snee, J. E. P. Shera, F. C. Wright, R. M. Hamilton.

Passed in Medicine: H. Herrick, S. J. Scott, J. Sheridan.

Passed in Surgery: M. Cahill, G. F. Cathness, R. M. Hamilton, R. Hassard, T. G. M'Grath, J. Sheridan.

Passed in Midwifery: C. J. Burke, M. Cahill, W. M. Cummins, R. M. Hamilton.

Passed in Ophthalmology: M. Cahill, G. E. Cathness, R. M. Hamilton.

Passed in Hygiene: G. E. Cathness, M. A. J. J. M. Carner, F. Ludy.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

DENTAL EXAMINATION.—Mr. John Stanton, having passed the necessary examinations, has been admitted a Licentiate in Dental Surgery of the College.

APOTHECARIES SOCIETY OF LONDON.

At the Preliminary Examination in Arts held on December 6th and 7th, eighteen candidates were successful, of whom one was placed in the first class. Three candidates passed in certain subjects under the old regulations.

PUBLIC HEALTH AND POOR-LAW MEDICAL SERVICES.

HEALTH OF ENGLISH TOWNS.

In thirty-three of the largest English towns, including London, 5,785 births and 3,844 deaths were registered during the week ending Saturday December 13th. The annual rate of mortality in these towns, which had declined from 22.1 to 11.9 per 1,000 in the four preceding weeks, was again 17.9 last week. The rates in the several towns ranged from 10.

in Croydon, 10.9 in Derby, and 11.3 in Brighton, to 22.7 in Blackburn, 21.5 in Bedford, and 25.5 in Liverpool. In the thirty-two provincial towns the mean death-rate was 15.4 per 1,000, and was 1.1 above the rate recorded in London, which was 17.3 per 1,000. The symptomatic death-rate in the thirty-three towns averaged 2.5 per 1,000; in London the rate was equal to 3.0 per 1,000, while it averaged 2.6 in the thirty-two provincial towns, and was highest in Wolverhampton, Liverpool, Blackburn, and Halifax. Measles caused a death-rate of 2.1 in Manchester, 3.7 in Oldham, 4.3 in Bedford, and 4.5 in Blackburn; scarlet fever, 1.1 in Gloucester, whooping-cough of 1.3 in Bradford; and "fever" of 1.0 in West Ham, Nerram, Birkhead, and Newcastle-upon-Tyne. The 109 deaths from diphtheria in the thirty-three towns included 35 in London, 8 in Liverpool, and 4 each in Wolverhampton, Birmingham, and Manchester. Two fatal cases of small-pox were registered in West Ham, 1 in London, and 1 in Croydon but not one in any other of the thirty-three large towns. The number of small-pox patients under treatment in the Metropolitan Asylums Hospitals and in the Highgate Small-pox Hospital, which had been 50, 60, and 70 at the end of the three preceding weeks, had risen again to 87 on Saturday last, December 7th; 15 new cases were admitted during the week, against 23, 30, and 8 in the three preceding weeks. There were 2,653 scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and in the London Fever Hospital on Saturday last, against 2,845, 2,607, and 2,790 at the end of the three preceding weeks; 313 new cases were admitted during the week, against 293, 295, and 335 in the three preceding weeks.

HEALTH OF SCOTCH TOWNS.

During the week ending Saturday last, December 7th, 765 births and 562 deaths were registered in eight of the principal Scotch towns. The annual rate of mortality in these towns, which had declined from 21.4 to 17.3 per 1,000 in the four preceding weeks, rose again to 19.5 last week, and exceeded by 1.6 per 1,000 the mean rate during the same period in the thirty-three large English towns. Among these Scotch towns the death-rates ranged from 14.2 in Leith to 24.4 in Dundee. The symptomatic death-rates in these towns averaged 2.3 per 1,000, the highest rates being recorded in Greenock and Aberdeen. The 287 deaths registered in Glasgow included 12 from whooping-cough and 6 from diphtheria. Four fatal cases of scarlet fever were recorded in Aberdeen, and 5 of measles in Greenock.

ENTERIC FEVER AT PONTARDAWE.

A serious state of things prevails at Pontardawe, in the Swansea valley, where enteric fever has occurred to the number of upwards of 40 cases, with no fewer than 8 deaths. The disease is said to have been imported to the workhouse by a tramp, towards the end of September, spreading thence it is held to the western side of the town, to which the disease seems to be confined. Much indignation is felt locally at the inaction, especially in the part of the rural district council of the Pontardawe Union, the county health officer, Dr. Williams, having so far back as April, 1894, made certain recommendations for the placing of the sanitary district in proper condition. These he repeated in July, 1895, as few had been carried out. The disgraceful state of the town may be in some measure imagined when we say that there is no sewerage system, that slop water is allowed to create nuisance in the public roadways, that the canal is polluted, that the compulsory notification of infectious diseases is not in operation, that there is no hospital accommodation, no means of public disinfection of clothing, bedding, &c., and that no building by-laws are in existence. The cause of the present epidemic has not yet been traced, but one of the sources of water supply is suspected, and recent chemical analysis made nothing wrong, a sample has also been sent for bacteriological examination.

THE TURN OF THE TIDE.

It is satisfactory to note from the returns presented to the Metropolitan Asylums Board on December 7th that the number of notifications received during the preceding fortnight, both as to scarlet fever and diphtheria, show a substantial diminution. We may fairly hope, then, that we have now reached and passed the turn of the tide, that for this year the worst is over and that, in accordance with the well-known facts as to the seasonal variation in the prevalence of these diseases, the pressure on our hospitals will now for some months to come diminish. In this relation the following figures are not without interest.

Number of cases notified in the two weeks ending—

	Scarlet Fever	Diphtheria
September 20th-27th	1,145	550
October 10th-17th	1,130	604
October 24th-31st	1,335	651
November 7th-14th	1,175	604
November 21st-28th	1,007	604
December 5th-12th	1,177	584

TYPHOUS FEVER IN BRILLFLASH UNION.

At the weekly meeting of the guardians of the Brillflash Union on November 10th it was reported that since the last meeting 7 fresh cases of typhous fever had been admitted to the workhouse hospital, making in all 21 cases with 3 deaths. Mr. Wilson, Hackstons, reported in reference to the cases from that district that the patients caught the disease by having communication with the people from Hackstons. After a discussion the sanitary officer was directed to serve notices on all the householders in Moffatt Lane, Hackstons, to have the houses cleaned, disinfected, and disinfected.

ENTERIC FEVER AND PRIVY SICKNESS IN SHEFFIELD.

Dr. HARVEY LITTLEJOHN, the Medical Officer of Health for Sheffield, has prepared a report on the prevalence of typhoid fever in that city. He points out that with variations as to the number enteric fever has never been absent since the establishment of notification in 1890. The rise in numbers, general all over the country, in the autumn months appeared in certain quarters to have given rise to some uneasiness. Careful inquiry in the present instance has been made in each case as to the sanitary sur-

roundings of the house where the disease occurred, as to the milk supply, and other possible sources of infection. As a result of these inquiries Dr. Littlejohn says he can exclude the milk supply with certainty, and with equal certainty he thinks the water supply may be excluded. He does not think the suggestion tenable that the present cases may be due to defects in the water supply caused by the severe frost last winter, whereby infected matters may have been soaked into the pipes. If this were the case the great prevalence of the disorder would have been shortly after the time when pollution would have taken place. The chief cause in Dr. Littlejohn's opinion of enteric fever is the effect of the offensive and insanitary condition of the majority of the privy middens, which admit of accumulations of filth in close proximity to dwelling houses. He goes on to point out how when cases have not been removed to hospital but treated at home the disease tended to spread from the house first affected to those who used the same midden. Statistics are given showing the greater mortality in cases treated at home to those who have been removed to hospital, and in regard to the present privy-cleaning system, removal of cases to the hospital as one of the most effective and important which the authorities possess for limiting the spread of the disease.

MILK POISONING.

Dr. GRASSWELL, the Health Adviser to the City of Manchester, has published a report by his assistant, Dr. Gray, as to the cases of poisoning by milk, which report, though two years old, has of late become of interest for our readers as tends to be led upon for a short summary of its contents.

Briefly, the facts are that milk purchased from a local dairy farm on August 11th, 1893, by two households, proved, as it can be ascertained almost with certainty, to be of such poisonous quality as to cause the death of two children, was part of it in a raw and fresh condition. The three cows of the farm yielded some seven or eight quarts daily, and this amount was consumed by 51 persons, in 9 families. Of these persons 10 were under 5 years of age, and 36 over 10 years of age. On the date in question only three or four quarts were consumed by 7 of the persons, and of these 7 were under 5, but only one of them took the milk as drink, and that one drank it in a boiled condition. In one household, taking two quarts, all the members were affected. The two households, taking two quarts between them, contained the following children, aged respectively 3 years and 17 months. They were the youngest in the families, and the only ones who took much of the milk in a raw state. Indeed, with one exception, they were the only children consuming the milk raw. They developed the symptoms which usually follow the ingestion of milk which contains typhoid bacilli. No trace of poison was found post mortem, but vomiting was a marked symptom in both cases, and no milk had been taken for some hours preceding death. All other known conditions likely to have caused these fatal illnesses could be excluded; and these were the only cases of the sort at the time or place. They both fell ill the same day, one dying after two and the other after three days' illness. In the one case the home surroundings were deplorably dirty, but not so in the other. The whole locality was in a wretchedly insanitary and commercially polluted condition. But the state of the dairy premises and vicinity was worse enough to set aside all question of where the milk acquired its high quality. The sleeping apartment of the farmer's family was infested with vermin. The cows in wet weather stood up to their udders in mud and filth; they are milked standing on an accumulation of dry manure; the water used is from an adjacent tank, and contained an average of 10 grains of solid residue and 4 grains of chlorine per gallon, being grossly polluted.

These are the chief of the circumstances which Dr. Gray has to report, and one wonders when reading the account what the local authorities can have been about to have permitted the occupants of premises so grossly filthy to go on with the sale of milk and farm produce. All we need say is that it was not for want of caution by the responsible medical adviser that the conditions leading to this report were allowed to persist.

ACTION AS TO WELL CLOSURE.

We congratulate the Ipswich Corporation on having taken action in the case of a neglected order causing for the closure of a polluted well, with the use of the water in which typhoid fever had been associated. From the report of the public-health officer in the final decision of the case we learn that the state of the well was discovered only after the occurrence of a case of typhoid fever in one of the houses supplied by the water. It was this state of the matter we stated, and that the local authorities, as it should not be left for actual disease to bring it about, the defects in a water supply. Especially is this the case in a district which, we are told, is "a low-lying well, and with the water from the tank percolating into the drinking water." It is the order of the magistrates demanding the closure of the well within a fortnight and granting the defendant in the costs of a sanitary authority to close a well may be serious in its resulting sickness and even death. It is not only the individual owner of the well that may suffer, but his neighbours.

INFECTIOUS DISEASE AND SCHOOL CLOSURE.

J. W. H.—The power of a medical officer of health in the matter of school closure on account of the prevalence of an infectious disease is that contained in the current issue of the Code of Regulations of the Education Department, and on part represented by the Local Government Board in their memorandum on the mode of control of infectious disease on public health grounds. Article 16 of the Code prescribes that the managers of public elementary schools (including those referred to by our correspondent as "voluntary schools") must at once comply with any order of a sanitary authority or of any two members acting under the advice of the medical officer of health requiring them to suspend the school for the purpose of preventing the spread of disease, either to close the school or to render it impracticable to attend therefrom. But although the power of the health officer stops that of continuing

advice, he should nevertheless keep schoolmasters posted up as to the presence of illness in the homes of scholars when he becomes possessed of this information, and should request the exclusion from school of children from infected homes. If our correspondent does not already know the memorandum of the Local Government Board to which we have referred he will do well to make application for a copy.

THE AERIAL DISSEMINATION OF SMALL-POX.

Dr. W. ARNOLD FRANK (TOWN HALL, Bradford) writes: In the Public Health column of the BRITISH MEDICAL JOURNAL of November 2nd I see that you refer an inquirer, "J. B. L.," for information on the subject to Mr. Fowler, Dr. Priestley, and Dr. Bruce Low; and I merely write to point out Dr. McVail, of Doncaster, also gave a valuable contribution on the matter to the Epidemiological Society in 1894, which is published in the Transactions. I also read a paper on the same subject at the meeting of the British Medical Association in Bristol in August, 1894, which was afterwards published in the BRITISH MEDICAL JOURNAL. I could send "J. B. L." a copy of my paper.

INFECTIOUS HOSPITAL CHARGES.

D. SOL. has written saying that his district council have had a summons issued for the attendance before a committee of their number of a working man for the non-payment of a bill in respect of the maintenance of his child in the isolation hospital, well knowing that he is unable to meet the demand. There is a prevalence of scarlet fever in the district, and the action of the council in demanding payment for hospital treated cases is having the result of preventing parents from making use of the hospital which is desirable in the best interests of the public health. D. SOL. desires to know whether such action has been adopted by other authorities, and if it is in accord with the recommendations of the Local Government Board and of county councils.

"*." We think the attitude described is to be deplored. We know that almost all the leading health officers are in favour of free treatment of isolated cases in hospitals provided out of local rates. These institutions have been erected with the prime object of preventing the spread of infectious disease. Anything which tends to lessen their use is detrimental to their avowed object. We believe we are correct in stating that cases have been brought into court with the view of obtaining payment from persons in respect of isolation charges. We cannot, however, suppose the Local Government Board or county councils are favourable to such action. Rather, we should look for support from these bodies in all attempts to free our hospitals for infectious cases, just as they are free in London to-day.

DEPUTY PUBLIC VACCINATION WORK.

C. R. D.—The regulations of the Local Government Board with respect to the granting of awards to public vaccinators who have appointed deputies are extremely simple and explicit. They lay down the rule that no award will be made to any vaccinator who has not habitually done his duties in person. Then, again, the employment of a deputy must be limited to those occasions when the vaccinator is unavoidably absent from his station. This being so, the fact that an award is granted to a public vaccinator shows that there has been no excessive use of a deputy's services, and any such award will be made in respect of all vaccinations performed by both contractor and deputy, since "all the successful infantile vaccinations recorded in the vaccinator's register" are to be taken into account for the purposes of award.

ALTERATION OF DISTRICT AND SALARY OF A POOR-LAW MEDICAL OFFICER.

MEDICAL OFFICER writes: I hold an appointment at a salary of £30 per annum, and my district has been altered by a portion of it having been transferred to another union, and the guardians have reduced the salary to £25. Can they do this without consulting the Local Government Board and without giving me a quarter's notice, and can I appeal to the Local Government Board for adequate remuneration?

"*." Even if our correspondent holds a life appointment as district medical officer by Art. 5 of Medical Appointments Order, May 26th, 1887, this may be determined with the sanction of the Local Government Board by six months' notice in writing, signed by the clerk to the guardians, if at any time an alteration of the district appears necessary. If this has been done a fresh appointment will have to be made, and the salary for this fixed by the guardians. It would then be for "Medical Officer" to decide whether he would accept the fresh appointment or not on the terms offered. If he decides on doing so, we apprehend that any subsequent appeal to the Local Government Board on the question of salary would not be entertained.

SCOTTISH PARISH COUNCILS AND MEDICAL OFFICERS.

ANON.—We are in a position to state authoritatively that, in the absence of any agreement to the contrary, a parish council in Scotland may dispense with the services of their medical officer without consulting the Local Government Board, provided due notice is given.

A FEVERSTRICKEN VILLAGE.

TYPHOID fever is raging in Pottersbury, a small Northamptonshire village, and from the report of the Local Government Board inspector who has just visited the place, matters are likely to grow worse. The medical officer of the rural district reports 25 cases and 4 deaths since November 17th. He believes that the wells are contaminated.

MEDICAL NEWS.

ST. THOMAS'S HOSPITAL has now obtained nearly £97,000 towards the £100,000 asked for last February to enable the five wards which have long been closed to be opened. In consequence two of the wards are to be opened in January. This will add sixty beds to the hospital.

A PASTEUR INSTITUTE FOR INDIA.—Brigade-Surgeon-Colonel W. A. C. Roe, of the Indian Medical Service, has been appointed Honorary Secretary of the Association which has been for some time collecting funds for the foundation of a Pasteur Institute for India, and has received sufficient support to assure the success of the scheme.

THE eighth annual *conversations* of the Royal British Nurses' Association was held in the galleries of the Royal Institute of Painters in Water Colours, Piccadilly, on December 9th, and was largely attended. The guests, who numbered fully 2,000, included a large number of nurses in their working costumes.

FRENCH CONGRESS OF SURGERY.—The following are the questions proposed for discussion at the meeting of the French Congress of Surgery fixed to take place in Paris in October, 1896: 1. Surgical Treatment of Flat-foot, to be introduced by M. Forgue, of Montpellier. 2. Treatment of Prolapse of the Genital Organs, to be introduced by M. Bouilly, of Paris.

A MEETING of the Selection Committee of the Royal Infirmary, Newcastle-on-Tyne, was held on December 5th to elect a pathologist in succession to Dr. Drummond, who had served for fifteen years, and did not seek re-election. The candidates were Dr. Beattie and Dr. George Murray. As a result Dr. Beattie was elected. At a meeting of the House Committee, held the same day, Mr. W. H. Vickery, F.R.C.S., was elected Surgical Registrar.

At a meeting of those interested in self-propelled traffic and horseless carriages, held on December 10th under the presidency of Sir D. Salomons at Cannon Street Hotel, an association was formed to deal with the subject, which, it was suggested, closely affected agriculture, trade, and private interests. The first vice-presidents elected were Lord Winchelsea, Sir F. Bramwell, Mr. Alexander Siemens, and Mr. John Philipson. A provisional council was also chosen.

GIFT TO THE NATIONAL PORTRAIT GALLERY.—The trustees of the National Portrait Gallery have just received as a gift from Mr. Watts, R.A., seventeen portraits painted by him, including those of Matthew Arnold, Robert Browning, Thomas Carlyle, Sir Andrew Clark, Sir Charles Hallé, Lord Lawrence, Sir Henry Layard, the Earl of Lytton, Cardinal Manning, John Stuart Mill, Sir A. Panizzi, D. G. Rossetti, the Earl of Shaftesbury, Viscount Sherbrooke, Sir Henry Taylor, Lord Tennyson, and Thomas White the philanthropist.

TREATMENT OF DEFECTIVE CHILDREN.—At a meeting held on December 2nd at the Hotel Victoria, on the initiative of the Council of the Charity Organisation Society, to consider the question of the care of defective or feeble-minded children, Sir Douglas Galton presided; and addresses on various aspects of the subject were delivered by Dr. F. Warner, Mrs. Burgwyn (superintendent of schools of special instruction under the London School Board), and Mr. O. S. Loch. The meeting approved of a proposal that a Bill dealing with the subject should be prepared by the Charity Organisation Society and introduced into Parliament.

A HOSPITAL RECORD.—The following extract from the yearly report of the Medical Board of the North Staffordshire Infirmary, read at the annual meeting of the governors on November 27th, is worthy of note: "The medical staff regret to record the loss of their colleague, Mr. Daniel Ball, at the advanced age of 96. Mr. Ball joined the infirmary as a pupil in 1816, and was elected on the staff in 1835. He continued to take a deep and active interest in the surgical work of the hospital, attending at consultations and operations up till within a few months of his death, his connection with the institution therefore extending over the phenomenal period of eighty years."

ANTITOXIN FROM THE EXCISE POINT OF VIEW.—The Board of the United States General Appraisers, New York, has decided that antitoxin is vaccine virus, and as such is exempt from duty under Par. 604, Act of August 28th, 1894. The decision is satisfactory in substance, although in form it rather recalls John Leech's railway porter adjudicating upon the question of a tortoise considered as freight: "Cat is dogs and rabbits is dogs, and must be paid for; but this 'ere tortis is a insect, so there ain't no charge for it."

The thirty-third annual meeting of the Surgical Aid Society was held on December 9th at the Cannon Street Hotel, under the presidency of the Lord Mayor. The report of the Committee, which was read by the Secretary, showed that the scope and efficiency of the Society's work had been further augmented during the past year. The income had amounted to £10,599, which was a larger sum than that obtained in any previous twelve months. The total sum subscribed by the provincial branches, which now numbered fourteen, had been increased to nearly £800. During the period under review 13,345 patients had been relieved, including 1,562 children, among whom 20,046 surgical instruments had been distributed. In addition great relief had been afforded in many cases of temporary disablement and illness by the loan of air and water beds, invalid chairs, and other articles. In the course of the proceedings the Secretary announced that the contributions received in connection with the meeting amounted to £204.

ANTIRABIC INOCULATIONS AT ODESSA.—In the *Archives des Sciences Biologiques*, published by the St. Petersburg Imperial Institute of Experimental Medicine, Dr. Diatropoff gives the annual report of the bacteriological station at Odessa for 1894. In the course of that year 1,000 persons were subjected to antirabic inoculation by Pasteur's method; of this number 16 did not, for one reason or another, complete the course of treatment. Of the 984 who were fully treated 42 had not been bitten, but had been exposed to infection either in treating animals or men suffering from rabies, or in examining the bodies of animals which had died of the disease. Of the remaining 942 cases, in 2 the bites had been inflicted by human beings, in 883 by dogs, in 46 by cats, in 4 by horses, in 3 by wolves, in 1 by a cow, and in 1 by a pig. The nature of the disease was proved experimentally in 137 cases, by the symptoms observed in the animals which inflicted the bite in 176, by the development of rabies in men or animals bitten at the same time in 18 and by post-mortem examination in 251. The bites were severe in 109 cases, moderately severe in 522, and slight in 311. The wound had been cauterised in 246 cases. Treatment was begun in the first week in 717 cases, in the second week in 181, in the third in 21, in the fourth in 8, and more than a month after the infliction of the bite in 15. Among the 940 persons who went through the whole course of treatment the mortality was 0.32 per cent., or, deducting 1 case in which death occurred within a fortnight of the termination of the treatment, 0.21 per cent. In 1893 the percentage of deaths, corrected by the addition of a case which has proved fatal since the issue of the report for that year (hydrophobia having developed just a year after the completion of the treatment) was 0.25.

MEDICAL VACANCIES.

The following vacancies are announced:

- BATH ROYAL UNITED HOSPITAL.**—Resident Medical Officer. Appointment for three years. Salary, £100 per annum, with board, lodging, and washing. Applications to the Secretary-Superintendent by December 15th.
- BRIISTOL INCORPORATION.**—Medical Officer for the Workhouse at Stapleton; doubly qualified. Salary, £50 per annum, with residence and rates and taxes free, together with vaccination fees. Applications to J. J. Thompson, Clerk to the Guardians, St. Peter's Hospital, Bristol, by December 15th.
- DENTAL HOSPITAL FOR LONDON,** Leinster Square, W.C.—Assistant Dental Surgeon; must be L.D.S. Applications to J. Francis Pink, Secretary, by January 6th.
- DENTAL HOSPITAL FOR LONDON AND LONDON SCHOOL OF DENTAL SURGERY,** Leicester Square, W.C.—Demonstrator. Honorarium, £50 per annum. Applications to J. Francis Pink, Secretary, by January 6th.
- DERBYSHIRE ROYAL INFIRMARY.**—Resident House-Surgeon and Resident House-Physician; doubly qualified. Appointments tenable for twelve months, with a possibility of extension. Salaries, £50 and £60 per annum respectively, with apartments and board. Appointments, endorsed "House-Surgeon" or "House-Physician," to Walter G. Clark, Secretary, by December 21st.

- DEVON COUNTY ASYLUM.**—Assistant Medical Officer, single. Salary, £200 per annum, with board, lodging, and washing. Applications to Arthur E. Ward, Clerk to the Visitors, 2, Bedford Circus, Exeter, by December 21st.
- DEVONSHIRE HOSPITAL,** Buxton.—Assistant House-Surgeon. Salary, £200 per annum, with furnished apartments, board, and washing. Applications, endorsed "Assistant House-Surgeon," to the Secretary by December 21st.
- EVELINA HOSPITAL FOR SICK CHILDREN,** Southwark, S.E.—Four qualified Clinical Assistants and eight unqualified Clinical Clerks in the Out-patient Department. Applications to the Secretary by December 15th.
- LIVERPOOL DISPENSARIES.**—Assistant Surgeon, unmarried. Salary £50, to be increased to £60 per annum after the first year's service, with apartments, board, and attendance. Applications to R. E. Green, Secretary, 34, Moorfields, Liverpool, by December 21st.
- POPLAR AND STEPNEY SICK ASYLUM DISTRICT.**—Second Assistant Medical Officer for the Asylum at Bromley, Middlesex. Salary, £50 per annum, increasing £20 yearly to £70. Applications, on forms provided, to be sent to Robert Fockett, Clerk to the Managers, Bromley, Middlesex, E., by January 2nd.
- SWANSEA GENERAL HOSPITAL.**—House-Surgeon. Salary, £50 per annum, with board, residence, washing, and attendance. Applications to Jno. W. Morris, Secretary, 9, Castle Street, Swansea, by December 15th.
- TAUNTON AND BOMERREY HOSPITAL.**—Assistant House-Surgeon. Appointment for six months, without salary, but board, washing and lodging in the institution provided. Applications, endorsed "Assistant House-Surgeon," to J. H. Kinsleigh Pinchard, Secretary, 23, Hammet Street, Taunton, by December 21st.
- TOTTENHAM UNION.**—Medical Officer and Public Vaccinator for the No. 3 District (Patington and Marston). Salary, £40 per annum, to include all extra medical fees that may be obtained. Applications to Thos. W. Windhead, Clerk, by December 30th.
- WEST LONDON HOSPITAL,** Hammer-smith Road, W.—House-Physician and House-Surgeon. Appointments for six months. Board and lodging provided. Applications to R. J. Gilbert, Secretary-Superintendent, by December 15th.
- WESTMINSTER GENERAL DISPENSARY,** Gerrard Street, Soho, W.—Resident Medical Officer. Applications to the Secretary by December 30th.
- WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL,** Wolverhampton.—Resident Assistant. Appointment for six months. Board, lodging, and washing provided. Applications, endorsed "Application for Resident Assistant," to the Chairman of the Medical Committee by December 21st.

MEDICAL APPOINTMENTS.

- BEATTIE, Thomas, M.B.Durh., B.S.,** appointed Pathologist to the Newcastle Infirmary.
- BELDING, D. T., M.R.C.S., L.R.C.P.Lond.,** appointed Medical Officer of Health to the Derham District Council.
- BROWN, W. Croumbie T., B.A.Lond., M.B., Ch.B.Vict.,** late Medical Officer in charge of small-pox outbreak in district and town of East London, appointed to supervise the outbreak in Kimberley, Cape Colony.
- BYERS, Henry Slagg,** of the Northern Hospital, Liverpool, appointed House-Surgeon of the Stockton and Thornaby Hospital, vice Dr. H.C. Hoffmeister, resigned.
- CALWELL, William, M.A.Q.U.I., M.D.E.U.I.,** appointed Assistant Physician to the Belfast Royal Hospital.
- CHAMBERLAIN, E. T., L.R.C.P.Lond., M.R.C.S.,** appointed Medical Officer for the Binstead District of the Epsom Union, vice J. B. Jacob, M.B., resigned.
- CLARIDGE, H. A. H., M.B., B.S.Durh.,** appointed Medical Officer for the Norton Canes District of the Cannock Union.
- DAUNER, J. H., M.A., M.D., B.Ch.Oxon., M.R.C.P., M.R.C.S., L.S.A.,** appointed Honorary Assistant Physician to the Hospital for Women, Leeds.
- DAWKINS, George Mansel, L.R.C.P., M.R.C.S.,** appointed House-Physician to the London Hospital.
- DOUGLAS, M. J., B.A.Camb., M.R.C.S.Eng.,** appointed Medical Officer for the Fourth District of the Wotton Union, vice J. A. Wright, M.R.C.S., L.S.A., resigned.
- FARMER, W. H., M.R.C.S., L.R.C.P.,** appointed Assistant House-Surgeon to the Royal Portsmouth Hospital.
- GRAVELY, H., M.R.C.S.Eng.,** reappointed Medical Officer of Health to the Chalvey Rural Council.
- HARDWICK, A. M.D.,** appointed Medical Officer of Health to the Newquay Urban District Council.
- HEATH, H. T., L.R.C.P.Edin., L.R.C.S.I.,** appointed Medical Officer of Health to the Hensfield Woodhouse Urban District, vice T. Jones, M.R.C.S., resigned.
- HEDDERN, J. M., M.B., C.M.Edin.,** appointed Medical Officer for the Sharncliffe District of the Wakefield Union.
- MACGREGOR, D. A., M.B., C.M.Edin.,** appointed Medical Officer of Health to the Sharncliffe Urban District Council.
- MIDDLEBROOK, K., L.S.A., L.M.,** appointed Medical Officer to the St. Ives Union.
- MURDOCH, J., M.R.C.S.Eng., L.S.A.,** appointed Medical Officer for the Rhinoid District of the Aberystwyth Union.
- MORTON, A. C., M.R.C.S.Eng.,** reappointed Medical Officer of Health to North Walsham Urban District Council.

Norris, O., L.R.C.P.I., L.M., F.R.S.A., appointed Medical Officer of Health for the Sherburn Rural District, *vice* H. Oak, M.R.C.L., M.R.C.S. Eng.

Postle, L., M.R.C.S. Eng., L.S.A., appointed Medical Officer for the Headley District of the Epsom Union, *vice* W. O. Hearnden, M.R.C.S., resigned.

Rice, T. E., L.S.A., appointed House Surgeon and Dispenser to the Tiverton Infirmary, *vice* H. H. Chilton, M.R.C.S., resigned.

Scott, G. W., appointed Ophthalmic Surgeon to the Leicester Infirmary, *vice* — Hodges.

Salter, Charles E., M.D., B.S. Lond., F.R.C.S. Eng., appointed Honorary Medical Officer to the Scarborough Hospital and Dispensary.

Smith, C. J., L.R.C.P. Lond., M.R.C.S., reappointed Medical Officer for the Worplesdon District of the Guildford Union.

Smith, R., Stroud, M.D. R.U.I., M.Ch., appointed Physician to the Belfast Royal Hospital.

Snaw, L. M., L.R.C.P. Lond., M.R.C.S. Eng., appointed Medical Officer for the No. 3 District of the Harrogate Union.

Stevie, W. C., M.B., C.M., appointed Medical Officer for the Seventh District of the Tendring Union, *vice* J. C. Potter, resigned.

Sturges, D. R., appointed Medical Officer for the Woodstown Dispensary District.

Vickers, W. H., F.R.C.S., appointed Surgical Registrar to the Royal Infirmary, Newcastle-on-Tyne.

Wagner, Frank, M.R.C.S. Eng., L.S.A., reappointed Medical Officer of Health for Canterbury Urban District.

Wallington, W. T., L.S.A., appointed Medical Officer for the Bushbury District of the Cannock Union.

Ward, C. Carew, M.B., B.C. Cantab., appointed Dispensary Surgeon to the Bradford Infirmary, *vice* A. Rutherford, M.B. and C.M. Edin., resigned.

West, R. Melbourne, M.R.C.S., L.R.C.P., appointed Surgeon to the Leicester Provident Dispensary.

Wild, R. H., M.D. Lond., M.Sc. Viet., appointed Honorary Assistant Physician and Medical Superintendent of the Cancer Pavilion and Home, Manchester.

DIARY FOR NEXT WEEK.

TUESDAY.

PATHOLOGICAL SOCIETY OF LONDON, 20, Hanover Square, W., 8.30 P.M.—*Dr. Peters: The Varieties of Diphtheria Bacilli. Mr. Eyle: The Xerosis Bacillus. Messrs. Kanthack and Stephens: The Escape of Diphtheria Bacilli into the Blood and Tissues. Card Specimens: Dr. Weber: Heart from Case of Angina Pectoris. Dr. Snow: Colloid Carcinoma of Breast. Mr. Lennex Browne: Malignant Growth of Tonsil. Dr. Rolleston: Crateriform Ulcer. Dr. Hugh Walsham: Tuberculous Liver with Lardaceous Change.*

THE CLINICAL MUSEUM, 211, Great Portland Street.—Open at 2 P.M., Lecture at 4.

WEDNESDAY.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen Square, W.C., 3 P.M.—Lecture by Dr. Beever.

ROYAL METEOROLOGICAL SOCIETY, 23, Great George Street, Westminster, 1.30 P.M.

HOSPITAL FOR CONSUMPTION, Brompton, 4 P.M.—*Dr. Percy Kidd: Demonstration of Laryngeal Tuberculosis.*

THURSDAY.

HARVEIAN SOCIETY OF LONDON, 8.30 P.M.—*Dr. M. Handfield-Jones: Third Harveian Lecture on the Heart in its Relation to Pregnancy, Parturition, and the Puerperal State.*

SOCIETY OF ANÆSTHETISTS, 20, Hanover Square, W., 8.30 P.M.—*Dr. R. W. Carter (Weymouth): A Precise and Scientific Method of Administering Chloroform and Ether, with Demonstration of the Inhalers by which these Results are obtained.*

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths to 3s. 6d., which sum should be forwarded in post office order or stamps with the notice not later than Wednesday morning, in order to ensure insertion in the current issue.

BIRTHS.

NICHOLSON.—October 29th, at Mayfield, Grassendale, Liverpool, the residence of her father, Surgeon Lieutenant-Colonel Cavaye, A.M.B., the wife of Lieutenant M. S. Nicholson, R.N., of a daughter.

ROOPE.—November 20, at Finsell Park, Bromsgrove, Worcestershire, the wife of Sidney Jacob Scott, M.A., M.B., F.R.C.S., of a daughter.

MARRIAGE.

ALEXANDER-MITCHELL.—At Brechin Cathedral, on December 4th, by the Rev. John A. Clark, B.D., Minister of the First Charge, assisted by the Rev. J. T. Forbes, M.A., Duff Street Church, Edinburgh, John Alexander, M.D., Glasgow, to Jane Morgan, only daughter of the late Charles Mitchell, formerly at Kintockat, near Brechin.

DEATH.

OUR.—On the 6th of November, at Grove House, Ffiley, Yorkshire, Hugh J. H. Orr, Physician and Surgeon.

LETTERS, NOTES, AND ANSWERS TO CORRESPONDENTS.

COMMUNICATIONS FOR THE CURRENT WEEK'S JOURNAL SHOULD REACH THE OFFICE NOT LATER THAN MIDDAY POST ON WEDNESDAY. TELEGRAMS CAN BE RECEIVED ON THURSDAY MORNING.

Communications respecting Editorial matters should be addressed to the Editor, 429, Strand, W.C., London; those concerning business matters, non-delivery of the JOURNAL, etc., should be addressed to the Manager, at the Office, 429, Strand, W.C., London.

Authors desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate beforehand with the Manager, 429, Strand, W.C.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look to the Notices to Correspondents of the following week.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

IN order to avoid delay, it is particularly requested that all letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL, and not to his private house.

PUBLIC HEALTH DEPARTMENT.—We shall be much obliged to Medical Officers of Health if they will, on forwarding their Annual and other Reports, favour us with duplicate copies.

Our Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUERIES.

CAREWORN asks whether there is any hospital or home into which could be received, upon payment of some small sum annually, an orphan girl, 8 years old, who is suffering from lupus in a mild form, principally affecting the scalp.

P. I. F. would be glad to know the cause of and best treatment for persistent pain and tenderness in the muscles of the thigh and leg in a case of fracture of the upper third of the femur persisting for some time after complete osseous union. Various liniments have been tried, but without success.

GAS AND ETHER APPARATUS.

X. Y. Z. asks for particulars as to the cost of a gas and ether apparatus, as well as the advantages and disadvantages of the various kinds. There is little doubt that ether is a much safer anæsthetic than chloroform, but the difficulty of administration, owing to the struggling stage, is often very great in private practice, where there is usually little if any help at hand. A portable gas and ether apparatus at a moderate cost would be a great boon.

BATHS.

INQUIRER asks the address of an establishment in London where sulphur baths can be obtained for a case of muscular rheumatism.

* There are baths at Argyll Place, Regent Street, and at York Terrace, Regent's Park.

THE PROLONGED USE OF SACCHARIN.

R. W. W. wishes to know if any harm is likely to accrue from small doses of saccharin continued for an indefinite period. He is inclined to think it is harmless, having taken it daily in tea or coffee for the last six years, but would like to be assured that there is no ground for a rumour he has lately heard to the contrary.

* Dr. Pavy informs us that nothing is known of any injurious effect being produced by the prolonged use of saccharin in the quantity employed for sweetening purposes.

ANSWERS.

MEDICO.—The papers set for examination for entry into the Naval Medical Service can be obtained by candidates on written application to the Medical Department of the Admiralty.

R. M.—Information as to appointments in the Colonial Medical Service is given in the BRITISH MEDICAL JOURNAL of September 26th, 1895, p. 610. Copies of the memorandum issued by the Colonial Office can be had on application to the Colonial Office.

INQUIRER.—A person really suffering from delirium tremens and doing himself harm, etc., is held responsible or not on the same conditions as apply to anyone else with regard to whom the plea of abnormal mental state at the time of the act is raised.

B. A. G.—We referred our correspondent's query to our Paris correspondent, who writes that the best maker of gluten bread in Paris is F. Laporte (successor to Durand), 21, Rue des Grands Augustins, Paris, but there are others.

J. O.—Diphtherial antitoxic serum can be obtained from the British Institute of Preventive Medicine, 101, Great Russell Street, Bedford Square, London, W.C. Messrs. Allen and Hanbury, Plough Court, Lombard Street, E.C., are agents for the Institute. Diphtherial antitoxic serum is also supplied by Messrs. Partridge and Wellcome, 8, New Hill Buildings, London, E.C.

method since 1823 or 1824. He writes, referring to that period: I was called to a strong young farmer who had been thrown out of his dog-cart, and falling in my attempt to reduce the dislocation by the old and semibarbarous means of the heel in the arête. I made the man sit on the edge of his bed principally on his right buttock in order to bring his left shoulder (the injured one) prominently forward, and grasping the arm firmly above the elbow with the left hand, and making steady traction downwards and outwards, at the same time inserting the fingers of the right hand closely wedged together well between the head of the humerus and side of thorax, the dislocation was at once reduced. I have tried it frequently since, and with, I might say, perfect success, with the exception of one case, and that was in a powerful countryman who had fallen off a cart twenty-four hours previously, and when all methods failed short of being chloroformed, etc. I published my first case in the JOURNAL at the time it occurred.

DR. J. C. FERRIER (South Norwood) writes, with reference to the same subject, that two years ago in Switzerland a young American, about 20 years of age, slipped on a mountain side and put his left shoulder out. I happened (the confusion) to be near, and reduced the dislocation (uncomplicated) by manipulation after two tries with heel in arête had failed. The following was the method used. The fingers of my left hand grasped the patient's left arm from above, and my left thumb was in the patient's arête against neck of humerus. Then with my right hand the patient's left elbow was brought across his chest, so that my thumb acting as a fulcrum the head of the humerus was worked by leverage into the glenoid cavity. I was much struck by the ease with which reduction was effected.

A "SYSTEM OF MURDER."

MR. BRAXTON HICKS on December 5th held an inquest on an unknown male child, which was picked up in Chicheley Street, York Road. Medical evidence proved that the child had been born alive, but that it had been suffocated immediately after birth. The coroner said the people concerned showed more than ordinary coolness. As a rule they attempted to hide dead bodies, but in this case they absolutely throw it in the middle of the road. The unfortunate child had never had a "legal" existence, but there could be no doubt that many so-called midwives carried on a system of what was certainly murder, if not legal murder. There should be an act to compel the registration of all still-born children.

INSANITY OF CONDUCT.

THE following paragraph, which has appeared in the lay press, has caused a good deal of excitement: "The laughing negro is a type very well known to medical men, and several curious cases are on record of grave personages, who had rarely been seen to smile, suddenly breaking into a habit of uncontrollable and contagious laughter. Dr. Clouston tells of a solid, prudent, business man who one day startled his family by a fit of laughter which lasted so long and was so hilarious that everyone in the room had to join in. From time to time after that he would be seized in the church, in a train, or the streets, and whenever he started all who heard him would have to follow. It was the first symptom of mania. Very soon delusions and the most outrageous conduct supervened, and then—the asylum." The above paragraph is of interest as evidence of a form of insanity of conduct; in such cases there is defect of the highest control, and some very slight external cause gives rise to an emotional display which cannot be readily stopped. This is of the nature of impulse, a kind of exaggerated emotional reflex. It is interesting, but quite in accordance with experience that such emotional disorder should be the first symptom of grave mental disorder. Such disorder, if occurring in men, is most frequently met with as an early warning of general paralysis of the insane.

ACETYLENE AS AN ILLUMINANT.

ORDINARY coal gas, though a convenient, is by no means a perfect illuminant, since it contains various constituents which have no illuminating power, while they are injurious when mixed with the air of a room. Acetylene—a gas which burns with a brilliant light—can now be obtained from what is practically a waste product—carbide of calcium, a crystalline body which, when treated with water, yields acetylene almost quite pure. The gas which is thus obtained has a distinct garlic-like odour, so that its presence in air, due to leakage of pipes, would easily be perceived. During combustion it produces less heat than coal gas, less moisture, and less carbonic acid, and uses up about half the quantity of oxygen. The light is white, and for the same volume yields fifteen times as much light as coal gas with an ordinary burner. Dr. Newer, who has published a note on the subject in the *Revue d'Hygiène*, believes that acetylene thus produced has a considerable future, since the case and simple appliances with which it may be made will render it suitable for use for small installations. Further, its addition in certain proportions to ordinary coal gas will increase very much its illuminating power.

LETTERS, COMMUNICATIONS, Etc., have been received from:

A LECTURE ON VACCINATION AGAINST CHOLERA.

Delivered in the Examination Hall of the Conjoint Board of the Royal Colleges of Physicians of London and Surgeons of England, December 18th, 1895.

By W. M. HAFKINE, Sc.D.

THE PRINCIPLES OF PREVENTIVE INOCULATION.

BEFORE dealing with my work in India allow me to recapitulate here the chief circumstances connected with the problem of preventive inoculation. After experimental medicine had been inaugurated the efforts of bacteriologists remained for a long time concentrated on that classical form of infectious disease, splenic fever, in connection with which the fundamental laws of the new science have been elucidated. It was reserved to Dr. Koch to discover in the formation of spores the means by which the microbe of this disease, when outside the animal body, protected itself against the external world. Shortly after this it has been found that the spores not only preserved the life, but also all specific properties of the microbe, and that it is owing to this circumstance that the bacillus of anthrax is one of the most constant species of schizomycetes known. On the other hand, a great mutability of properties has been discovered in all microbial virus not possessing spores, or in which sporification is arrested for a certain period. On the bacillus of chicken cholera Pasteur observed for the first time the loss of virulence in a microbe of a high infectious power. Since then it has been found that the virus of every disease, although it remains constant in the nature of the affection it produces, varies without limit in virulence; that in one and the same specimen this property can be diminished or strengthened by special proceedings, and that in this we have the greatest part of the explanation of the variability of disease in individuals and communities.

This variation in virulence was familiar to all observers, and from time immemorial has been turned to advantage by the peoples of the East. It is known that the practice of inoculation against small-pox was originated from the observation that there are mild and severe epidemics of the disease, and that people affected in mild years remained immune in severe years. At the appearance of a non-fatal epidemic every one wished to get through the disease, and not only did not avoid infected people, but sought their presence and a close contact with them. A practice thus arose in Asia to take artificially the infectious stuff from mild cases and to communicate it to healthy people. Unfortunately, very often in a resistant patient a mild semblance of disease conceals an infectious agent of unexpected virulence, and such virus, on being transferred to a less resistant subject, produces a terrible attack, not infrequently leading to a fatal epidemic in the community. In view of this dangerous character the religious laws of the Hindus, by special regulations, restrict the practice, and the Government from time to time find themselves under the necessity of instituting legal proceedings against those who apply the method. As soon as Jenner discovered an attenuated virus, and showed the method of keeping it in the desired strength by passage through the calf, the practice became immediately safe and certain, and the Eastern method has been abandoned in the whole civilized world.

In the case of small-pox, however, as in the case of rabies or syphilis, the disease is communicated from individual to individual, and the morbid virus is cultivated exclusively in the animal body, under conditions varying little in their character. The modifying influences become infinitely greater when a virus can grow in a saprophytic form and is exposed, in the interval between visiting animal bodies, to the vicissitudes of nourishment, oxidation, light, temperature, which are to be found in the external world. Even microbes, like that of anthrax or tetanus, provided with protective spores

do not escape this law, and one finds in Nature their specimens presenting a very large scale of modifications; but there appears to be no limit to variability in infectious virus leading a saprophytic life and deprived of the specialising faculty. The microbe of cholera is one of the most striking examples of this phenomenon.

VARIABILITY OF THE CHOLERA MICROBE.

When the cholera bacillus was first discovered, eleven years ago, its properties were described with great precision, which helped in concentrating for a long time all studies on well-defined and carefully-chosen specimens. Little by little, as the field of investigation grew larger, a number of varieties have been found with characteristics differing so largely as to annihilate almost completely the original description. When we open the intestines of deceased cholera patients and investigate the microbes there, the adopted methods will bring to the surface vibrios in which the external form, instead of the characteristic comma or spirillum, will vary between a coccus and a straight thread; the number and disposition of the cilia, the secretion of acids, the form of growth in broth, will vary; instead of giving in gelatine a discrete and well-defined figure of liquefaction, the variation will extend from the complete loss of this property to a rapid dissolution of the whole of the medium; there will be varieties which grow luxuriantly in given media, and others which do not grow there at all; some will be phosphorescent in the dark, and others not; some will give the indol reaction, and others will be deprived of this property, and so on. The first thing to be done is carefully to select amongst these the most typical specimens, rejecting the others, and then we try their pathogenic power. We shall find such a divergence in strength that the extreme forms will not be believed to be of the cholera species. There will be commas deprived of any virulence demonstrable on animals, and others which kill the most resistant species. Some will be fatal to a guinea-pig at a dose of $\frac{1}{25}$ of a culture tube, and others harmless in doses 500 times stronger. The average comma dies out when introduced under the skin to an adult animal; others will spread in the system and give a fatal septicæmia. The ordinary comma will be without effect on birds; but several specimens have been isolated, and believed to be typical, which easily killed pigeons by hypodermic or intramuscular injection. I believe to be of great value the method worked out by Pfeiffer for comparing all such varieties with one selected as typical, and which he employed for the preparation of an antitoxic serum. This method will be found of efficient help in distinguishing specimens of the greatest affinity with the average cholera comma. But once such specimens are selected and their particular properties studied, they begin to change from the first day they are introduced into the laboratory, and no calculation based on these studies is possible. In a case quoted by M. Metchnikoff, the proportion of initial power of the microbe, and the strength it showed at a later trial, was of 75 to 1, the microbe having gradually sunk to $\frac{1}{2}$ of its initial virulence. If, for producing a certain infectious, or preventive, or curative effect, we had to use, in the first days, 1 c.c. of this culture, later on a dose smaller than 75 c.c. would be without effect, and the changes of the microbe would certainly continue still further.

THE SYSTEM FOLLOWED IN INDIA.

In all operations on men done in India we used exclusively living cholera virus, for the reason that sterilized cultures or products of cultures, as a rule, produce an effect of a far shorter duration than living microbes. The symptoms in anticholera vaccination consist in localised swelling and pain in the side, at the seat of injection, and in an attack of fever. The pain is felt only on pressure, and its amount is such as to prevent a soldier from putting on his belt for a couple of days, and a coolie worker from doing work involving bending the body or stretching otherwise the interested tissues. But the intensity of the symptoms and their duration vary in direct proportion with the virulence of the cultures and the doses administered. On the other hand, in all forms of preventive treatment the amount of protection depends on the intensity of reaction produced in the subject. A small dose of a given virus, or

else the same dose of a weakened virus, will produce less reaction and afford less protection; a higher dose of the same virus, or the same dose of a stronger virus, produces more reaction and affords a higher and, probably, more lasting protection.

In the first period of my work in India I adopted $\frac{1}{2}$ of a standard culture, of a given strength, as a dose for an adult person. The reduction of this dose by a small fraction is sufficient not to produce in the subject any noticeable reaction at all. Later on, after the first series of observations was collected, I was induced to apply a treatment by increased doses of a stronger vaccine. A series of experiments and observations, for which I am especially indebted to Dr. Arthur Powell in Cachar, have been instituted with this object. It has been found that with the increase of the doses the amount of local pain, and especially that of general discomfort, was proportionately increasing, the fever was of a more severe type, and lasted longer, disabling the men for work for four, five, and more days. In Dr. Powell's mind there remained no room for doubt that with the increase of the doses the operation would become fatal to man. The limit of the doses adopted for the strength of the vaccines we used was between $\frac{1}{4}$ and $\frac{1}{2}$ of a culture.

From this it will be seen that it is a matter of vital importance, *a sine qua non*, in order not to exceed or fall below the intended reaction, to have a method of fixing the properties of this modifiable microbial virus, to keep it at the same degree of activity, and to know exactly the amount of power contained in a given dose.

The general method worked out for that purpose consists in finding out an animal susceptible to the given virus, and discovering the conditions in which the virus can be transplanted from animal to animal without interruption and without having recourse to artificial media. Jenner's method in its essential features remains intact, and our proceedings correspond exactly to the cultivation of vaccinia from calf to calf, or from vaccinated man to man. The particular difficulties which were connected with the diseases for which vaccines have been worked out, have been treated in the technical literature, and I believe there is no room for dealing with the matter in the present lecture. The terms virus and vaccine are still used in the same sense as they were used in regard to small-pox. The infectious substance from a subject who naturally fell ill from a disease—a small-pox patient, a rabid dog, a person affected by cholera—is a virus; the Eastern practice of inoculating small-pox virus against small-pox is variolisation. On the other hand, the substance cultivated under conditions intended to keep the morbid agent at a given and fixed state of virulence, permitting the use of it with safety and sure measurement, such as Jenner's calf lymph, or Pasteur's rabies emulsions, is a vaccine, and the application of such substances for preventive treatment is called—following the suggestion of Pasteur and in honour of Jenner who first used the term—vaccination.

The method which I worked out for the preparation of two cholera vaccines, one weakened and a second one strengthened, has been described in my previous lecture delivered in this hall three years ago.

It is the difference between vaccination and variolisation that distinguishes the method which I have applied in India from that tried in Spain by Dr. Jaime Ferran in 1885. Ferran's operations consisted in inoculating vibrios collected from cholera patients. The method employed in India consists in inoculating a vaccine worked out following the proceedings of Jenner and Pasteur.

The difference between the two operations is such that Jenner's method has survived criticism and the test of a century's daily application, and has been vastly generalised; the other method, imitating the inoculation of small-pox virus against small-pox, had to be abandoned on every occasion where attempts to apply it were made. At present there is not a single practice, in therapeutics or in preventive medicine, where the use of living virus taken directly from infectious persons, is allowed, whether on individual subjects, or, still less, in application to whole populations. The attempts made by Toussaint, previously to Pasteur's operations, of inoculating anthrax virus against anthrax, died out without the slightest possibility of practical application. In the treatment against anthrax by Pasteur's method, an ex-

cessive attenuation of the first anthrax vaccine, which was permitted to fall below the desired amount of virulence, caused on some occasions serious accidents. The neglect to make strict distinction between vaccine and virus was responsible for a disaster which occurred in the inoculation of sheep against anthrax in the south of Russia. The misadventure led to a prolonged suspension of all anthrax inoculations in that country, and partly in Austria-Hungary, and Italy; but one shudders to think of any similar accident occurring, instead of a flock of sheep, in a regiment of men. The attempts at inoculating cholera virus against cholera by Ferran had to be stopped by the Spanish Government, and was disapproved by all commissions sent out to investigate these operations by the Governments of Spain, Great Britain, France, Russia, Belgium, a result which was used as one of the arguments, seven years later, by the Government Committee in Russia, in refusing to admit the trial of my method of protection against cholera. On the other hand, vaccination against rabies has been going on these ten years with a marvellous precision, and has been already applied to about 15,000 people in France alone; innumerable flocks of domestic animals are vaccinated yearly in different parts of the world, against anthrax and pig-measles. And now we come to record the results of upwards of 70,000 injections of living bacteria, performed on 42,179 people, without having to record a single instance of mishap or accident of any description produced by our vaccines.

INDIAN EXPERIENCES.

My actual work in India lasted twenty-nine months, between the beginning of April, 1893, and the end of July, 1895. During this period the anticholera vaccination has been applied to 291 British officers, 3,206 British soldiers, 6,629 native soldiers, 869 civil Europeans, 125 Eurasians, and 31,056 natives of India. The inoculated people belonged to 98 localities in the North-West Provinces and Oudh, in the Punjab, in Lower Bengal and Behar, in the Brahmaputra valley and in Lower Assam. No official pressure has been brought on the population, and only those have been vaccinated who could be induced to do so by free persuasion. In every locality efforts were made to apply the operation on parts of large bodies of people living together, under identical conditions, in order to compare their resistance in outbreaks of cholera with that of not-inoculated people belonging to the same unit of population. This object has been obtained in 64 British and native regiments, in 9 gaois, in 45 tea estates, in the fixed agricultural population of the villages parallel to Hardwar pilgrim road, in the *bustees* of Calcutta, in a certain number of boarding schools where the parents agreed to the inoculation of their children, in orphanages, etc. The vast majority of inoculated people lived thus under direct observation of the sanitary and medical authorities of India.

Cholera broke out in the inoculated localities from 1 to 459 days after the operation, and careful statistics of occurrences were immediately collected by the corresponding civil and military and medical authorities, as well as by myself. The whole number of observations made, as they were at the time when I left India, may be grouped in three categories: (I) the first, containing unsuccessful results, or such in which no conclusion was possible; (II) the second, with results slightly favourable to the method; and (III) the third with results satisfactory.

I. To the first category belong observations made on a series of tea estates in Assam. The coolie workers on these plantations live in well-defined isolated bodies, distant from the villages, and not mixed with outside population. The inoculated individuals were scattered among the non-inoculated, and shared with them food, water supply, and all other conditions of life. In all instances belonging to this category the people had undergone only one part of the preventive treatment—namely, were inoculated with first attenuated anticholera vaccine given in maximal doses; the second inoculation, with the final vaccine, was applied after the cholera season had ceased. The disease occurred from one to six months after the first inoculation with the following results.

ADAM TILA.

557 non-vaccinated had no cases.
318 vaccinated had 2 cases (0.63 per cent.) with 1 death (0.31 per cent.).

KALACHHERA.

586 non-vaccinated had 4 cases (0.67 per cent.) with 3 deaths (0.51 per cent.)
 241 vaccinated had 1 case (0.41 per cent.) with 1 death (0.41 per cent.)

CHANDOLA.

1,007 non-vaccinated had 3 cases (0.30 per cent.) with 1 death (0.10 per cent.)
 591 vaccinated had no cases.

PALLABHUND.

1,170 non-vaccinated had 3 cases (0.25 per cent.) with 2 deaths (0.17 per cent.)
 681 vaccinated had no cases.

LAKOLA.

249 non-vaccinated had 1 case (0.40 per cent.) with 1 death (0.40 per cent.)
 621 vaccinated had no cases.

BURNIE-BRAES, LOOHACHHERA, KALACHHERA, AND BANDHURA.
 Number of non-vaccinated not stated; had 11 cases with 5 deaths
 877 vaccinated had no cases.

II. To the second category, with results slightly favourable, belong (a) two observations made on people inoculated with maximal doses of the first vaccine only, cholera occurring a short time after the inoculation, and (b) two observations on people inoculated with weak doses of both vaccines, cholera occurring thirteen to fifteen months after vaccination had been applied.

(a) The 2nd Battalion Manchester Regiment at Dinapore 2 to 3 days after injection of first vaccine only:

739 non-inoculated had 6 cases (0.82 per cent.) with 3 deaths (0.41 per cent.)

100 inoculated, no cases.

Regiment at Tez Khatia, 24 months after inoculation of first vaccine only:

387 non-inoculated had 3 cases (0.78 per cent.) with 1 death (0.26 per cent.)

387 inoculated, no cases.

(b) The British troops in Cawnpore, 18 months after inoculation with small doses of both vaccines:

797 non-inoculated had 19 cases (2.38 per cent.) with 13 deaths (1.63 per cent.)

75 inoculated, no cases.

The East Lancashire Regiment in Lucknow, 14 to 15 months after inoculation with small doses of both vaccines:

510 non-vaccinated had 120 cases (23.53 per cent.) with 79 deaths (15.37 per cent.)

193 vaccinated had 18 cases (9.33 per cent.) with 13 deaths (6.74 per cent.)

III. To the third category, with results satisfactory, belong (a) observations on maximal doses of first (mild) vaccine made on the Karkurie and Kalin Tea Estates, one to three months after inoculation; (b) observations on small doses of both vaccines, made on the prisoners of the Gaya Gaol inoculated during an epidemic; (c) observations on middle doses of one and of both vaccines in the *bustees* in Calcutta, collected during a period of 450 days, and finally, (d) the observation made quite lately on the Kassia Hill coolies, from the survey party of the Assam-Burmah Railway.

(a) Karkurie Tea Estate, 2 to 3 months after inoculation with strong doses of first vaccine only:

203 non-inoculated had 5 cases (2.46 per cent.) with 2 deaths (0.98 per cent.)

769 inoculated had 1 doubtful case (0.21 per cent.) with 1 death (0.21 per cent.)

Kalin Tea Estate, 1 to 3 months after inoculation with strong doses of first vaccine only:

1,375 non-inoculated had 23 cases (1.67 per cent.) with 11 deaths (0.8 per cent.)

681 inoculated had 2 cases (0.29 per cent.) with 1 death (0.15 per cent.)

(b) In the Gaya Gaol the inoculations were for the first time applied in a prevalent epidemic, and very weak doses of relatively weak vaccines have been used. The gaol contained over 400 inmates. After 6 cases with 5 deaths had occurred, a half of the prisoners, including aged and young people, women, children, patients from the hospital, and people affected with premonitory diarrhoea, was inoculated; the other half, of an exactly similar composition, was left uninoculated. The result was a gradual disappearance of cases and deaths among the inoculated, the difference in susceptibility having gradually increased during the period of 10 days necessary for the two vaccines to produce their full effect.

During the first period of 5 days necessary for the 1st inoculation:

319 non-vaccinated had 7 cases (2.20 per cent.) with 3 deaths (0.94 per cent.)

212 vaccinated had 5 cases (2.36 per cent.) with 7 deaths (3.30 per cent.)

During the second period of 5 days necessary for the 2nd inoculation:

197 non-vaccinated had 0 cases (0 per cent.) with 7 deaths (3.55 per cent.)

246 vaccinated had 1 case (0.41 per cent.) with 1 death (0.41 per cent.)

During the last 4 days of the epidemic:

195 non-vaccinated had 3 cases (1.54 per cent.) with 1 death (0.51 per cent.)

301 vaccinated had no cases.

The total results are as follows:

The non-vaccinated half had (0.90 p.c.) of cases with (1.55 p.c.) of deaths.

The vaccinated half had (0.89 p.c.) of cases with (0.41 p.c.) of deaths.

The treated prisoners showed a reduction of 2.56 times of

cases, and of 2.05 times of deaths. I wish to call your attention to the fact that the inoculations had been applied in this instance not before the epidemic, but a week after it had actually broken out, in order to arrest it, and to cure, so to say, the community from the disease. The reduction of deaths by one half will therefore justify the application of the method in all similar conditions, there being up to now no other method known in medicine by which such an effect could be obtained. We shall see directly an instance of the same kind when far higher results have been obtained by an application of stronger doses.

(c) In the *bustees* situated round the tanks in Calcutta, where cholera exists in a permanent state, the disease occurred in 36 houses with inoculated people. In each of these houses there was one part of the family inoculated and another not. The observations were continued for 450 days, with the following results:

During the first period of 5 days subsequent to the inoculation with first vaccine cholera occurred in 5 houses:

75 non-inoculated had 5 cases (6.67 per cent.), with 3 deaths (4 per cent.)

52 inoculated had 3 cases (5.77 per cent.), with 3 deaths (5.77 per cent.)

During the second period of 5 days subsequent to the second inoculation cholera occurred in 3 houses:

8 non-inoculated had 2 cases (25 per cent.), with 2 deaths (25 per cent.)

17 inoculated, no cases.

After the 10 days necessary for the preventive treatment had elapsed, and up to the 450th day, the disease visited 26 houses, with the following results:

263 non-inoculated had 38 cases (14.45 per cent.), with 34 deaths (12.93 per cent.)

137 inoculated had 1 case (0.73 per cent.), with 1 death (0.73 per cent.)

In a child that had not been brought up for the second inoculation.

Thus, after the expiration of the first 10 days, the inoculated members of the affected houses had 17.24 times fewer deaths and 19.27 times fewer cases than the non-inoculated inhabitants of the same houses, and this proportion was maintained up to the 450th day after vaccination.

(d) The last observation comes from the Brahmaputra valley, where Surgeon-Captain Hare, of the Indian Medical Service, my co-worker during the last eight months of my stay in India, is continuing now the work of inoculation for the Assam Government. Dr. Hare's full account of this observation has not yet reached me, but from a communication of the Health Officer of Calcutta, and from the Indian papers, it appears that 350 Khassia Hill coolies had been collected for the survey party of the Assam-Burmah Railway and put under the escort of a detachment of Goorkhas, when cholera broke out amongst them. The largest part of the coolies immediately submitted to the preventive inoculation, the rest remained uninoculated. The result was that among the not inoculated minority there were 34 cases, with 30 deaths; whereas the inoculated had 4 fatal cases. In this instance, also, the inoculation appears to be applied not as a preventive but as a curative for an existing epidemic, and the result, if the information is complete, has been the reduction of the mortality of more than seven times.

SUMMARY.

The following seems to be a summary of the results observed up to now:

1. In all those instances where cholera has made a large number of victims, that is to say, where it had spread sufficiently to make it probable that the whole population, inoculated and uninoculated, were equally exposed to the infection, in all those places the results appeared invariably favourable to inoculation.

2. The treatment applied after an epidemic actually breaks out tends to reduce the mortality even during the time which is claimed for producing the full effect of the operation. In the Gaya Gaol, where weak doses of a relatively weak vaccine had been applied, this reduction was to half of the number of deaths; in the coolies of the Assam-Burmah survey party, where, as far as I can gather from my preliminary information, strong doses have been applied, the number of deaths was reduced to one-seventh. This fact would justify the application of the method independently of the question as to the exact length of time during which the effect of this vaccination lasts.

3. In Lucknow, where the experiment was made on small doses of weak vaccine, a difference in cases and deaths was still noticeable in favour of the inoculated fourteen to fifteen

months after vaccination, in an epidemic of exceptional virulence. This makes it probable that a protective effect could be obtained even for long periods of time if stronger doses of a stronger vaccine are used.

4. The best results seem to be obtained from application of middle doses of both anticholera vaccines, the second one being kept at the highest degree of virulence obtainable.

5. The most prolonged observations on the effect of such middle doses were made in Calcutta, where the mortality from the 11th up to the 459th day after vaccination was, among the inoculated, 17.24 times smaller, and the number of cases 19.27 times smaller than among the not inoculated.

RESULTS OF ANTICHOLOERA INOCULATION.

The evidence accumulated up to now is decidedly in favour of the anticholera vaccination, and my own conviction in the matter is more and more strengthened. The special responsibility, however, which lies on me in this subject forces me to point out that the number of observations is not yet very large, and that it is most desirable that the results obtained should be further confirmed by new and more ample information. At the same time, you will find it, I hope, pardonable on my part if, before finishing the review of the results, I cite the opinion expressed on the subject by the scientist who himself accomplished the first and the most difficult part of the cholera problem, and whose discovery was the starting point of the whole of the modern researches on cholera.

When recapitulating with Professor Koch the data of my report to the Government of India, I said that, in my idea, the results tend to prove the efficacy of the method, but that I feel necessary to do all in my power in order to confirm them by new observations. I was most happy to learn that, for Professor Koch, the demonstration was already complete; that he believes the protective power of the method to be established finally by the observations collected in India up to now; that further perfections and simplifications may be possible, but that the main question at issue, the chief part of the problem, is solved by the facts recorded in the above report. Professor Koch gave his kind permission to quote these decisive conclusions in this Hall and to use the very terms I used, and he added that, in his conviction, the chief struggle against cholera must certainly take place on the banks of the Ganges, in the home of the disease; that this struggle is to be effected by preventive inoculation, and that he sees in the application of this method the way in which, by gradually restricting the area of the extension of the disease, it shall be brought to such a limit when it will become possible to control its prevalence by simple measures of a sanitary police.

PROGRAMME FOR NEXT OPERATIONS.

Allow me now to consider the question whether the new facts brought to light during my absence in India ought to be incorporated into my method of anticholera vaccination. The treatment by antitoxic serum, which by now may be considered as having proved a decided success in diphtheria, could not, unfortunately, be substituted for a preventive vaccination, its effect being rapidly worn out by the system. According to the observations made up to now, neither the antidiphtheritic nor an anticholera serum could be used for protecting a population against an epidemic lasting more than a few days, not to speak of an endemic prevalence of the disease. The question stands otherwise as regards the possibility of treatment in individuals actually affected with cholera. Although in this particular disease we have against us the great rapidity with which the symptoms take hold of the system, the antitoxic serum has accomplished in other instances such excellent results that there is every possibility of its being beneficial in the case of cholera also. I intend, therefore, on my return to India, to give, in connection with the physicians of the country and with the help of Professor Pfeiffer from Berlin—who most kindly put at my disposal all his experience in the matter, as well as a supply of a very active antitoxic serum—an extensive trial to this method.

In case a simple application of the antitoxin serum proves to be insufficient to stop the rapid course of the symptoms, I intend to combine it with intravenous saline in-

jections and to prolong in this way the period left for treatment. And if in this case also the attempt should fail, I shall try to utilise the new therapeutic for accelerating the effect of my vaccines in a manner which I will characterise in a few words. We have seen up to now that in the places where anticholera vaccination has been applied in a prevalent epidemic, the total number of deaths was reduced from two to seven times in comparison with the deaths in the non-inoculated, but the effect of the treatment was not in the first four or five days after the first inoculation. There is the possibility that, by injecting a mixture of my vaccines with a powerful antitoxic serum, the mortality may be reduced also in the first days after the treatment, the serum arresting the disease for the time necessary for the vaccines to produce their full effect. The admixture of antitoxic serum with the vaccines may mitigate the vaccinal reaction, as has been suggested to me by Professor Wright from Netley, and this reduction of reaction may possibly reduce the amount of active protection conferred by the vaccines. A series of experiments have therefore been undertaken in the Netley bacteriological laboratory in order to investigate this important question.

Mr. Chairman and Gentlemen.—On the day when I came back from my expedition to India, I found my former chief, M. Pasteur, lying on his bed of death. Whatever might have been his appreciation of the work done in India, there can be only one desire on my part, that all the honour for the results which may possibly come out of my efforts, should be referred to him, to his sacred memory.

To the Government of India, the gentlemen of the Indian and Army Medical Staff in India, to Professor Hankin in Agra, Dr. Powell, and especially to Dr. Simpson, the eminent health officer of Calcutta, I address my hearty expressions of gratitude for the assistance they have given me in carrying out my work. I beg these gentlemen, if my present words are destined to reach them, to accept this public acknowledgment that without their most efficient help I would have never been able, with all my individual powers, to accomplish in India the smallest part of the work which has been done.

I also beg the Chairman and the organisers of the present meeting to accept my best thanks for having given me this opportunity of making the present communication.

A RINGWORM HOSPITAL.—In the *Journal des Praticiens* Dr. A. F. Plicque gives an account of a hospital for children suffering from ringworm and other contagious affections of the scalp at Moisselles. This hospital was opened in 1894 for the reception of 212 children, who had to be sent away from the seaside hospital at Berck-sur-Mer on account of ringworm. The improvised hospital was installed in some farm buildings which had formerly been used for a penitentiary colony. The buildings, though very defective in structure, are situated in a wide, airy space, near the great forests of Montmorency, in the Isle of Adam. Drs. Queyrat and Beurnier had medical and surgical charge of the children, all of whom were suffering from tuberculous joint or gland disease besides their ringworm, for which they were under the care of M. Sabouraud. In the course of eighteen months there have been only five deaths. There are at present 105 children in the hospital; although not yet cured of ringworm their general health is said to be most satisfactory. During their stay at Moisselles the children's education is not neglected. The hospital, however, is it seems, doomed to disappear as soon as the last little patient has been discharged. This is a pity, for there will then be no place to send children suffering both from tuberculous disease and ringworm who cannot be received at Berck. Moreover, as M. Plicque testifies, the inland country air of Moisselles has a most beneficial effect on many cases of conjunctivitis, bronchitis, and pulmonary tuberculosis, which are made worse by the sea air of Berck.

At an examination for inspectors of nuisances held in London by the Sanitary Institute on December 6th and 7th, 123 candidates presented themselves, of whom 83 passed. At an examination in practical sanitary science held on the same days, 22 candidates presented themselves, and 10 passed.

THE USE OF ANTISEPTICS IN THE TREATMENT OF INFANTILE DIARRHŒA.¹

By W. SOLTAU FENWICK, M.D., M.R.C.P.,

Research Scholar to the British Medical Association, Assistant Physician to the Evelina Hospital for Sick Children.

DURING the last few years a considerable amount of attention has been directed to the various chemical changes which occur in the digestive tract as the result of bacterial activity, and certain facts have come to light which prove beyond doubt that many clinical phenomena, which formerly were either ignored altogether or regarded as symptoms of a fortuitous nature, must now be attributed to the direct absorption of organic poisons from the stomach or intestine. The various researches which have so materially contributed towards this discovery have also indicated that certain morbid conditions of the digestive organs which are usually assigned a simple etiology owe their origin in reality to diverse and often complex causes which are themselves intimately connected with abnormal fermentations of the food. In view of these facts it is not surprising to find that the principles which were formerly laid down for the treatment of disordered digestion have undergone a corresponding change, and that instead of employing sedatives or astringents for the relief of gastric or intestinal irritation, our principal efforts are now directed to control the immediate cause of the disorder by the exhibition of drugs which possess the power of inhibiting the processes of fermentation.

The question of gastro-intestinal antiseptics extends over such a wide field, and embraces so many subjects, that any attempt to deal with it in an adequate manner is beyond the scope of a single paper. I will therefore confine the few remarks I have to make to the antiseptic treatment of the intestinal dyspepsia of infants, the chief symptom of which is diarrhœa.

ETIOLOGICAL CONSIDERATIONS.

The researches of Escherich, van Puteren, and others have shown that, although at birth the contents of the digestive tract are sterile, bacterial infection is brought about within the first twelve hours of life through the medium of the atmospheric air which the infant swallows in large quantities. The various micro-organisms thus introduced into the system thrive and multiply in the mucus and undigested food which soon fills the intestine, and are constantly reinforced in numbers and diversified in species by the ingestion of contaminated milk or the swallowed secretions of the mouth. The danger which arises from these natural sources of infection is greatly increased by the fact that during infant life the gastric juice is incapable of exerting any decided control over microbial growth, owing to its comparative deficiency in free hydrochloric acid. Milk fermentation ensues from the presence of *B. lactis aerogenes* and the *B. butyricus*, which along with several other varieties of lesser importance are constantly found in the stomach of infants suffering from indigestion. The first-named converts the milk sugar into lactic acid with the precipitation of casein, while the latter changes a portion of the lactic into butyric acid, and in so doing liberates free hydrogen gas. The presence of these abnormal products in the contents of the stomach give rise to abdominal pain, distension, and vomiting, a series of symptoms which characterise the disorder known as acute dyspepsia.

The entrance of undigested and fermenting material into the intestine induces violent peristalsis, with the result that the infant suffers from colic and diarrhœa until the bowel has succeeded in ridding itself of its irritating contents. If proper means be taken to assist this effort of Nature and to prevent a recurrence of the disorder, the stools soon resume their normal appearance, and perfect recovery ensues. But if these evidences of digestive derangement are overlooked or neglected and the child is constantly piled with food, each fresh supply of milk undergoes the same process of fermentation in the stomach and hastens the advent of the second stage of the disorder—namely, gastro-intestinal catarrh. This inflammatory condition probably arises from direct irri-

tation of the mucous membrane of the digestive tract by the acid products of fermentation, and since it is always accompanied by a diminution in the secretion of hydrochloric acid, gastric digestion becomes greatly enfeebled, and the various bacteria are afforded an unlimited scope of action. Within a short period of time the intestine becomes affected in a similar manner, and the child begins to lose flesh and strength and to present all the symptoms characteristic of chronic intestinal catarrh. The third and last stage of the disease is marked by a more or less extensive cirrhosis of the mucous membrane of the digestive tract, often associated with the follicular ulceration of the colon. The diarrhœa continues and the stools are largely mixed with mucus or streaked with blood; the marasmus increases, and death finally ensues either from exhaustion or from some nervous phenomena due to the absorption of toxins from the alimentary tract. This sketch of the etiology of the infantile diarrhœa serves to emphasise three important facts. In the first place the disorder is a direct result of the activity of certain bacteria which produce abnormal fermentations of the food with subsequent inflammation of the stomach and intestines. Secondly, the intestinal derangement is primarily dependent upon gastric indigestion, and hence the symptomatic diarrhœa will not be overcome until the gastric disorder has subsided. Lastly, the prognosis in chronic cases depends upon the extent of the organic changes which have taken place in the digestive organs, and the influence they exert upon the assimilation of the food.

MEDICINAL ANTISEPTICS: THEIR ADMINISTRATION AND MODE OF ACTION.

Although the theory of intestinal antiseptics is comparatively modern, its practice dates from the earliest times. Thus the empirical value of emetics and purgatives in cases of dyspepsia obviously depends upon the fact that these measures serve to rid the system at once of the agents of putrefaction and their products; while in the routine treatment of diarrhœa by such drugs as calomel and subacetate of bismuth, the same unconscious adoption of antiseptic principles may be discerned.

The various antiseptic drugs which are specially adapted for medicinal use can be roughly divided into two classes according as they are soluble or insoluble in water. The first group comprises such substances as carbolic acid, perchloride of mercury, lactic acid, hydrochloric acid, salicylate of sodium, and resorcin. The chief members of the insoluble class are naphthalin, *s*-naphthol, betol, benzol-naphthol, salol, the salicylates of bismuth and strontium, and calomel. In addition to the question of solubility there exists another and more important distinction between the members of the two classes. The soluble varieties possess germicidal and toxic properties in direct proportion to the dose in which they are administered, and since they are absorbed rapidly from the alimentary tract it is obvious that they can only exert their specific action in the stomach and upper part of the small intestine. The insoluble drugs, on the other hand, remain for the most part unaltered in the stomach, and therefore exert but little influence upon the fermentative processes which occur in that organ. In the intestine, however, the majority of them are subjected to chemical influences by which they are decomposed, with the ultimate production of secondary substances that exhibit both antiseptic and poisonous properties far in excess of the original drug. These latter remedies are accordingly reserved for cases where it is necessary to control bacterial activity in the intestine, and for this purpose they are administered in full doses at short intervals of time.

Hydrochloric acid inhibits the growth of most species of bacteria when it exists in the proportion of more than 0.17 per cent. (Miller). It is probable that in its natural combination with pepsin the acid not only kills but actually digests many bacteria, and in this manner serves to protect the intestine from the action of pathogenic organisms introduced with the food. The acid has been much extolled as an efficient antiseptic in cases of infantile dyspepsia, and is usually administered either in the form of 0.4 per cent. solution or as the Pharmacopœia preparation of the dilute acid. Its use is contra-indicated by the presence of gastric catarrh. Lactic acid possesses less than one-fifth of the antiseptic

¹ Read in the Section of Pharmacology and Therapeutics at the Annual Meeting of the British Medical Association, held in London, July-August, 1895.

power of the mineral acid aforementioned. It has been chiefly recommended by certain French physicians as a remedy for the green diarrhœa of infants, attributed by them to the presence of a chromogenic bacillus. It is most advantageously employed as a 2 per cent. solution, of which a teaspoonful may be given every two or three hours. This acid occasionally gives rise to gastric pain and vomiting, especially if the mucous membrane of the stomach be inflamed. It is excreted by the kidney in the form of lactate of sodium.

Carbolic acid is undoubtedly one of the most powerful germicides we possess, but unfortunately its medicinal value is considerably impaired by its unpleasant taste and poisonous character.

Although the presence of pyrocatechin in the urine does not necessarily indicate danger to life, it should always be regarded in the light of a warning, and the dose either decreased or the drug discontinued altogether. Carbolic acid can be administered to children either in the form of the pure acid (1 minim well diluted), or as the glycerine preparation (2 to 4 minims).

The use of perchloride of mercury is also somewhat limited on account of its toxic properties. In severe cases of diarrhœa it has been used with success when given in doses of $\frac{1}{4}$ to $\frac{1}{2}$ of a grain every two hours. It is rapidly eliminated by most of the excretory organs of the body.

Resorcin (metadihydroxybenzolum) is a crystalline powder, freely soluble in water, and possessed of a harsh sweet taste. Its solution is powerfully antiseptic, 0.4 of the substance inhibiting the growth of all the micro-organisms which are found in the stomach and intestine. It is rapidly absorbed by the mucous membrane of the alimentary tract, and can be detected in the urine by means of perchloride of iron (violet colour) within a short time of its ingestion. In moderate doses resorcin is devoid of toxic properties, but when a drachm or more is given at a time giddiness, headache and sweating are apt to supervene. For these and other reasons, which will be mentioned immediately, I consider it one of the most useful remedial agents we possess for the treatment of infantile diarrhœa.

Among the insoluble aromatic compounds of the carbon series naphthalin has, perhaps, enjoyed the greatest amount of reputation. Although insoluble in water, a certain amount is absorbed by the intestine, and is excreted by the kidney in the form of naphtho-sulphite of sodium, thereby producing a brownish-black coloration of the urine. When mixed with nutritive media this substance exhibits comparatively feeble antiseptic properties, as much as 1.5 per cent. being usually required to inhibit the growth of the intestinal bacteria. Naphthalin possesses a powerful and disagreeable smell, and in certain cases its administration is followed by renal and vesical irritation. The dose for a child is from 2 to 5 gr., either mixed with sugar or suspended in some sweet emulsion.

Naphthol is a powerful germicide when it exists in a proportion greater than 0.05 per cent. It is only slightly poisonous, but its taste and smell are unpleasant. It has been used with success in cases of infantile diarrhœa, about 2 gr. being given every four hours either mixed with white sugar or dissolved in olive oil and emulsified.

Salol (salicylate of phenol) is a white, tasteless powder which remains unchanged in the stomach, but in the duodenum is rapidly split up into phenol and salicylic acid, the latter of which can be detected in the urine within seventy minutes of its administration. In test-tube experiments this substance only retards the growth of bacteria when it exceeds 0.6 per cent. of the medium. To infants 10 gr. may be administered in divided doses during the course of the twenty-four hours.

Benzol naphthol is a tasteless powder, which in the intestinal canal becomes decomposed with the liberation of naphthol and benzoic acid. The latter is excreted in the urine, partly in combination with alkaline bases, and partly in the form of alkaline hippurates. This substance is not poison when given in moderate doses, and it is therefore of considerable value in case of infants and young children, to whom it may be administered in doses of 30 grains per diem.

Iodoform was formerly advocated as a medicinal remedy, but it has now been to a great extent replaced by the before-

mentioned preparations. Its antiseptic properties are probably greater in the intestine than laboratory experiments would indicate (0.3 per cent.), since it undergoes partial decomposition in the bowel with the liberation of free iodine. In combination with charcoal, it has been strongly recommended by Bouchard as a means of diminishing the toxicity of the urine and feces.

The salicylates of bismuth and strontium both undergo chemical changes in the intestine with the formation of salicylic acid and the corresponding metallic sulphides. The acid exerts a powerful antiseptic influence upon the contents of the bowel, and is slowly eliminated by the kidney. The sulphide of bismuth betrays its presence by the characteristic blackening of the motions. Both preparations are tasteless and insoluble, and may be given to infants in doses of 1 to 3 gr. every four hours. It is usually stated that the salicylic acid exerts an irritant action upon the kidney, and that the drugs which cause its elimination in the urine are contraindicated in cases of albuminuria. This objection is, I believe, more theoretical than real.

Calomel is an excellent example of that class of remedies which owe their antiseptic properties to a change in their chemical composition occurring after ingestion. It is probable that the subchloride of mercury when given in minute doses is partially converted in the stomach into the perchloride, and in the intestine into the sulphide. It is by far the most reliable remedy we possess for acute cases of diarrhœa in infants when administered in fractions of a grain at frequent intervals.

RESULTS

In the selection of an appropriate drug for a child several factors have to be taken into consideration which in the case of an adult can safely be neglected. Substances which possess a nauseous taste or offensive smell are hardly tolerated by a child even when mixed with an excess of sugar; and hence naphtholin, β -naphthol, and iodoform can seldom be prescribed with success. Again, absorption takes place so readily from the alimentary tract of an infant that it is often impossible to obtain any degree of intestinal antiseptics from the use of perchloride of mercury and the phenol compounds without running great risk of poisoning the patient in the process. Lastly, powders like charcoal, which have to be administered in large bulk in order to produce any effect at all, are obviously inapplicable to the treatment of disease in infants. In the majority of cases, therefore, our choice is limited to the tasteless and comparatively non-toxic powders, such as calomel, benzol-naphthol, and the salicylates of bismuth and strontium, or to the soluble antiseptics like resorcin and the acids. During the last three years I have used the various medicinal antiseptics in more than 500 cases of digestive disorders in children which have come under my notice at the Evelina Hospital and elsewhere. The results which have accrued from their use in cases of infantile diarrhœa have been so satisfactory that for more than twelve months I have never once had occasion to resort either to astringent drugs or to opium, whilst in almost every instance where these latter remedies had been previously tried without effect the substitution of an antiseptic was at once followed by complete success. Acute dyspepsia is readily cured by dietetic treatment combined with the use of castor oil or an emetic. Antiseptics are only necessary when the disorder has already continued for several days, and has resisted the simpler methods. Under these conditions calomel is of the utmost value when administered in doses of one-sixth to one-third of a grain every three or four hours. Hydrochloric acid has been extolled by many authorities, but, according to my experience, the mineral acid more often does harm than good. It is most serviceable when all acute symptoms have subsided, and the child is suffering from weak digestion as the result of catarrhal process. It may then be combined with pepsin with great advantage.

It is in cases of chronic diarrhœa due to fermentation that the systematic employment of antiseptic drugs proves of the greatest value; and for this purpose the insoluble substances which act exclusively upon the intestine are usually recommended. This, however, is a mistake. The disorder always commences in the stomach, and is most easily controlled by the administration of remedies which exert their specific action within that organ. Formerly I was wont to employ

carbolic acid for this purpose in all cases of infantile diarrhoea, but its hot taste and unpleasant smell, as well as the occasional occurrence of carbolicuria, has made me transfer my allegiance to resorcin. This drug has the advantage of being extremely palatable to children, devoid of toxic properties when given in ordinary doses, and very inexpensive. According to the *Pharmacopœia*, the dose of resorcin is 1 to 5 gr., and it is probably on account of this insufficient dosage that the value of the remedy has been so much overlooked. As a matter of fact, the drug produces no ill effects in an adult unless the dose exceeds a drachm, and I have long been accustomed to prescribe 3 gr. every four hours to infants only a few weeks old without the least ill effect.

In cases of diarrhoea the first effect of the drug is usually noticeable after the third or fourth dose, when the motions decrease in frequency and in amount, the dejects at the same time acquiring a more natural appearance and losing their excessive foetor. At the end of the second day the diarrhoea has generally ceased, and is not infrequently replaced by obstinate constipation. I have before me the notes of 120 cases of intestinal dyspepsia in infants and young children which have been treated in the manner described. Of these, in 53 per cent. the disorder had lasted from one to two weeks, in 34 per cent. from two to four weeks, in 10 per cent. from four to eight weeks, and in the remaining 3 per cent. for a period of more than two months. Out of the entire number in only nine instances did the diarrhoea continue after the treatment had been pursued for a week, the majority ceasing within three days. Of these nine refractory cases two were instances of cholera infantum, both of which succumbed within a short time of being brought to the hospital; in one case tuberculous ulceration of the intestine was found to exist after death, while the remaining six, most of which were very chronic in their nature, were rapidly cured as soon as benzonaphthol or salicylate of bismuth were added to the original mixture. These results go to prove that when given in sufficient quantity resorcin constitutes a reliable remedy in cases of infantile diarrhoea arising from fermentative processes in the stomach and intestine. When, however, the disorder has lasted for a long time and follicular ulceration of the large intestine exists, the drug may be advantageously supplemented by those remedies which exert their antiseptic properties in the intestine. Benzonaphthol is particularly valuable in this connection since it is but slightly toxic, but in order to prove effective it must be given in full doses at short intervals. Thus in some cases where the symptoms were obstinate I have prescribed as much as 40 gr. to a child during the course of twenty-four hours with only the most excellent results. My experience with the most recent antiseptic, the salicylate of strontium, has not been altogether satisfactory, and I have been unable to convince myself that it possesses any superior advantages over the corresponding salt of bismuth.

THE ATROPINE GROUP:

AN EXPERIMENTAL AND CRITICAL NOTE.¹

By GORDON SHARP, M.B. EDIN.,

144c Research Student in Pharmacology, The Owens College, Victoria University.

SOME twelve months ago, I had under my care for a considerable period, a lady of 25, who suffered from repeated attacks of renal colic in whom a $\frac{1}{2}$ gr. of atropine sulphate (along with $\frac{1}{2}$ gr. morphine hydrochlorate) although always relieving the distressing conditions, produced unpleasant flushing of the face, dryness of the throat, and confusion of the senses. Having read of scopolamine being free from the disagreeable properties of atropine just named, I thought I might be able to get all the advantages of atropine with none of its disadvantages. I resolved to try the drug for myself, but after trial I found it differed little or not at all from atropine. Previous acquaintance with hyoscyne taught me that it was little different from atropine, and after some experiments with daturine and duboisine I was led to extend my studies of the whole atropine group, and to read up the literature for the past twenty years, hence this paper.

¹ Read in the Section of Pharmacology and Therapeutics at the Annual Meeting of the British Medical Association, held in London, July-August, 1895.

To the student of pharmacology no group of bodies is more confusing than the so-called mydriatic alkaloids known by the names of hyoscyamine, hyoscyne, daturine, duboisine, scopolamine, and atropine, etc., all of which possess the property of dilating the pupil. A vague examination of them might lead one to the belief that each had some peculiar action of its own, but closer examination and increased knowledge show them to be very closely related if not identical one with another. True their sources are varied, but reasoning by analogy we know that tea, coffee, ginseng, Paraguay tea and kola-nut are all very widely different plants, and yet they all contain one common alkaloid, theine, and not each a different base as at one time supposed.

The literature of the group of the atropine bodies is most interesting, because it shows the conflicting views of authorities; but as one comes to the present period it further shows a tendency to the view that we have only one or two bases to deal with. One other point it teaches us is that we cannot clear up the difficulty from the chemical side alone, but must call in the aid of pharmacology and therapeutics. With regard to Gerrard's test for the mydriatic group, I find after repeated trials that we do not, as is often supposed, get a yellow colour with one and a red colour with another member of the group, but with a trace of any one of them an alcoholic solution of mercuric chloride heated gives a yellow, while an appreciable quantity of any one of them gives a bright red colour of red oxide of mercury. The test is difficult to apply, and failures to obtain colour reactions with certain members may be accounted for in this way.

HYOSCYAMINE.

Whether hyoscyamine be identical with atropine or no one thing is certain—that they are very closely related; for in 1880 A. Ladenburg converted hyoscyamine into atropine, and in the following year the same authority found that both bases split up into tropic acid and tropine. Further comparisons show both to give a bitter almond odour with potassium bichromate and monohydrated sulphuric acid, a d both, when heated with nitric acid and afterwards treated with alcoholic solution of caustic potash, become of a violet colour. Chemically so far, then, they would appear to be identical, and pharmacologically I do not know if we can distinguish between them.

DUBOISINE.

The introduction of duboisine about the year 1878 by Hancock, Holmes, Gerrard, Ringer, and Tweedy stimulated research, and soon it was found that it was not a new base, but only an impure atropine. At this time A. Ladenburg gave it as his opinion that we had only three mydriatic alkaloids—namely, atropine, hyoscyamine, and hyoscyne agreeing in formula and in decomposition products. Later Ladenburg so far modified his views as to believe only two bases exist—namely, atropine and hyoscyamine, and these are isomeric and very closely related.

DATURINE.

The introduction of daturine led to disputes amongst authorities. Some believed it to be identical with hyoscyamine, while A. Ladenburg considered daturine, duboisine, and hyoscyamine as identical. In the same year (1880) E. Schmidt said he failed to detect the difference between daturine and atropine. Deduction from this makes atropine and hyoscyamine identical. Passing to the year 1885 we find E. Schmidt saying atropine and daturine are identical, and in this view he is joined by Ladenburg.

HYOSCYNE.

Coming to hyoscyne we have seen that A. Ladenburg had so modified his views as to regard this body as not a different base from atropine or hyoscyamine. Pavloff in 1880, in summing up the pharmacology of hyoscyne, regarded it as differing from atropine only in that it (hyoscyne) diminished the irritability of the brain. Bender in 1892 looked upon hyoscyne and scopolamine as identical, while in 1893 A. Ladenburg disputed the identity of the two. In the same year E. Schmidt said the so-called Ladenburg's hyoscyne was really scopolamine, and in this view he was supported by O. Heuss.

SCOPOLAMINE.

In 1880 the alkaloids from both the Austrian plant and from

Japanese belladonna were looked upon as either a mixture of hyoscyamine with other alkaloids or as a mixture of hyoscyamine, atropine, and hyoscyne; but in 1892 E. Schmidt named the supposed pure base scopolamine, and said it occurred in belladonna root, stramonium seeds, and occasionally in *Dubautia myoporoides*. O. Hesse looked upon scopolamine as identical with hyoscyne. Last year, however, O. Hesse, as the result of experience, came to look upon scopolamine as made up of two bases: one identical with hyoscyne, and the other isomeric with it, and he proposes to name it atropine. Kachlman quotes Kobert as saying scopolamine has a paralyzing action on the brain, and does not accelerate the pulse, differing in this respect from atropine. He believes as a mydriatic, analgesic, and antiphlogistic it is superior to atropine, and is free from the objection of causing dryness of the throat, congestion of the head, and acceleration of the heart's action. Bokenham in 1894, as the result of his experience, said in some animals the pulse was slowed where it would have been rendered rapid by atropine, and in himself it caused no dryness of the throat. As an offset to these opinions we have the experience of Thos. K. Pooley, who found that six instillations of the conjunctival sacs of a one-fifth per cent. solution of hydrobromate of scopolamine produced in a girl of 13 irregularity in the heart's action, with a pulse of 130, staggering gait, complaint of dryness of the throat, and of "pins and needles" sensation in the soles of the feet, and there was continual working of the muscles of the face and lips. Two adult women in whom the drug was employed were similarly affected.

The conflicting views held as to the identity or non-identity of the various named bases makes it certain that our knowledge of them is yet far from exact. When we come to search for a cause of all this confusion, we have to bear in mind the following points: (1) the difficulty of obtaining a pure alkaloid; (2) the great readiness with which the members of the atropine group decompose, heat above a certain degree, acids, and alkalies readily breaking them up; (3) in certain animals atropine slows, while in other animals it makes the pulse rapid. Temperature of the surroundings, too, alters its effects, and in small doses it has one action, in large doses another, and individual peculiarities must not be forgotten, hence the difficulty of deducing from clinical experience. I have known atropine produce no dryness of the throat and no flushing in one patient, while in another these symptoms were very marked.

In favour of there being only one base we have the following considerations: (1) All authorities are agreed that the one base readily passes into the other, as, for example, atropine can be changed into hyoscyamine and hyoscyamine into atropine. (2) In experiments on the frog's heart every one can replace the other; stop the heart with muscarine and any one of them will start it; stop the heart by simple exposure to the air and any one will start it—under certain limits, of course. (3) They all dilate the pupil and all increase the intraocular tension, and, although this latter property is denied some of them, it is well-nigh impossible to prove the negative. (4) They all possess hypnotic action. (5) They all react in the manner of caustic soda or potash towards alcoholic solution of mercuric chloride.

Each new mydriatic base, when introduced to the notice of the profession, has had some special property ascribed to it, but time and trial have generally proved it to be in most cases only another name for atropine. As well-known examples we have daturine and duboisine. In this country we now regard them as impure atropine. Neither has been employed extensively internally, although it must be mentioned that recently Belmondo found hypodermic injections of duboisine equal to hyoscyne, and Mazzochi and Antonini believe it to be superior to atropine and morphine. Hyoscyamine in some respects has been less studied than the other members of the group, and most people seem afraid to hazard an opinion whether it is or is not identical with atropine. All are agreed that at least it is closely related to atropine. A curious point is that the source does not determine whether the product be hyoscyamine or atropine but rather the manner of manufacture. All agree that at least one is a conversion product of the other, but it does not matter which you start with; if you have atropine and wish hyoscyamine you have only to convert it, and if you have

hyoscyamine and wish atropine conversion is easily accomplished. Another interesting point must be mentioned. Samples of supposed atropine, employed as such and giving atropine results, have by experts been declared to be hyoscyamine. A further point of interest is that daturine has by authorities been declared identical with both atropine and hyoscyamine; if this be so we must infer that atropine and hyoscyamine are identical with one another, that is if expert opinion is worth anything at all. We must here mention that we mean the white hyoscyamine, not the brown amorphous substance which is a calmate in delirium.

Hyoscyne has not been sufficiently long before the medical world for a definite opinion to be formed regarding its effects and therapeutic value. Different samples may vary and account for the varying results obtained. I have used the drug in the form of hydrobromate both clinically and pharmacologically, and am unable to think it differs in any way from atropine. Its hypnotic action may be more marked, but I do not know but what I could have obtained the same results by means of atropine. It certainly produces dryness of the throat, rapid pulse, flushing of the face, and delirium (in fairly large doses).

Scopolamine is the newest member of the atropine group, and is only now on its trial, so that all the evidence one can collect is important. My own experiments with scopolamine hydrobromate were repeated again and again, and every effort made to eliminate error, and I gave the results in detail, so far as is necessary, to illustrate every point. From the hydrobromate the pure alkaloid was obtained and compared with pure atropine in its behaviour towards alcoholic solution of mercuric chloride, and no difference could be detected. One-hundredth of a grain of hydrobromate placed on the frog's heart, the pericardial sac being opened, caused diminution of the ventricular contractions. Another frog's heart was stopped by the application of muscarine nitrate. It commenced to beat strong and regularly after $\frac{1}{100}$ of a grain of the hydrobromate had been applied, and the subsequent exhibition of muscarine in the same heart failed to produce stoppage. A frog's heart, allowed to stop for some hours, did not start when $\frac{1}{100}$ of a grain of the hydrobromate was applied, but did beat when the same quantity of atropine sulphate was exhibited. (See later trials.) At another time a frog's heart poisoned by muscarine applied well over it failed to beat when scopolamine hydrobromate increased to the $\frac{1}{2}$ of a grain was applied. Atropine sulphate freely applied also failed to bring about heating of the organ. On the heart-rate the following notes were made. A frog's heart beating regularly 38 in the minute was brought down to 29 in five minutes by $\frac{1}{100}$ of a grain. In an hour another $\frac{1}{100}$ of a grain was instilled, and the rate became 28. Atropine sulphate in 1 per cent. solution was afterwards applied, and the rate fell to 26.

Some weeks later than the foregoing the following trials were made.

As before a frog was pithed, the cord destroyed, the pericardial sac opened, and the animal allowed to lie till the heart had ceased to beat spontaneously. The $\frac{1}{100}$ of a grain of scopolamine hydrobromate applied in five minutes caused it to beat afresh. The same heart standing overnight had ceased beating, and another $\frac{1}{100}$ of a grain started the heart, the contractions being chiefly in the sinus and auricles, while still another $\frac{1}{100}$ of a grain caused the ventricle to contract more powerfully, at the same time increasing the contractions in the auricles and venous sinus. In three hours atropine sulphate was applied freely, but the contractions remained the same in character.

One-hundredth of a grain instilled in my own eye at 10 one night produced complete dilatation by 7 the next morning. In twenty-five hours after complete dilatation the diameter had become reduced by half; and in sixty hours after complete dilatation the pupil had nearly, but not quite, returned to normal. The $\frac{1}{100}$ of a grain taken by the mouth on myself gave dryness of the throat, some slight hypnosis, and some slight slowing of the pulse. In a month later $\frac{1}{10}$ of a grain was taken, and there was some acceleration of the pulse, distinct mydriasis, hypnotic tendency, very dry throat, and some confusion of the senses. Some ten days later the $\frac{1}{10}$ of a grain was swallowed, and the noticeable symptoms were: the pulse was at first more rapid, then slower

than normal, but full and bounding all along; throbbing was felt in the temples; the throat and nostrils were disagreeably dry; the sight was blurred and the pupils markedly dilated; the gait was staggering, and there was confusion of the senses; the face was flushed, and there was a tendency towards sleep, but the uncomfortable conditions prevented rest for any considerable time. In less than twelve hours all discomfort had passed off, and no ill effects remained. (Results have been detailed as they occurred, and without comment.)

All my experiments with scopolamine were conducted with the salt supplied to the profession by Messrs. Burroughs, Wellcome, and Co. The temperature at which the experiments on frogs were carried on was 85° F. In the cases where the salt was applied the heart muscle was moistened by normal saline solution, and a tablet of the named strength laid on the surface of the heart and allowed to slowly dissolve.

To gather up the various threads of our essay. Daturine and duboisine we might call impure atropine. The varying effects obtained by different observers in the case of hyoscyne and scopolamine may be accounted for on the supposition that neither is a definite base. Hyoscyamine we might further suppose to be identical with atropine. Atropine is the alkaloid of which we know most, and we might call it the fundamental or representative base; and our knowledge permits us to say at least that in hyoscyne and scopolamine we have a certain proportion of atropine along with a varying proportion of a conversion or decomposition product of atropine, and which one might call a tropeine.

Instead, then, of multiplying names, we should call atropine what is usually atropine, and get hyoscyne and scopolamine free from any admixture, and name the resulting products by names corresponding to hemotropine. For my own part, as I have already said, my experience of hyoscyne, scopolamine, daturine, and duboisine has led me to think they differ little from atropine but other observers think different, and for this reason I have endeavoured to indicate the lines upon which investigations might be carried on, and by means of which we might arrive at the truth.

LORETIN: A NEW ANTISEPTIC.¹

By HERBERT SNOW, M.D.LOND., ETC.,
Surgeon, Cancer Hospital.

LORETIN is an organic iodine compound, discovered by Professor Claus, of Freiburg. Its formula is $C_{10}H_{15}NOH.SO_3H$, and its euphonious proper title in chemical nomenclature meta-iodo-ortho-oxyquinoline-ana-sulphonic acid. It is a bright yellow odourless crystalline powder, very slightly soluble in water and alcohol; cold water takes up 1 to 2 parts per 1,000, boiling water 5 to 6; it is insoluble in ether and oils, forms emulsions with the latter and with collodion. Being an acid it forms neutral salts with sodium and potassium, with ammonium and magnesium, which are readily soluble in water, forming solutions of a deep orange-yellow colour; the neutral calcium and barium salts are only slightly soluble. The manufacture process consists in boiling together in water equal parts of potassium iodide, potassium carbonate, and oxyquinoline-sulphonic acid with chloride of lime, representing one atomic equivalent of chlorine. After cooling a little hydrochloric acid is added. Thus is formed the calcium salt of loretin, which is again decomposed with hydrochloric acid to obtain the crude drug,

subsequently carefully purified. The pure acid is extremely stable for an iodine compound, being unaffected by prolonged exposure to air or even to direct sunlight; it is easily decomposed only by oxygenising compounds, by free chlorine and bromine, or by certain organic compounds already undergoing decomposition.

Ammeiburg administered, for several weeks in succession, loretin to dogs in doses up to 10 g., rabbits to 5 g. Hypodermic injections amounting to 5 c.cm. of a 5 per cent. solution of the sodium salt of loretin, were made daily into guinea pigs for long periods. In no case did any objectionable symptoms follow; and in the urine, which was carefully collected by means of specially constructed cages, no iodine, blood, sugar, or albumen. These physiological experiments were continued by Professor Albrecht in the Veterinary High School at Munich, the results being published in the *Deutsche Zeitschrift für Tiermedizin und vergleichender Pathologie*, 1894, vol. xx., p. 353.

Ammeiburg's bacteriological investigations proved loretin to be a powerful microbicide, much superior to iodoform, with which comparison more particularly holds weight. They deal with the micro-organisms of cholera, anthrax, suppurative, typhus, etc. Some of the more significant tables are appended; the experiments are being still continued.

Schinsinger has extensively used loretin for burns and operations of all kinds, including empyema, herniotomy, resection of the upper jaw, arthrotomies, carious and tuberculous processes, etc.; in six months he had not a single instance of toxic symptoms, much less of death. Heusinger has largely employed it in veterinary practice, with the most favourable consequences. The former remarks: "The absolute absence of any irritant effect upon the skin is a very important advantage. Artificial erythema or eczema I have never yet observed caused by it; but, on the other hand, very persistent eczema has been cured by loretin." Extensive burns were healed by dusting with loretin, and left very slight scars.

Loretin is recommended for use as a dusting powder, either alone or mixed with calcined magnesia, starch, or French chalk; as collodion (2 to 10 per cent.); in pencils of cocoa butter (5 to 10 per cent.); in ointment, 5 to 10 per cent., with vaseline or lanoline; in solution of 0.1 to 0.2 per cent. of the free acid, or 1 to 2 per cent. of the soluble sodium salt; lastly, as gauze impregnated with precipitated calcium salt. My own experience is confined to the powder, which I have never found occasion to mix with any other substance. Dusted on the skin, or over a granulated wound, this causes not the slightest irritation or unpleasant sensation. It immediately destroys the maldour of the most fetid cancerous sore, controlling this in a manner which no other agent I have yet tried will do. Copiously puffed with an insufflator into the deep cavity formed by evacuating the axilla of carcinomatous glands, it efficiently precludes suppuration, even when free hemorrhage has taken place after the closing of the wound, an occurrence almost inseparable from anæsthetic vomiting when the patient has been removed from the operating table. Not the slightest bad symptom from its employment in this way has so far been detected. When there is no deep cavity a wound dusted with loretin heals rapidly by first intention. I have had recourse to loretin in some 60 cases, mainly operations on the breast and axilla, noticeably a test region for antiseptics. In my hands it has proved an ideal antiseptic and deodorant, with no single drawback; and I am sure that no surgeon who has once tried it will ever again resort to the noxious and toxic iodoform from the free use of which I have seen more than one death. Though whenever well-established agents answer sufficiently the purpose I have a strong prejudice against novelties, yet this substance—non-poisonous, devoid of smell, and absolutely preventive of suppuration—seemed to me so marked an advance upon anything previously brought forward, that I felt constrained to direct thereto the notice of the Section.

APPENDIX (Abstract of Dr. Ammeiburg's Bacteriological Experiments).

In each 20 c.cm. of a solution or mixture containing 2 per cent. of one of the following disinfectants was employed: boric acid, lyso, carbolic acid, loretin, iodoform, as well as a control experiment. In some cases 20 c.cm. of a 2 per mille

¹ Read in the Section of Therapeutics and Therapeutics at the Annual Meeting of the British Medical Association held in London, July-August, 1904.

loretin solution, or a 1-2 per cent solution of loretin-sodium. To each 20 c.cm. three drops of a bacteria culture or of pus were added repeatedly shaken and allowed to stand twenty minutes. With each of the mixtures four test tubes, containing sterilised gelatine broth were then inoculated in the following way: to the first 1 c.cm. of the infected antiseptic solution, to the second and third each $\frac{1}{2}$ c.cm., and to the fourth $\frac{1}{4}$ c.cm. was added by means of a pipette, thoroughly mixed and poured upon plates (4). (For the sake of brevity the experiments with lysol, beta-cresol and carbolic acid are mostly omitted):

THE GENERAL THERAPEUTIC EFFECT OF THE ALTERNATING ELECTRIC CURRENT OF HIGH FREQUENCY AND OF HIGH TENSION.

Dr. G. APOSTOLI (Paris), together with Dr. Berlioz, on March 18th, 1895, presented a paper on the above-mentioned subject to the Academy of Sciences of Paris. He now, after longer and riper experience, desires to present a summary statement of his general conclusions: (1) According to Professor d'Arsonval's discoveries alternating currents of high frequency and of high tension exert a powerful action upon all living bodies submitted to their inductive influence. (2) The best methods of applying these induced currents is to place the patient, free from all contact with electrodes, in the circuit of a large solenoid traversed by the currents. The patient being thus completely insulated, the currents, which circulate in his body by auto conduction, have their origin in his tissues. The body plays the rôle of a closed induced circuit. (3) By this method the physiological discoveries of Professor d'Arsonval are confirmed, and we are able to prove the powerful influence of these currents upon the vasomotor system, although they produce absolutely no sensation, and although they have no apparent effect upon the motor or sensory nerves. These currents have nevertheless a powerful action upon all the nutritive functions, as has been verified by Dr. d'Arsonval's numerous analyses of the gaseous products of respiration, and by Dr. Berlioz's not less numerous analyses of the urinary excreta. (4) The general therapeutic applications can be deduced from this physiological action are confirmed by clinical observation. Dr. Apostoli has now treated more than a hundred patients by this method at his clinic and at his private consultation rooms. The greater number of these patients have been greatly benefited by this new treatment, which, he it remarked, has been used to the exclusion of all other forms of medication, dietetic or otherwise. (5) These currents exert in the majority of cases a most powerful and generally beneficial action upon diseases due to slackening of the nutrition by accelerating organic exchanges and combustion. This is proved by analyses of the urine made by Dr. Berlioz, of which the following is a brief summary: The quantity becomes more normal; the products of organic waste are better eliminated. The increased combustion is shown by the diminution of uric acid, while the percentage of urea is generally increased. The relative proportion of these two substances changes under treatment so as to reach in general the figure of 1:40. The elimination of the mineral products is also affected, but to a less marked extent. (6) When daily sittings are given, each lasting fifteen minutes, we may generally observe in patients submitted to the influence of

these currents the following modifications in their general condition. We mention them in the order of their occurrence: Return of sleep; increase of strength and vital energy; increase of gaiety, of power for work, and ability to walk; improvement of appetite, etc.; in short, general progressive improvement. This general improvement often manifests itself after the first *séances* before any local influence is apparent, and before any change has occurred in the urinary secretions. (7) Local pain and trophic changes are often more slowly affected by these currents, and at times they are entirely refracted for a longer or shorter period. In such cases the same currents must be applied locally by contact with the electrodes. This subject will be treated later on in a separate communication. (8) The diseases which have appeared incurable by this treatment are those not associated with well-defined organic changes, such as hysteria and certain forms of neurasthenia. Dr. Apostoli has also observed that certain localised neuralgias are refractory to this form of currents; they require its more direct local application. (9) The diseases which have derived most benefit from this therapeutic agent belong to the arthritic class, rheumatism and gout. (10) In certain diabetic subjects the sugar has disappeared altogether from the urine under the influence of these currents, while in others there has been no such change, notwithstanding the manifest and constant improvement in the general condition. Is this difference due to the imperfection of the electric apparatus or to the manner of its application? It is hoped that further experience will soon afford an answer to this question, although the fact that diabetes has many different causes may in itself explain the difference in the results obtained by this treatment. (11) In conclusion, the currents of high frequency and of high tension introduced into electrotherapeutics by Dr. d'Arsonval greatly increase the field of action of medical electricity. They furnish general medicine with a new and valuable means of treatment, capable of modifying more or less profoundly the processes of nutrition.

THE PHARMACOLOGICAL ACTION OF BERBERINE.

Dr. O. D. F. PHILLIPS read the following paper, founded on experiments undertaken by him in conjunction with the late Dr. Herbert Ashdown in the physiological laboratory at University College, London: Berberine was first obtained from the bark of the *xanthoxylum clava herculis* L. by Chevalier and Pelletan¹ in 1826, and named by them xanthopiorit. Buchner² in 1835 isolated from the root of the *berberis vulgaris* an alkaloid, to which he gave the name berberine, and Perrins³ in 1862 showed that these two substances are identical. Since then it has been found in *calumba* root, in the rhizome of *podophyllum peltatum*, of *hydrastis Canadensis*, and in a number of other plants belonging to different natural orders. When pure it occurs in yellow acicular or prismatic crystals, having a bitter taste and neutral reaction, readily soluble in boiling water, very slightly so in cold water. Its salts are also yellow in colour and very insoluble in cold water. Previous researches have shown that $\frac{1}{2}$ to 1 g., administered hypodermically to rabbits caused death after some hours, with muscular tremors, *paralysis*, especially marked in the hind limbs, and great embarrassment of the respiration. The alimentary canal was not distinctly affected when the substance was given subcutaneously. In dogs 2.75 g. by the mouth produced symptoms of severe gastro-intestinal irritation, abundant watery and mucous diarrhoea, marked salivation, general muscular tremors and *paralysis*. The respiration was not markedly affected. After death the spleen was found to be much contracted, as also the whole intestine, and the abdominal organs generally much congested; the heart contracted. Cural has pointed out in an elaborate series of observations that locally its action is very irritating, and readily causes chronic inflammatory thickening. Berberine exerts a very decided action on the alimentary tract when given by the mouth, but when given hypodermically so much irritation is caused locally, and such large quantities of fluid are required to dissolve it, that the slowness of its absorption renders its action very uncertain. In rabbits and dogs the first manifestations after medium doses are profuse salivation with

loose motions, followed by severe watery diarrhoea and colic, great thirst and muscular tremors also occur. After death from an overdose the intestines are found very much contracted, generally empty or containing an abundance of mucous and watery fluid, the mucous membrane being much inflamed. There does not appear to be any direct action on the liver, as there is no increase in the quantity of bile produced, but the gall bladder is usually found contracted. When applied to the heart of a pithed frog *in situ* the effect is not very marked. A solution of 1 in 400 produces a slight slowing, the systole being prolonged and the diastole apparently less complete; with stronger solutions stoppage occurs in systole. Observations made on the detached heart with Williams's apparatus showed that 1 part of berberine in 5,000 parts of circulating fluid slows the heart and strengthens its contractions, the rhythm remaining perfectly regular, and the general character of the beat being unaltered. The blood pressure is a little increased, or may be unaltered. Larger doses (1 in 2,500) slow the beat very considerably, the systole becoming more prolonged and the diastole less complete. The pressure may be increased at first, but symptoms of cardiac failure soon begin to appear, with irregularity of action and a rapidly falling pressure, until death occurs with the heart in systole. The action on the heart of warm-blooded animals appears to be very similar to that just described in the case of the frog. Intravenous injection of 0.035 to 0.08 g. in cats, dogs, and rabbits causes an immediate and rapid fall in blood pressure, with great slowing and more or less irregularity of action. These effects, however, are transient, the pressure soon returns to normal, and then rises somewhat above it. During the period when the blood pressure is rising, irregularity of the heart's action, if it has not previously occurred, is generally more or less pronounced, and, though lasting only a few seconds at a time, recurs at intervals. This effect, however, seems to be due rather to stimulation of the cardio-inhibitory centre in the medulla than to any direct action on the heart itself, since the irregularity never occurs if both vagi be divided. The rise of blood pressure which succeeds the primary fall is apparently due to the vasomotor centre being thrown into action and causing a constriction of the peripheral arterioles throughout the body. It does not occur if the spinal cord be divided high up in the neck, the scarcely appreciable rise which then takes place being explained by the contraction of those vessels of the head and neck, the connections of which with the centre in the medulla are still left unsevered. In this series of experiments the heart was found to have stopped in systole, although Guenette⁴ and Falck⁵ state that in rabbits they generally found it dilated and engorged. The left ventricle is always contracted and empty, but a small amount of blood may be found in the right side of the heart. Berberine does not appear to exert any marked effect upon the respiratory system, excepting in the case of rabbits, which appear to be more susceptible. In them small doses injected into a vein cause a gentle excitement of the centre in the medulla, and this, increased in its activity, manifests itself by the respiratory movements becoming quickened. Large doses cause respiratory embarrassment to a very considerable extent, great irregularity, occurring not only in the frequency but also in the labours of the inspiratory efforts. The serious cardiac and vasomotor disturbances, already alluded to as being produced by the exhibition of this drug in quantity, render it impossible to recognise how much of the respiratory embarrassment may be due to a direct action on the centre in the brain alone, or to the vascular disturbance. That the action is directed rather upon the medulla than upon the terminations of the vagi in the lungs is readily recognised, since the influence upon the respiratory functions is still well marked, even after both vagi have been divided. The methods employed to appreciate any special action that this drug might exert upon the function of the kidney were the following: First, to collect and measure the quantity of urine secreted by the kidneys for several hours previous to the exhibition of the drug, and then to observe the alteration in the quantity of urine estimated during and after the intravenous injection of different solutions of berberine. This

⁵ *Drugs and Alkaloids*, 1864.

was readily ascertained by placing a cannula in both of the ureters and collecting the urine as it was secreted, this method being much more reliable than that of emptying the bladder at stated times, as it is always difficult to ensure complete evacuation of its contents in living animals. And, secondly, to record by means of the oncometer any alterations in the volume of the organ, collecting and measuring the urine at the same time. The influence that berberine exerts upon the urinary flow does not appear to be a very pronounced one. It does, however, cause a slight increase in the quantity of urine eliminated, even after the injection of small quantities of solutions into the venous circulation, quantities not sufficiently large in themselves to cause any increase in the urinary flow apart from the action of the drug. By studying the condition of the organ by means of the oncometer, and at the same time collecting the urine secreted, the conclusion was come to that the increased diuresis is dependent rather upon the elevation of the blood pressure brought about by the drug than by any direct stimulation of the renal cells themselves. The volume of the organ as registered by the oncometer is found to follow very closely the variations in the blood pressure. After intravenous injection, when the blood pressure falls, the kidney contracts and becomes smaller; at the same time there is diminution in the urinary flow, and again when the pressure gradually again returns to, and rises above the normal, the volume of the kidney increases to a greater size than previously. Although the diminution in bulk is synchronous with the lowering of the blood pressure, the subsequent increase does not precisely correspond in point of time with the rising pressure, but rather is a little delayed, and is prolonged over a longer period. The period of greatest activity of the kidney is during the state of full distension, the urine may then flow sometimes twice as fast as prior to the injection. By repeating small doses with sufficient frequency a state of almost constant contraction of the organ may be brought about, and thus a diminution in the urinary flow. Berberine cannot therefore be said to have any very marked action upon the kidneys themselves as a special diuretic, though it undoubtedly does cause under ordinary conditions an increase of the urinary eliminative processes. As has already been stated, after death the spleen is found to be very much contracted, but if the organ be studied during life with the oncometer it is seen that this organ follows much the same course as the kidney, diminishing in size with the fall in pressure, and again expanding when the pressure has risen. This latter effect—expansion—however, does not occur at the same time as the rise in pressure, but comes on gradually a little later, and after a short duration the organ again contracts to a little less in size than the volume previously occupied, and thus the spleen is a little smaller after each dose, until finally it becomes very markedly contracted, and will no longer respond except by a further contraction to the subsequent administration of the drug.

SCIENTIFIC MASSAGE.

Dr. F. CHURCHILL read a paper on this subject. After some introductory remarks on the proper use of massage and the kind of cases in which it was likely to be beneficial, he said that, while approving generally the accustomed methods of dry massage by kneading, rolling, and local friction, he did not object to the employment of local remedies. The innunction of soothing liniments in certain obstinate and painful cases would greatly facilitate the employment of other methods of treatment. The cutaneous tissues, contracted and hardened by long confinement, became supple and elastic, and the deeper structures participated in this. He often ordered the liniment to be warmed at the fire before use, as this would help to give a glow to the vascular system, was a sedative to the cutaneous nerves, and favoured innunction to the deeper structures. For the efficient carrying out of the "movement cure" it was necessary to abandon the use of machines and apparatus which the patient was taught to rely upon for communicating external activities to his torpid muscles. By skilful, well-tutored, and firmly-applied manipulation it was possible to arouse the slumbering activities of vital organs by energising the natural motive powers of the individual, so that the confirmed invalid became gradually self-reliant, and kept within the range of undue

fatigue. By scientific massage was to be understood the application of well-trained fingers to the groups of muscles or tissues requiring special manipulation, endeavouring to promote the flow of blood and lymph plasma, and to accelerate the metamorphosis of tissue in the disorganised part. Much depended upon the patience, skill, anatomical knowledge, and proper appreciation of the actual mischief requiring to be rectified by systematic daily application of massage. The manipulator must have a soft, warm, and well-padded hand, carefully trained to use the needful amount of pressure required in each case, according to the properly-defined prescription of the medical attendant. There must be accurate knowledge of the anatomical situation of the attachment of muscles, the course of the arteries and veins, and the situation of the nerves. The masseur should have a general idea of the structure and function of the alimentary canal, especially the course of the colon and the situation of the liver and gall bladder. He should be warned of the danger of using massage without skilled directions as to the details of manipulation required. The effect of massage was to improve the circulation, to increase the nutrition of the part, to remove accumulations, adhesions, and inflammatory products; to promote health and vigour; to increase the appetite, and in so doing to act as a general tonic to an enfeebled constitution; to increase the electrical contractility of muscular tissue; to raise the temperature of the body, and to increase the flow of lymph in the lymph channels and glands. When one remembered the wide distribution of the sympathetic nerves, the regulating control which they exercise over the abdominal organs, the large splanchnic nerves being situated at the back of the abdomen, contributing branches of communication to the muscular coats of stomach and bowel, it could not be doubted that the influence of these nerves upon the hollow viscera and their contents must be largely increased by inhibitory and excito-motor action, when stimulated to contract by efficient massage. For dyspepsia and functional disorders of the alimentary canal massage might be applied with advantage, as it increased the flow of gastric and biliary secretions. It was eminently successful in the case of anæmic and hysterical girls with sluggish circulation and indolent habits; also in infantile paralysis, gout, rheumatism, writer's cramp, etc. In the Weir-Mitchell treatment, which was designed to promote active nutrition of internal organs, scientific massage was an essential part of the treatment. Patients suffering from corpulence and what was now known as neurasthenia were greatly benefited by massage over the back, spine, and abdomen. In cases of neuralgia of the spine, face, and limbs the local pain was much relieved by *tâpetement* or *pétrissage* over and around the painful part. Dr. Churchill related some cases, limiting them to those patients who had been certified by their medical attendant as depending largely upon manipulative treatment for efficient cure.

1.—A ponderous Scotchman, 6 feet in height, and weighing about 16 stone, was alighting from a hansom cab at London Bridge station late one evening after excessive indulgence in his native mountain dew—a by no means rare occurrence with him. He stumbled and fell heavily on to his left ankle. When picked up he was taken back to his home in South Kensington, having sustained a severe sprain of the ankle with fracture of the internal malleolus. Dr. Ridge Jones requested Dr. Churchill to take charge of the case. He found the limb very much swollen, with much extravasation of blood around the ankle, effusion into the joint, the patient complaining of much pain. He ordered evaporating lotions to be applied to the leg. The limb was placed on a Liston splint with adjustable foot piece. The patient remained under treatment for several weeks. Owing to his luxurious habits and the swarthy condition of his body generally, the effusion around the ankle did not subside; the torn ligaments and tendons became matted together, and the joint quite stiff. Dr. Churchill engaged the services of a skilled masseur, and superintended the treatment. Considerable pressure was required to break down the agglutinated tissues and to promote active absorption of the extravasated blood. The patient ultimately made a very good recovery.

2.—A young girl, 15 years old, still growing rapidly, was playing at lawn tennis, when, with a sudden lunge forward, she felt something give way in her spine. She was put to bed and attended by Dr. Hewer, of Stoke Newington. Mr. Adams was called in, and he treated her for slight displacement of the third lumbar vertebra with effusion into the sheath of the erector spinal muscle at this part. She came to Dr. Churchill some months after and he could detect some thickening and effusion in this situation, with some local tenderness. There was a hemic murmur at the base of the heart, and she had some menorrhagia. The pupils were much dilated. He treated the constitutional symptoms with arsenic and digitalis. For local treatment he ordered a reclining board for the spine, a firm flannel binder, and massage to the spine; also warm sea-water baths and massage directly after the bath. Her health considerably improved, and she made a good recovery.

III.—A middle-aged lady, married ten years, during which she gave birth to eight children in rapid succession, with two sets of twins and some miscarriages. She had been under Dr. Churchill's care for several years, coming up from Essex for the London season. She was ordered to Bourne mouth for her health, and he met Dr. Emdin in consultation there. She was suffering from neurasthenia and feeble circulation. Her body was well nourished and her general condition good. There was nothing to indicate organic disease. The heart was fairly sound, with slight dilatation of the right ventricle. She suffered from insomnia. They arranged for her to have a thorough course of massage by a skilled masseur. After some months of this treatment she returned to Essex very much benefited by the treatment. Dr. Churchill placed her under strict régime of diet, baths, and regular habits of going to bed early.

Dr. Playfair in his book on *Functional Nervous* remarks that in neurasthenic patients "drugs, pessaries, uterine treatment, hydropathic establishments, and health resorts, have been tried in vain." "But a scientific and rational means of dealing with such illnesses rarely fails to effect a cure in well selected cases." The cases in which the Weir-Mitchell treatment had proved eminently successful were nervous exhaustion without organic disease, hysteria, habitual use of narcotics, etc. In prescribing massage it was essential to make a clear distinction between collapse of nerves and hysteria. In the former one was able to trace the origin of the illness to some definite shock or exhausting malady which had for the time prostrated the patient; whereas hysteria was due to functional disorder from emotional causes and degeneration of moral and mental stamina. When writing on "high pressure education" he referred to the breakdown of physical health from overstrain in competitive examinations, and the too close application to study, producing complete prostration of nerves. The neglect of hygienic measures for the proper ventilation of schoolrooms, and failure to provide a daily allowance of active exercise out-of-doors frequently induced a breakdown of health, the result being a constant feeling of weariness and fatigue. The appetite gradually failed; dyspepsia, flatulence, and constipation followed in due course. Fine constitutions had been wrecked by neglect of physical education. In such cases massage might prove of great value. As regards indulgence in narcotic drugs, it was astonishing how patients acquired the habit of gradually increasing the dose until the nervous system was quite broken down. It was by prompt isolation of such cases under direct supervision and management by dieting and regular habits, combined with effectual massage by a competent nurse, that a speedy cure was effected. There were numerous kindred cases of *malades imaginaires* that it was well to leave to their own resources. These were melancholic dyspeptics who lived in affluence, were well nourished, and surfeited with the luxuries of life. Such people were self-centred, and much enjoyed their invalidism, though they would be the last to confess it. They made no effort to rid themselves of their vicious surroundings. They were pampered by their husbands, spoilt by their friends, and sometimes faddied by their doctors. For such cases there seemed little hope unless by the strict régime of the Weir-Mitchell system, (1) isolation, (2) massage, (3) systematic feeding, (4) moral training, and (5) outdoor exercise. Accepting these views of the scientific application of the movement cure for the relief of deep-seated pain and deep-seated mischief about a joint, how essential it became to keep the sufferer under constant supervision so that the varying amount of pressure and innervation of appropriate remedies might be prescribed according to the particular circumstances of each individual patient, with a definite determination to restore the activities of the crippled limb if possible. The rationale of all scientific treatment must be based upon an accurate consideration of the special requirements of each patient as distinguished from those of a sufferer from a similar complaint, but with a different constitution and with different recuperative powers. The one patient lends himself more readily than the other to the precise direction of the surgeon, and gained the benefit thereof. Derangement of nerve function was largely due to exhaustion and fatigue of nerve energy. City merchants overtaxed their mental powers by the hurry and rush of business, with its keen competition, and the limited periods given to recreation. Those who, like actresses, were called to lead a very active life in public under high mental pressure, exposed to public criticism in crowded, ill-ventilated theatres, with late hours, turning day into night, suffered from neurasthenia. In such cases "weary Nature seeks repose." The result of such over-

strain was exhaustion of physical energy and impaired assimilative functions. The overworked brain declared itself by excessive irritability; the sufferer attempted to rectify the depression by recourse to alcoholic stimulants or narcotics. The vital powers became depressed the appetite failed. The blood plasma became impoverished; the brain cells were poorly nourished; and there was a general break-up of the constitution. In such cases, when the disease could be arrested in its earlier stages before structural decay had set in, much might be done to restore the shattered health by recourse to the manipulative treatment and proper regulation of diet, sleep, and exercise.

TREATMENT OF DISEASE BY DIETETICS

Dr. DUTTON said disease, taken generally, was due to some malnutrition of the cells which composed the various organs through the food being defective in quantity or quality, hence the astonishing results of treatment which often followed when nourishment was ordered which could be easily digested and assimilated. The main cause of disease, exhaustion, and debility, particularly among the poor, was bread, their staple food, being deprived of the most nourishing part of the corn. Physicians should study not only the chemical side of food, but the practical side also; they should also be well versed in all agricultural matters, and be good judges of food in its raw state, and above all they ought to possess a sound technical and practical knowledge of the culinary art, in order to be able to give sound advice to their patients on dietetic subjects.

EFFECT OF CHLOROFORM ON THE LIVER.

Dr. J. T. HEYMANS (Ghent, Belgium) showed some anatomical specimens and microscopic slides of the liver of a rabbit. They showed that in chronic poisoning by subcutaneous injection of chloroform the hepatic cells underwent a gradual change, and also the tissues immediately surrounding them, so that at length the liver presents all the appearance of true cirrhosis.

TREATMENT OF TUBERCULOSIS BY PURE FORMED FERMENTS.

Dr. DE BACKER (Paris) read a paper on this subject, in course of which he stated that he had succeeded in obtaining varieties of yeasts which threw well in the living tissue, and which, when injected into tuberculous patients, produced a remarkably beneficial effect on the local lesions and general symptoms. He attributed these effects to a phagocytic action of the living yeast cells. He exhibited an ingenious apparatus for making the injections of yeast cultures.

TABLOIDS, TABELLÆ, ETC.: THEIR USES AND ABUSES.

Dr. C. R. ILLINGWORTH read the following paper: I wish to consider what advantages tabloids of various medicaments offer to the practitioner in lieu of the long tried forms of mixture, pill and powder; and also to point out the dangers which lurk in them, first to the patient, and secondly, though importantly, to the doctor's pocket. 1. A solution is much more easily dispensed than a solid, because the former is measured whilst the latter has to be passed through the tedious process of weighing. 2. Solids have to be dissolved to make a bottle of medicine, and solution is far better effected *en masse*, as in ordinary dispensing for the making of stock solutions, than bit by bit for each bottle of medicine needed. 3. Tabloids are never made for children, who are the greatest anxiety of the physician in active practice; and the calculation of doses for them is more complicated and fractional in the case of "tabloid prescribing" than might be thought or supposed. 4. If the calculation of dosage be left to the parent or guardian or nurse, it therefore stands to reason that the door is widely opened to grave mistakes, possibly with fatal consequences in the case of children's diseases. 5. Much remunerative practice is unavoidably thrown into the hands of chemists and druggists, who become thus the middlemen between the manufacturer and the public for the sale of thousands of remedial agents in handy form, with full instructions on their labels, rendering, in the opinion of both, the intervention of a medical man totally unnecessary; and putting the noble science of medicine into the position of a degrading trade. 6. There is a very grave doubt as to the solubility

In the semifluid contents of the stomach and bowels of very many of the drugs put up in tabloid form. Indeed, it is well known that many have been found by accident quite unchanged in the defects on the casual giving of an enema during their administration. For these reasons it is, I think, impossible that we shall ever submit to a revolution in the methods which have obtained for so many generations in the dispensing of medicines to our patients, whether effected personally or by prescription, as was recently and very forcibly asserted to be imminent, in the columns of the JOURNAL. Tabloids dosed for adults only can be put with safety into the hands of adults for their own use only, and children remain an unlooked-for and yet a more important, because a more numerous, quantity in the proposed change of administration; and if the difficulty be fairly met, the accompanying trouble is not compensated for by the advantages of such a form of medication for children, whether calculated by the doctor or left to the arithmetical wisdom of the parent or guardian of the little patient. Of the great usefulness of tabloids and tabellæ in subcutaneous medication no one doubts. But that is no argument for the invasion by the said tabloid into the whole arena of the dispensary. As an instance of the extreme danger of some undissolved tabloids I may name iodide of potash. Careful instructions are, I know, given by most if not all firms regarding this drug, as to dissolving each tabloid in water; and all hypodermics are of necessity first dissolved. But there is a growing tendency I find to cultivate a rapid and easy mode of despatching tabloids by swallowing them like pills rather than a safer one of dissolving or pulverising them first. Of the insolubility of many, taken whole, I have had ample proof in my practice, and my desire in this paper is to advocate most strongly the solution of all which are soluble before administration, and the pulverising of all which are not; if so be, that is, that a course of tabloids instead of mixture has been determined upon. In this way only I feel convinced from experience will the results which are expected be secured. For instance, I had seven cases of a common disorder recently to treat. Six of these I treated in the ordinary way, and one, because he wished it, by the tabloid and tabella method. The six were cured in one-eighth part of the time, although larger doses were given by tabloid than by mixture. It will readily appear that if a form of tabloid of a more soluble nature, made not by great compression but by simple enclosure of the ingredients in some soluble capsule, could be administered, much that is objectionable might thus be removed, although other improvements might still be needed in other directions. I refer to the soluble gelatinous or glycerine jabbe capsules named by some palatinoids and by others *cachets*, which latter are, I understand, so largely used on the Continent, and are superseding the compressed drugs very extensively in America. The objection of the insolubility of a tabloid, tabella, etc., being in these ways completely overcome, there remains the question of causality of the contents, a matter of no slight importance. Manufacturers of all these specialties need only a general recommendation emanating from the Council of this department of our Association to place on their labels full directions for the prior solution in water of all these capsules containing either suspiciously or actually caustic drugs, or to dilute them so thoroughly with harmless vehicles that their causticity is rendered absolutely nil. And this difference in the capsules might be indicated and accentuated the more readily by a difference in the shape of the tabloid, palatinoid, *cachet*, etc., by making those which are to be first solved square or oblong, and labelled as desirable.

THE ETIOLOGY OF ACUTE PEMPHIGUS.

By GEORGE PERNET, M.R.C.S. ENG., L.R.C.P. LOND.

A FATAL CASE of acute pemphigus,² which came under my care recently, led me to look up the literature of the subject, with the view of throwing some light on a morbid condition, which has given rise to much controversy. The

facts of the case just alluded to were briefly as follows: A journeyman butcher, aged 31, injured his little finger in the course of his work. He paid no attention to the wound, and it remained as a small gathering for about three months. A large blister then appeared on the site of the injury. This was treated as a whitlow, and healed. Ten days after the blister formed, a bullous eruption appeared, which rapidly became general. The patient died sixteen days after the first appearance of the eruption. The case may be described as one of acute bullous eruption, accompanied by severe constitutional symptoms, occurring in a journeyman butcher, and evidently as the result of a wound.

I have been able to collect four very similar cases, all occurring in young journeyman butchers. In three the disease was fatal in from ten to twenty-eight days. In two cases, one of which recovered, there is a distinct history of a wound.

In 1856 Sir George Burrows³ published a lecture on a case of acute bullous eruption. A young butcher was admitted to St. Bartholomew's Hospital on April 8th, 1856. Five weeks before admission the patient, whilst chopping a sheep's head, cut his left thumb. The wound continued to discharge, but he remained well until April 5th, when the eruption commenced. The patient suffered severely, but recovered. He was convalescent a month after admission.

Burrows compares this case with another, which had come under his care in 1854. The patient was also a young butcher, with a precisely similar eruption. In this case, too, there was a history of a wound, inflicted whilst dressing sheep's heads. He was admitted to St. Bartholomew's in March, 1854, in a more advanced stage of the disease than the case just referred to, and died at the end of a fortnight.

Horand,⁴ of Lyons, had a case under observation in 1872. A journeyman tripe butcher, aged 17, first noticed some small boils on the sides of the fingers and toes on August 21st. He was admitted to the Antiquaille Hospital on August 22nd. During the night the eruption became general, and the patient died on August 30th.

Gibier⁵ refers to a case of a journeyman pork butcher, aged 17, under the care of Vidal at St. Louis. The eruption commenced on August 14th, 1881, four days before admission to hospital. The patient died on August 31st.

In the two last cases there is no mention of a previous wound. The occupation is one, however, in which wounds of the hands and fingers are frequent.

In a case referred to by Moissenet⁶, but of which no details are forthcoming, an alcoholic pork butcher is stated to have succumbed in twenty-four hours to acute pemphigus.

There is another case of acute pemphigus on record (1813), occurring in a weaver, who also slaughtered animals. The patient was seen by Henning⁷ eight days after the commencement of the eruption. Two days later the patient died.

Adding these seven cases together, including my own, no fewer than six terminated fatally, and in three there is a distinct history of preceding injury.

In a second series of cases (8), apart from butchers, but where the nature of the occupation brought the patient in contact with animals or with dead portions of animals: meat, hides, etc., the acute bullous eruption was fatal in 5 (4 females, 1 male). In 3 of the 8 cases there is a distinct history of injury to the hands, and in two others a whitlow of the finger was noticed on admission to hospital. In as few words as possible the data of these 8 cases are as follows:

CASE 1.—A tanner, aged 50, under Dr. G. Newton Pitt⁸ at Guy's. Health good up to October, 1887, when the patient poisoned his left little finger; ill five weeks. Five weeks later he poisoned his left thumb; ill three weeks; then noticed small vesicles on arms, neck, and thighs. These disappeared. On December 27th, 1887, fresh vesicles appeared on the perineum, penis, and thighs. Admitted to Guy's Hospital on January 3rd, 1888. Died on January 10th. This case was very much like the one I had under observation, but was not so extensive.

CASE II.—Published by E. Ballard.⁹ On August 16th a man, aged 21, whilst administering a physio-bath to a horse, was slightly bitten on the dorsum of the right hand, blood flowing from the wound. The same day he milked some cows suffering from a bullous eruption on the udders and teats. About a week after a bleb appeared at the bitten spot, and a few blebs of a similar kind appeared on the skin just around it. About a week later a large crop of bullae appeared; this was followed by another crop. The forearms, hands, legs, knees, buttocks, face, neck, and scalp were affected. There were also blebs in the mouth and throat. The patient was very ill for a time, but gradually recovered. On October 8th he was practically convalescent.

CASE III.—Malherbe's¹⁰ case. A female servant, aged 46, admitted to St. Louis on February 12th, 1869. Eruption commenced February 12th; death February 19th.

CASE IV.—Under Bleibtren,¹¹ of Cologne. A female servant, aged 20. Eruption commenced on June 1st, 1863; admitted to hospital on June 8th; death on June 27th. On admission a subcutaneous whitlow was noticed round the nail of the right index finger, which Bleibtren suggests may have arisen from a suppurating bulla.

CASE V.—Under Sautley's¹² (1875). A general servant, aged 19, came to the hospital on October 28th for a sore on the side of the hand, which commenced as a blister. It had been commenced. She first felt very ill on November 15th, the day the eruption commenced. The patient recovered.

CASE VI.—Reported by Spillmann.¹³ A fatal case in a housewife, aged 36. Eruption severe; ill from May 25th to June 5th.

CASE VII.—Under Dr. S. Coupland.¹⁴ A hard-worked woman, aged 45. On admission to the Middlesex Hospital it was noticed she had a whitlow at the base of the right thumb-nail. The patient recovered.

CASE VIII.—Under Dr. Penrose,¹⁵ at St. George's. A kitchen-maid, aged 22. Eruption first noticed on November 13th; she got rapidly worse on November 22nd, and died on November 29th. The patient had been treated previously as an out-patient for sore throat.

In the case of a married barmaid, aged 23, under the care of Dr. West¹⁶ at St. Bartholomew's, the patient was bitten on the right thumb by a dog a month before admission. A week after the bite small spots like blisters appeared on the back of the right hand. This was followed by others on the arms, legs, and trunk. She was discharged a fortnight after admission.

The case of the man¹⁷ who attended horses and milked cows is specially interesting from the fact that the disease which followed a wound of the hand was contracted by inoculation from the teats of a cow. There appears to be a bullous pemphigoid, or vesicular eruption on the teats and udders of cows which is distinct from true vaccinia.¹⁸

Acute bullous eruptions are also described as occurring in cattle and horses. Seaman¹⁹ mentions a case of pemphigus in a bullock resembling pemphigus in man, in which the illness commenced on May 14th. The animal was seen on the same day by Seaman, and he noticed bullae or bladders, from a small nut to a fowl's egg in size. The animal was very ill at the time. Excoriations and loss of hair disfiguring the animal followed.

Loiset²⁰ observed a "pemphigus enzootic" in cows near Lille during September and October, 1887. There were no febrile symptoms. A woman with an excoriation, it is stated, presented bullae, similar to those seen on the cows, on the right hand, arms, and breast.

Gibier,²¹ with Bouley, observed two horses with acute pemphigus.

Bullous eruptions are also said to have been seen in dogs.²²

With regard to the bacteriology, a characteristic micro-organism has been described by Demme²³ under the name of "diplococcus of acute pemphigus." In Bleibtren's case²⁴ Chapman found an organism very much like the one described by Demme. More recently, Dr. W. B. Smith²⁵ from the case under my care, has found a diplococcus closely answering Demme's description, especially as regards culture experiments. On the other hand, Eschschardt²⁶ reports that he has found the organism in a case of chronic pemphigus. It should be added that in Demme's case, a boy aged 13, the eruption could not be traced to cattle, although inquiry was made in the patient's native village.

The subject is admittedly a complex one, and in the foregoing remarks a portion of it only has been touched upon. Sufficient has been said, however, to allow of the following conclusions being arrived at:

1. There is a group of rare cases of acute bullous eruption, accompanied by severe constitutional symptoms, and generally terminating fatally, which affects butchers.
2. The disease follows a wound of the hand or fingers.
3. Is probably due to a micro-organism.
4. The same etiological factors are probably at work in another group of very similar cases, in which the patients by their occupation are brought into contact with animals or dead portions of animals, such as meat and hides.

All these points require further investigation. In future it would be well if the following data were carefully sought for in all cases coming under observation:

1. Occupation: (a) butchers; (b) cooks, tanners, milkers, etc.
2. History of a wound.
3. Presence or absence of a characteristic micro-organism, that is, Demme's diplococcus.
4. Contact with animals suffering from a bullous or vesicular eruption.

As far as the last two points are concerned, veterinary surgeons might render valuable assistance, especially by the bacteriological examination of bullous eruptions in animals.

Before concluding, I would draw attention to a point of practical importance: wounds of the fingers and whitlows in butchers and those handling meat, etc., should be thoroughly disinfected with powerful antiseptics, such as perchloride of mercury solutions.

THE TREATMENT OF TRICHOPHYTOSIS (RINGWORM), BASED ON THE PHYSIOLOGY OF THE TRICHOPHYTES.

Dr. LESLIE ROBERTS (Liverpool) read a paper on this subject, in which he said that the conclusions he had arrived at were as follows: (1) There existed in the vegetable world a class of minute flowerless plants (fungi, capable of digesting and assimilating hair and other keratinous tissues; (2) that the process might be called trichophytosis, of which there were divers varieties; (3) that this process might take place on the skin of the living host, or in the hair that had no connection with a living organism. (4) It followed that trichophytosis follicularis was a combination of a saprophytic destruction of an inert body, which led to pathological cell processes; (5) that once the fungus had entered into the interior of the follicle any further direct control over it was lost; (6) that our therapeutic influence over the fungus lay in our power of exciting proliferation of the soft cells of the follicle; (7) that in many cases it was desirable to carry the excitement beyond physiological bounds, so as to produce pus; (8) that epithelial pus formation was not followed by any sensible loss of tissue, but that connective tissue pus led invariably to ulceration; (9) that we should therefore endeavour to limit suppuration to the epithelium.

A CASE OF ADENOMA SERACHUM, INTERMIXED WITH FLACCID MOLLUSCA FIBROSA; TREATMENT BY EXCISION.

Mr. WILLIAM ANDERSON (London) read a paper on this subject. He said that in the case of the man under his care, he had obtained very gratifying results. He considered that a great improvement could be gained in such cases by the judicious employment of the knife.

ALOPECIA AREATA.

Dr. HENRY WALDO (Chifton) read a paper on this subject.

observing that the conclusions he had arrived at were that, clinically, the great majority of cases of patchy alopecia areata did not appear to him to be due to a fungus. The causes were often, he considered, overwork, too little sleep, bad hygienic conditions, and perhaps, in addition to these, malnutrition. He had obtained the best results by improving the patient's general condition, combined with moderate stimulation of the more or less anæsthetic surfaces.

A CASE OF DERMATITIS REFERS.

Dr. J. H. STOWERS (London) read a paper on this subject, in the course of which he said that the special features clearly pointed to the affection being a distinct disease, however much it resembled eczema in some of its characters. He insisted on the following points in his case: 1. The age and circumstances under which the disease commenced, that is, fourteen days after confinement. 2. Its persistent character and long duration, that is, forty four years. 3. The involvement of both feet as well as both hands. 4. The disordered nervous system. 5. The presence of well marked glossy skin. 6. The association with recurrent acute gout; and 7. The absence of transmission and its probable idiopathic origin.

AN UNCOMMON PAPULO-PUSTULAR ERUPTION IN INFANTS.

Dr. COLGORY FOX (London) read a paper on this subject. The conclusions he arrived at were that the affection was not of syphilitic origin. He looked upon the eruption as one not due directly to tuberculosis, but as one occurring in certain infants with poor nutrition who were prone to tuberculous infection. In such children it was very likely that an organism found a favourable soil in the follicles. He was inclined to attach the affection to one now pretty well known in London, that is, *acne serofulosa*.

A CASE OF LICHEN PLANUS VERRUCOSUS.

Mr. GILBERT SMITH (Birmingham) in this paper said that the cause in this case was probably nervous exhaustion in a nervous woman, through derangement of the generative system. The case was also interesting from the extent of the affection, but more so from the fact that the warty patches were derived from the conical papules seated at the hair follicles, and not from the flat papules. The process was the same as lichen planus.

TWO CASES OF CHEIRO-POMPHOLYX IN ASSOCIATION WITH ECZEMA.

Dr. EDWARD MACKAY (Brighton) read a paper on this subject. He considered the connection of cheiro-pompholyx and eczema was closer than was thought; and, further, that the pathology was not far different. He expressed the view that cheiro-pompholyx was a variety of eczema.

A CASE OF CHEIRO-POMPHOLYX.

Dr. H. BARNETT (Liverpool) read a paper on this subject. He said it must be admitted that cheiro-pompholyx was a neurosis, that is, a disturbance of the digital vasomotor nerves; but whether this view helped them much etiologically was open to doubt.

CORNS, TRUE AND SO-CALLED.

Dr. ALFRED EDDOWES presented a paper on this subject. He said he might instance numbers of patients whom he had found to be suffering from what they termed corns, for which they had sought the advice of a surgeon or the help of a chiropodist without obtaining permanent relief. Moreover, many of them possessing ample means had spared no trouble or expense to obtain suitable boots. He would content himself with a brief description of one typical case. About two years ago a lady came to him and told him she had tried everything she had heard of for the relief of excessively painful corns. He found she had the typical horny formation on the classical position for a corn, namely, the joint of the little toe, as well as elsewhere. But the trouble she complained of most was underneath the foot, where he found a callosity which did not correspond exactly to the head of any bone. It was smooth upon the surface and possessed much the appearance of callosities such as were met with upon the palms of the hands of carpenters and others accustomed to work with hard tools. It was not until he commenced to remove some of the horny substance that he

realised the pathological condition with which he had to deal. The centre, after being cut down a short distance, presented numerous minute dark points which, when cut still further, commenced one after another to bleed. There was no difficulty whatever in diagnosing the real nature of the malady. It was nothing more than a wart. Warts were by no means uncommon on the feet, and a considerable number of them occurred on the soles; others between the toes (forming a considerable portion of the so-called soft corns) and in rare instances he had found them at the edge of the hard horny layer covering the sole. Recently he met with a group of three warts in the latter position on the heel. So far he had not been fortunate enough to find any literature on the subject, and should be much obliged if any of those present would refer him to such. Even if attention had been drawn to this subject he thought it was well worth while emphasising it, as probably few of the lesser maladies incidental to daily life caused more suffering and inconvenience than corns—true or false. The lady whose case he had mentioned above had to do her shopping in a cab, though she could not well afford it. She assured him that it was painful for her to walk about her own home, and that this unhappy condition had existed for at least two years, notwithstanding constant efforts to obtain relief. The practical point was that, although a wart and a corn might assume a similar external appearance, yet, for successful treatment of the two conditions measures must be adopted which were as different as the pathological processes involved. It would be obvious to those who gave the subject a moment's consideration that, while a cornplaster or modifications of a boot might completely cure a corn, which was nothing more than an accumulation of an inverted horny cone that could easily be removed or allowed to fall off, leaving the true skin and epidermis normal, in the case of a wart no amount of modification of boots or application of cornplasters could be of the slightest use. Naturally, the more room warts had the better they would flourish, and therefore their treatment when occurring on the feet must be in accordance with the principles of treatment of similar growths elsewhere.

THE SKIN LESIONS OF SYRINGOMYELIA.

Dr. GALLOWAY (London) read a paper on this subject, in the course of which he said that the conclusions he had arrived at were that the great weight of clinical evidence tended to corroborate the experimental results obtained by Mott, Sherrington, Ferrier, and Turner—namely, that sensory impulses in all their modes were conducted by grey matter, and not by the entero-lateral or posterior ascending fibres, as once asserted. The possible conduction of educated touch, in opposition to ordinary contact sensation, by the white matter of the posterior columns was admitted. Further, in the numerous lesions of the skin that played so important a part in Morvan's type of the disease, he felt inclined to consider that local infective processes played by far the preponderating part in their production. He was also of opinion that it was needless to seek for recondite causes for the production of the pustulo-vesicular eruptions, when there were plenty of common staphylococci and streptococci at hand to do the work. Dr. Galloway also mentioned the possibility of an ascending toxic neuritis from the affected part or due to absorption of bacterial poisons. The scarcity of herpetic eruptions was evidence that the irregular pustulo-bullous eruptions met with were of local rather than of central origin.

TWO CASES OF UNUSUAL VERRUCA NECROGENICA.

Dr. A. J. HARRISON (Clifton) read a paper on this subject, in which he said that the conclusions he had arrived at were that, although the two cases differed etiologically from, yet clinically they seemed to be identical with, verruca necrogenica. Both cases were very rebellious to treatment. The affection he had described might be neither verruca necrogenica nor lupus, but a tuberculosis of the skin, and not very active, but no bacilli were found.

A CASE OF PITYRIASIS RUBRA PILARIS (DEVERGIE): CLINICAL FEATURES AND MINUTE ANATOMY.

Dr. J. LIDDELL (Harrogate) read a paper on this subject, in which he said that the conclusions he had arrived at were that the alterations in the epidermis, hair follicles, sweat glands,

and sebaceous glands were primary and not consequent upon any change in the corium. There was certainly a source of irritation which produced the changes he had described, but whether it came from within or without remained an open question. From the circumstance that the lesions were symmetrical, some would be inclined to look upon the condition as a trophoneurosis. On the other hand the irritation might be external. He had found a parasite in his sections of excised portions of skin, but what its relationship was to the disease was not yet determined. It might have a causal connection, or it might be simply associated with the disease, the morbid products affording it a favourable nidus for growth and development.

REPORTS

ON

MEDICAL & SURGICAL PRACTICE IN THE HOSPITALS AND ASYLUMS OF GREAT BRITAIN, IRELAND, AND THE COLONIES.

ROYAL MARINE INFIRMARY, WALMER.

ISOLATED CASE OF DIPHTHERIA IN CONNECTION WITH FAULTY DRAINS: ANTITOXIN TREATMENT.

(By J. N. STONE, Fleet-Surgeon, R.N.)

[Communicated by the DIRECTOR-GENERAL OF THE MEDICAL DEPARTMENT OF THE ROYAL NAVY.]

W. D., aged 4 years 11 months, daughter of Private H., was brought to the infirmary July 14th. The tonsils, uvula, and soft palate were reddened and swollen, and characteristic yellowish-white patches were present on tonsils. Deglutition was difficult and painful. Pulse 140, temperature 102°, respirations 30. The child had been ill about forty-eight hours. The drains of the lodging house from which she came were found by the medical officer of health to be at fault. There were no other cases of diphtheria in the neighbourhood.

The child was admitted to the infirmary, and although there was little doubt as to the nature of the case, some membrane was forwarded to the Institute of Preventive Medicine, where the bacillus diphtheriae was isolated. At 1 p.m. on the day of admission 10 cubic centimetres of antitoxin were injected between the scapulae. At 6 p.m., there being no fall in temperature or pulse, a further injection of 10 cubic centimetres was given. At 10 p.m. the temperature had fallen to 101°.

July 15th. Little sleep last night, offensive nasal discharge. Respiration 24, pulse 136, temperature 100.8°. Bowels open. To have Liebig's extract and port wine in teaspoonful doses. Throat to be brushed from time to time with weak bichloride of mercury solution. 10.45 p.m. Temperature again rising, 102.8°. Much prostration; cannot be roused from lethargic condition. Membrane has extended from tonsils and uvula to soft palate. Breathing laborious; pulse 140, feeble. Injected 10 c.c.m. of antitoxin.

July 16th, 9 a.m. Slept well. Temperature reduced to 100.2°, respiration 24, pulse 136, stronger. Condition generally improved. Throat congestion less; portions of membrane come away, followed by slight bleeding. Trace of albumen in urine. To have 5 minims of liq. ferri sesq. three times daily.

July 21st. Continues to improve daily. Eruption like urticaria on face and extremities. Temperature 100°.

July 23rd. Urticaria gone, throat nearly well. Discharged on the 25th quite well.

QUETTA CIVIL HOSPITAL.

VESICAL CALCULUS WEIGHING ONE POUND.

(By A. SCOTT REID, M.B., Surgeon-Lieutenant-Colonel I.M.S., Civil Surgeon, Quetta.)

SHAHID KHAN, a native of Sheran, on the Persian border, was brought by his friends on June 1st, 1893. He was a very old man, apparently between 80 and 90, reduced to "skin and bone," and hardly able to stand. He stated that he had suffered from urinary trouble for upwards of fifty years, and that for the last thirteen his life had been a burden to him. He

had spent his time and substance in consulting numerous *hakims* and *fakirs*, and now applied for European aid as a last resource. The urine dribbled from him continuously night and day, and was found to be slightly acid, of specific gravity 1015, and to contain albumen to the extent of one sixth. On introducing a sound the bladder was discovered to be occupied by a large and very hard stone. The case was a hopeless one as regarded ultimate recovery, but as the patient prayed for relief from his present agony at any cost I consented to operate. I had previously successfully removed some large calculi by litholapaxy, and as it was desirable to save the patient if possible the risk of a cutting operation, and not realising that I had in this instance such an enormous stone to deal with, I first tried what I could do by crushing. No difficulty was found in introducing the largest lithotrite in my possession—a No. 17 Weiss. With this I worked for an hour, removing a large quantity of debris through a corresponding evacuating catheter. I then found that it was impossible to proceed further by this means, as the unreduced portion of the stone was encapsuled by the bladder, and I could not get the blades of the instrument round it. I accordingly introduced a grooved staff and performed lateral lithotomy. It was like opening into a miniature quarry; the base of the bladder was occupied by a quantity of debris, and behind a solid wall of rock. Having now my left forefinger as a guide, I managed to insinuate the female blade with a little difficulty behind the mass, and, with two actions of the instrument, to reduce it to fragments capable of passing through the incision. The bladder was then cleared as far as possible and washed out with boric acid lotion; but its walls, which were enormously thickened, were found to be encrusted, and calcareous particles continued to come away for several days.

The fragments and debris at first weighed 22 ounces, but after being thoroughly freed from blood clots, mucus, etc., the weight was reduced to 1 pound. A quantity of fine sand was unavoidably lost, but I leave that to counterbalance any moisture retained in the matter weighed. The stone appeared to consist entirely of uric acid.

The patient rallied well from the operation, and expressed himself as greatly relieved. The bladder was washed out twice daily with boric acid solution. No inflammatory symptoms supervened, and only on two occasions did the temperature rise slightly above normal. On June 15th, or seven days after the operation, the old man, however, began to sink, and died on June 17th, while his relatives, contrary to my wish, were in the act of removing him from hospital.

I am aware that the suprapubic operation has again come into vogue, and some may consider that this was the one I ought to have selected. The stone, however, in its entire condition, could not have been removed through an incision, compatible with safety in this region, and, in my opinion, the perineal route offered superior advantages for subsequent drainage.

REPORTS OF SOCIETIES

PATHOLOGICAL SOCIETY OF LONDON.

ALBAN DORAN, F.R.C.S., Vice-President, in the Chair.

Tuesday, December 17th, 1893.

THE VARIETIES OF DIPHTHERIA BACILLI.

MR. E. K. PETERS read a communication on this subject. The observations were based on experiments which had been carried on for over a year with specimens of diphtheria bacilli. Four species of bacilli were described. The appearance of the twenty-four hours' growths are as follows: 1. Long Klebe-Loeffler's bacillus. A twenty-four hours' growth on blood serum, short bacilli, numerous segmented forms, 0.003 mm. in length, long clubbed bacilli and short clubs. The bacillus is pathogenic to guinea-pigs, and does not readily lose this property. 2. Short diphtheria bacillus (described in detail for the first time). This bacillus when compared under the same conditions as the long Klebe-Loeffler's bacillus differs from it in that at six hours it presents a large number of short-pointed conical forms 0.0015 mm. in length, with a

few segmented elements, both of which are characterised by a pointed apex. The bacillus is pathogenic to guinea-pigs, but soon loses this character. 3. The short pseudo-diphtheria bacillus under the same condition appears as a short bacillus 0.6 mm. in length. Segmented forms are short and of rare occurrence, a few often appearing later. Segmentation forms appear in both cultures. The bacillus is never pathogenic to guinea pigs. 4. Bacilli which resemble the long Klebs-Loeffler bacillus, except for slight clubbing and more definite segmentation. These bacilli are not easy to distinguish by a microscopical examination. The clinical aspects of the cases in which these bacilli are found are as follows: (1) The long Klebs-Loeffler bacillus is found in cases of severe diphtheria. (2) The short diphtheria bacillus, which is less common than 1 and 3, appears in some mild cases of diphtheria. (3) The short pseudo-diphtheria bacillus is widespread, and is found in many cases of follicular tonsillitis, in scarlet fever, simple angina, laryngitis, and other catarrhal conditions. This bacillus does not cause a fatal affection *per se* as the long Klebs-Loeffler bacillus. The importance of distinguishing between these several bacilli, which is possible by a microscopical examination of a 24 hours' growth on blood serum, was urged. (4) These bacilli caused no apparent harm to the persons on whose throats they were found, and were possibly non-pathogenic long Klebs-Loeffler bacilli. Experiments which had been carried on by the author for over a year had not demonstrated a change from one variety to another. The short diphtheria bacillus had, however, readily lost its pathogenic quality. (These inoculation experiments were carried out by Dr. Washbourne.) It seems probable that these bacilli are allied species, while their morphological characters and clinical significance warrant the separation of the four, or at all events of the first three forms described. The paper was illustrated by lantern slides prepared by Dr. Bousfield, and by cultures and microscopical specimens.

THE XEROSIS BACILLUS.

Mr. J. EYRE read this paper on Neisser's xerosis bacillus, commenting on its close resemblance to the bacillus diphtheriae. He had isolated it from the conjunctival secretion of a series of cases which presented slightly different appearances from the ordinary form of follicular conjunctivitis, and which appeared to be somewhat infectious. Also from one case of trachoma; but had been unable to detect it in the secretion from normal conjunctivae. The cultural and morphological appearances upon various media were described and the difference between it and the Klebs-Loeffler bacillus pointed out. The chief points to be relied upon in differentiating the xerosis bacillus from the bacillus diphtheriae were summed up as follows: (1) First cultures from the conjunctival secretion, etc., do not make their appearance under thirty-six to forty-eight hours. (2) The production of an alkaline (never an acid) reaction when grown in broth or milk. (3) Retarded and scanty growth on gelatine, poor growth and rapid death upon potato. (4) The invariably innocuous character of both cultures when inoculated into animals susceptible to the bacillus diphtheriae. (5) The transition to a short straight bacillus staining evenly, after cultivation upon blood serum for ten to fifteen generations; and the restoration of those characters which render it liable to be mistaken for the diphtheria bacillus when transplanted on to glycerine blood serum.

Mr. LENNOX BROWN, after remarking that the two preceding papers had somewhat confused him, criticised the diagrams exhibited as not very faithfully reproducing the microphotographs, especially he did not see in the latter certain long spiral forms. The alterations in character that occurred on different media rendered it very necessary that some single medium should be selected for the purposes of diagnosis in practical medicine. As to Mr. Peters's statement that the shorter form was less virulent, he would say that some of the worst cases of diphtheria he had seen were associated with the presence of short bacilli, and one of the mildest with that of the long. Ordinary tonsillitis, in his experience, no pseudo-diphtheria bacilli were encountered. He observed too that in the first lantern slide exhibited of long bacilli there were also present short ones. He did not gather the practical purpose of describing the appearances of a ten-day

old culture; in some of these he thought micrococci were shown in the photographs.

Dr. WASHBOURN remarked that the pseudo-diphtheria bacillus described first by Hoffmann was non-pathogenic, but it might occur in conjunction with the Klebs-Loeffler bacillus. It was found in various affections of the throat. Roux and Yersin showed subsequently that there were varieties of diphtheria bacilli which were quite innocuous, though morphologically resembling the true form. The pseudo-diphtheria bacillus, which he thought Mr. Peters had shown to retain its characters without being convertible into the other forms, he had seen in German measles, when there was a slight inflammatory condition of throat, in scarlatina without diphtheria, in the nasal discharge associated with scarlet fever, etc. He did not reckon the case as one of diphtheria if this bacillus alone was present. Roux and Yersin had included under pseudo-diphtheria bacilli both the diphtheria bacilli which had lost their virulence and this other form of Hoffmann's. The shorter pseudo-diphtheria bacillus, if grown on blood serum, lengthened out and resembled the longer form. None of the photographs of Mr. Peters were from any but pure cultures.

Dr. A. A. KANTHACK thought that Dr. Washbourne and Mr. Peters had added to the confusion already existing on this subject, as two forms of pseudo-diphtheria bacilli were by them included under the term. The speaker would give up the expression pseudo-diphtheria bacillus altogether. There was only one reliable test, and that was inoculation of a susceptible animal with the culture; if no result followed this, the bacillus was not that of diphtheria. He knew of cases where the bacillus corresponded with the third kind of Mr. Peters, and when broth cultures were toxic for guinea-pigs. In severe cases of diphtheria the speaker had often found, not the long variety, but the short, and even the pseudo variety of Mr. Peters. It was easy to change the long kind into the short by reducing the supply of free oxygen, and by other means. He had usually noticed small varieties in association with the longer. The short forms, if sown on agar, grew into long; and this admixture was also shown in the microphotographs of Mr. Peters. The classification of long and short was a mere matter of convenience. As to the xerosis bacillus, he had obtained it from a series of different cases of conjunctivitis, two of them mucopurulent forms, as well as from the membrane resulting from the caustic action of lime and nitrate of silver. On gelatine the bacillus grew in extremely small colonies, not in a wrinkled streak like that of diphtheria. A long form of bacillus like that of diphtheria had been found in cow's milk, in ulcers, and by Dr. Kaem in cases of meat poisoning; in fact it was a type to which not a few bacilli conformed.

Dr. DURHAM did not think that the pathogenic action of cultures on animals was so absolutely diagnostic as Dr. Kanthack held; for other vibrios than Koch's produced results similar to the latter on animals. No one had yet raised a virulent diphtheria bacillus from a non-virulent one, and until this was done it would be open to regard the forms as different.

Dr. E. W. GOODALL remarked that isolated observations might be fallacious. Sometimes the true bacillus was overlooked in cases of virulent diphtheria, and a short form occurring with it might be cultivated. Of the two, he held the longer to be decidedly the more virulent; the short was not often found without the long in really grave cases. He had seen short bacilli in German measles, scarlet fever, etc., and did not think it very virulent, though he did not know what should be comprised under the term short.

Mr. PETERS, in reply, attached much importance to the fact that what he considered the more virulent forms might be overlooked; this might happen in laryngeal diphtheria, when examinations made from the throat might reveal a pseudo-diphtheria bacillus, whilst another variety might exist at the real seat of disease. He had only himself once seen a membrane formation associated with the pseudo-diphtheria organism, and he had not known of a fatal case in which the latter bacillus was found, though angina and obstructive laryngitis might be produced.

Mr. EYRE remarked that he had pointed out the differences of character in jelly-streak cultures between the xerosis and

diphtheria bacilli. One of the best means of diagnosis was the growth on potato.

CARD SPECIMENS.

CLINICAL SOCIETY OF LONDON.

THOMAS T. WHIPHAM, M.D., F.R.C.P., Vice President, in the Chair.

Friday, December 13th, 1895.

MEMBRANOUS COLITIS TREATED BY RIGHT COLOSTOMY AND SUBSEQUENT CLOSURE OF THE WOUND.

Dr. W. HAIN WHITE and Mr. C. H. GOLDING-BIRD reported the case of a neurotic lady aged 39, who first began to pass mucus from the rectum and suffer from constipation in 1885. From that time both these symptoms became more marked, and by 1891 she was suffering from severe abdominal pain. In the next year the motions often consisted of nothing but mucus and blood, and the pain was agonising. This state of things continued till 1894, when she began to pass tubular casts; the pain kept her in bed most of the day. Very strong purgatives were necessary to move the bowels, and she was a complete invalid. When seen by the authors in 1895 she was in the same condition, and had much tenderness over the descending colon and sigmoid. A motion was examined, it consisted of little faeces, much mucus, long tubular casts, and a considerable amount of blood. As during the previous ten years all sorts of drugs, various diets, prolonged rest in bed, and many health resorts had been tried, it was decided with the consent of Dr. Walter Smith, of Dublin, to perform a right colostomy. The bowel was fixed to the surface on May 10th, and opened on May 17th. Three days later the colon was washed out from the artificial to the natural anus with hot water, but already the membranes had ceased to be formed. For five weeks all the motions were passed through the artificial anus without the aid of purgatives. The faeces always appeared normal. As at the end of this time all the original symptoms had disappeared, the colostomy wound was closed and the bowels were subsequently kept confined for a week with opium. Some compound liquorice powder was then given and the motion which was passed contained neither mucus nor blood. The general health and strength improved, and she went into the country on July 24th, feeling better than she had done for many years, having passed no blood or mucus since the operation on May 10th. The authors submit that in a severe case of membranous colitis this treatment was justifiable and was the most rational, for by it the colon could have complete rest. Their patient, it was true, had since died, but, as far as could be made out, her death had nothing to do with the operation or the colitis. Her subsequent history was imperfect, but it could not be made out that she suffered from membranous colitis after she left London.

Dr. ADENEY (Tunbridge Wells) had attended the patient in her final illness, which occurred nearly two months after her departure from London. She died after about forty hours' illness with symptoms of acute suppurative general peritonitis, due apparently to the rupture of something in the pelvis, possibly a suppurating gland. A post-mortem examination could not be obtained. The patient before death stated that the improvement in her condition which had been attained when she left for the country had continued until her final sudden seizure.

Mr. GOSWAMI said that the treatment of dysentery by colostomy had been suggested to him years ago by Dr. Manson. This year he had put the suggestion into practice. The patient, a lady, had had dysentery in India, and fistula, for which he operated. She became better, then had phlebitis after childbirth, and suppuration of the liver, from which she recovered; but the dysentery recurred, and he performed left colostomy. This, however, he found did not allow such complete treatment of the bowel as did right colostomy, which for the future he should prefer. On opening the gut the mucous membrane was found to be completely studded with

small polypoid growths. The dysentery and the patient's general condition were much improved, and she was relieved from the constant irritation. She eventually died from some return of the phlebitis, which had nothing to do with the dysentery.

Dr. TURNER said that Mr. Ballance had operated on a case of his which was diagnosed as dysentery. The man had been in India, but had no dysentery there. Subsequently he passed blood and mucus from the bowel, and became greatly emaciated. There was difficulty in fixing the appropriate time for the operation, so as to be neither too soon nor too late. Unfortunately it was eventually done a little too late. The operation was done on the right side by an inguinal incision. The ileum was completely cut through, the upper end being fixed to the wound. The lower end was reserved for irrigation. The patient recovered satisfactorily from the operation. The bowel was douched frequently, and he seemed to be improving when hypertrophic polypoid growths showed itself, and he died a week after the operation. The chance of recovery from severe dysentery under ordinary treatment was, he thought, almost hopeless, as the raw surface of the gut allowed the absorption of poisonous products which hastened the patient's death. The operative treatment, however, should be limited to cases in which the disease existed only in the large intestine. He considered colostomy preferable to division of the ileum.

Dr. FRANCIS HAWKINS (Reading), while admitting that the casts in the authors' case came from the colon, thought that the term "membranous colitis" should not be used, because casts similar in structure came also from the jejunum and ileum, as he himself had seen. The casts consisted of mucus, and he would describe the malady as a type of "mucous disease of the intestines." He doubted if it was so rare as some thought it, and considered that it might pass undetected when the stools were not systematically examined. He would advise operative treatment for intractable forms of the disease only, and thought it would be rarely called for. He cited a case, where casts had been passed for a year, which recovered, so that for two years no further casts had been passed.

Mr. BARKER asked the authors what was the exact nature, microscopic structure, and mode of production of the membranous casts? In a recent case he had found the casts structureless, containing a few epithelial cells, and having the appearance of coagulated mucus.

Dr. HERRINGHAM considered that the casts were not the cause but the consequence of the disease, inasmuch as they usually followed a long period of constipation. They were quite structureless. He had seen two cases. The patients had great pain, with swelling on the left side of the abdomen; one recovered, one died after operation from an abscess in the neighbourhood of the descending colon. Why should patients have an abscess there, except from some retention of faeces leading to ulceration? In the fatal case there was a pinhole opening into the bowel; in the other case the pus was sweet, and apparently there was no communication with the bowel. A German had called the condition "pericolicitis cystica," and asserted that it was as common as suppuration about the appendix. He suggested that possibly there was such suppuration in the authors' case, which broke into the peritoneum and caused the fatal termination.

Dr. S. PHILLIPS said that the case under discussion was colitis, not dysentery. The casts mentioned by Mr. Barker and Dr. F. Hawkins might come without any disease of the mucous membrane, being structureless and quite different from the sloughs of mucous membrane found in colitis, which were accompanied by much hemorrhage. Further, with colitis there was often disease of the small intestine as well. He could not notice that the end of all the three cases treated by operation which had been related had been a fatal one.

The CHAIRMAN had been consulted about a case similar to that related by the authors. The patient was a neurotic young lady who had passed mucous casts for years, and had before that suffered from constipation. She had constant pain over the descending colon. He ordered small doses of calomel, which secured evacuation of the bowels, the motions containing mucous casts. She was kept in bed on milk diet, but became so emaciated that it was thought she must die.

Then, without change of treatment, she improved, and now for six months had remained well and able to drive out. He added that since her recovery a sister had suffered from the same kind of colitis.

Dr. HALE WHITE, in reply, thought the term "mucous disease of the bowel" was not a good one, being already applied to a different disease of the bowel in children. He believed membranous colitis was fairly common, and often accompanied chronic constipation; and that when the bowels came to act it also ceased. It was not common in neurotic subjects. As to the abscess on the left side of the abdomen, it must be remembered that abscess of the vermiform appendix occasionally opened there. The patient had not gone to Kissingen until she had had the disease for many years. The microscopical appearances of the casts had been described by Drs. Wilks and Goodhart in the *Pathological Society's Transactions*.

Mr. GOLDING-BIRD, in reply, said that the reason for locating the disease in the descending colon was simply that the pain was there, just below the splenic flexure. He did not think it was necessary to divide the ileum. Mr. Godlee, for example, did nothing more than open the bowel in his remarkable case, and yet the patient was greatly benefited. In fact, the mere diverting of the stream of faeces of itself effected great relief. So soon as the contents of the bowel came within the range of the defaecating apparatus it made in these cases of ulcerated bowel a profound impression on the central nervous system, which was avoided by colotomy.

CONGENITAL MEDIAN CERVICAL FISTULA.

Mr. BARWELL related the case of a young lady, sent to him in April last by Dr. Bezly Thorne, with well marked lateral curvature of the spine. On June 11th, her back being nearly straight, she showed an opening in the mid line of the neck situated on the most prominent point of the thyroid cartilage, which occasionally, at least once a day, discharged a thin fluid. The small orifice was surrounded by depressed and reddened skin for about a quarter of an inch from side to side, nearly half an inch from above down it was partially overhung by a transverse narrow fold of healthy skin. While the deeper parts of the throat were at rest the coloured depression was very shallow, but in swallowing it deepened, being drawn upward and inward, gliding under the transverse fold, which thus became more overhanging, widening also so as to stretch almost from one sterno-mastoid to the other. On palpation a line of cylindrical somewhat hard tissue could be felt running up from the opening to the hyoid; it seemed about the size of a cedar pencil. The foramen caecum was not abnormally large. He diagnosed a tubular remnant of a suprahyoid accessory thyroid gland, and as she was exceedingly anxious to be rid of the blemish, he believed it would be feasible to remove the tube through an opening so small that the scar would be hardly visible. On June 19th ether was administered and caused considerable flow of saliva, about half a drachm of which escaped down the fistula and showed itself on the neck. He made an oval incision just wide enough to include the reddened skin, and seizing this together with the fibrous tube in a vulsellum, the whole was brought down, any retaining bands being severed with the scalpel. After about two thirds had thus been extruded it broke, but by gliding the skin and wound upward, the end was easily brought into view, again seized, and the truncated end removed flush with the hyoid. The little wound was dressed with sutures going deeper than the floor of the wound and secured by lead buttons. Adhesion took place rapidly, and she went down to dinner on the fifth day (23rd). 29th. She went into the country, and about a fortnight after the operation sang—contrary to his directions—several songs. A little saliva doubtless found its way through the foramen caecum downward, and when he saw her ten days after that event there was in the place of the wound a semi-globular enlargement; puncture with a tenotome liberated a drop or two of slightly turbid, not puriform, fluid. Pressure along the track of the old sinus caused no further flow, nor was any thickening to be felt. A letter, dated October 20th, received from the patient, said, "Nothing remains of the place but a little reddish mark, quite flat, smooth, and completely healed. It is delightful that my collars do not now get dirtied."

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

EDWARD NETTLESHIP, F.R.C.S., President, in the Chair.

Thursday, December 12th, 1895.

CLINICAL EVENING.

CASE OF RETINITIS CIRCINATA.

This was shown by Mr. HARTRIDGE. It presented the appearance of a grey degeneration at the yellow spot, with a mass of white deposit in the nerve fibre layer of the retina radiating from the yellow spot region. There were no retinal haemorrhages; it did not agree in every detail with the recognised appearances, but he thought it was possibly an early stage of retinitis circinata.

Mr. HOLMES SPICER thought that the characters of the white exudation in this case were more like those of renal retinitis than of retinitis circinata. In all the undoubted cases that had been observed there had been a remarkable constancy in the character of the exudation, a grouping quite different from that shown in this case.

Dr. HABERSHON asked if there were renal disease or hypertrophy of the heart present.

Mr. HARTRIDGE replied that there was no renal disease; the heart had not been examined.

RARE FORM OF NYSTAGMUS.

Mr. ERNEST CLARKE showed one case and Mr. GRIMSDALE three cases of nystagmus in the fixing eye and occlusion of its fellow. In Mr. Clarke's case the vision in the two eyes together was; when either eye was occluded by placing a card in front of it, the uncovered eye immediately began to oscillate violently. In Mr. Grimsdale's cases the nystagmus was of the same kind but less marked.

Dr. HABERSHON had examined Mr. Clarke's patient. There was no sign of actual nerve disease, but he was of a neurotic type; all his reflexes were rather more pronounced than usual.

Dr. ORMEROD remarked that the patient was a jeweller, and had been using a single watchmaker's glass to one eye; he thought this may have partly caused the nystagmus. It was not present before he began that work.

SUPERFICIAL PERIPHERAL CHOROIDITIS.

A case of peripheral choroiditis of obscure origin was shown by Dr. RAYNER BATTEN. The patient was a woman aged 40. The choroiditis was limited to the periphery; the outline of the patches was irregular, map-like; the deeper layers were not affected, but the surface layers had a bleached appearance; vision was almost unaffected except for slight contraction of the fields. No evidence of acquired syphilis could be found; the condition was probably a late manifestation of inherited syphilis. It was still progressing.

Mr. HOLMES SPICER thought the cause of the disease in Dr. Batten's case was hereditary syphilis, on account of the white lines along the smaller veins, which was a common feature in that affection; for the same reason he thought it had been progressive comparatively recently.

EMBOLISM OF THE CENTRAL RETINAL ARTERY.

Mr. MARCUS GUNN related the case of a young adult in whom this lesion occurred, without evidence of cardiac disease. About three weeks ago there was sudden failure of the left eye, with the appearance of a thick film before it, in a young anæmic girl. The vision had somewhat recovered in part of the field since. She was suffering from amenorrhœa at the time. Although there was not much change in the size of the arteries, there was the typical cherry-red spot at the macula. Although at first he regarded it as a case of embolism, he had since thought that it may have been a hæmorrhage into the optic nerve sheath which had affected the vascular supply of the nerve.

Mr. HARTRIDGE had lately seen a case of embolism of the central artery in a healthy man two and a-half hours after its occurrence. There was already œdema of the retina.

Mr. BICKERTON had seen a case recently in which there was very little appearance of change in the vessels. The pupil acted to light.

Dr. BATTEN had recently seen a case of sudden failure of

sight in an anæmic girl, in which there had been little change in the vessels.

Mr. DRAKE BROCKMAN had seen some time ago a lady who had a sudden attack of giddiness; she lost the sight of one eye completely. There was no cardiac disease and no albumen, but the patient was anæmic.

RETROBULAR OPTIC NEURITIS.

Mr. HOLMES SPICER showed this patient, a healthy man, 68 years old, whose sight had been failing seven months. He had been a great smoker, but had given it up. There was no history of rheumatism, gout, nor syphilis; no locomotor ataxy nor disseminated sclerosis, no renal disease nor diabetes. The optic discs were very pale and slightly swollen. The fields were quite full, but he had a large colour scotoma at the fixation point. The case presented all the features of a severe tobacco amblyopia, but recovery had not followed abstinence from the poison; he had got steadily worse.

Mr. GRIFFITH thought the pallor in this case was too great for tobacco amblyopia.

Mr. JOHNSON TAYLOR thought it was an aggravated case of tobacco neuritis combined with alcoholism.

Dr. HARRISON thought that this case occupied a place midway between tobacco amblyopia and the family cases of optic atrophy described by Leber.

The President said that cases were occasionally seen in which the action of tobacco did produce much more grave results on the nerve than was customary, and this generally occurred in old men. He thought it not improbable that this case might be one of tobacco amblyopia in an old man.

RECURRENT PARALYSIS OF THIRD NERVE WITH MIGRAINE.

This case was shown by Dr. ORMEROD and Mr. HOLMES SPICER. A boy, aged 15, had had complete paralysis of the left third nerve when a year old; recovery took place. When he was about seven years old he had a second attack; since then he had had an attack every nine or ten months. He was subject to "bilious" attacks, with intense headache in the left side, and the paralysis always came on during a bad attack. There was some atrophy of the left optic nerve, and some of the paralyzed muscles now never recovered. The present attack was passing off, but there was still slight ptosis, a dilated pupil, and complete paralysis of the external muscles of the eye supplied by the third nerve.

DOUBLE PTOSIS.

Mr. WARREN TAY showed a case of recent double ptosis with loss of convergence and weakness of the internal recti. There was no apparent cause for the attack; at first the movements of the eye were good, but complaint was made of diplopia; later the failure of convergence was marked. Recovery quickly followed the use of iron and nuxvomica.

PARALYSIS OF BOTH INTERNAL RECTI.

This case was shown by Mr. THACHER COLLINS. A man, aged 22, had suddenly had paralysis of both internal recti five days, accompanied by headache. He was unable to move either eye towards the nose either in looking to one side or in convergence. The pupils acted normally, and vision was good; his gait was unsteady, his knee-jerks were exaggerated, and he became unsteady on standing with his eyes closed.

Dr. TURNER remarked on the probable seat of the lesion in the two last cases.

OTHER CASES AND SPECIMENS

(1) Peripapillary Atrophy of Choroid of unusual character, shown by Mr. DONALD GYNN. There was a patch of atrophy around the O.D., the retina over the patch being raised, distended, and perfectly clear, with shining lines in it like a cracked ball of glass. (2) Specimen of an Eye lost after removal of a foreign body by the electro-magnet, shown by Mr. SPENCER WATSON. (3) Specimen of Papilloma of conjunctiva, shown by Mr. JESSON.

CO-OPERATIVE CARRIAGES—A number of medical practitioners in New York have formed a co-operative association for the care of horses, carriages, and harness. It is expected that by this means a considerable reduction in the expense of conducting a practice will be effected.

HUNTERIAN SOCIETY.

CHARLES J. SYMONDS, M.S., F.R.C.S., President, in the Chair.

Wednesday, December 11th, 1895.

TUBERCULOSIS OF THE CHOROID.

Dr. FRED. J. SMITH showed two specimens of tubercle of the choroid taken from a case tuberculous meningitis.

PERFORATION OF THE STOMACH.

Dr. COTMAN showed a specimen of perforating ulcer of the stomach, taken from a man aged 48.

The President spoke on some points in the diagnosis of the occurrence of perforation, and quoted some cases of correct and incorrect diagnosis within his own experience.

Dr. FRED. J. SMITH also spoke of the difficulties of diagnosis and advised operation (even exploratory) when perforation was diagnosed.

Mr. OPENSHAW said there was no difficulty in posterior perforations.

Dr. COTMAN replied.

RHEUMATOID ARTHRITIS.

Dr. JAS. H. SEQUIRA showed a specimen of rheumatoid arthritis taken from a dissecting room subject. The left shoulder-joint was affected and there was atrophy of the biceps muscle.

Dr. CAMPBELL McDONNELL discussed the relationship of rheumatism and rheumatoid arthritis, as did also Dr. GLOVAN LYON.

Dr. SEQUIRA replied.

SARCOMATOUS TUMOURS.

Mr. OPENSHAW showed (1) a solid and sarcomatous growth of the ovary, weighing 7 lbs. 7 ozs.; (2) a sarcoma of the kidney removed by operation from a man aged 24; it had only been growing five months, and weighed several pounds; (3) a myeloid sarcoma of the middle of the shaft of the femur for which he had performed amputation at the hip-joint by a method of his own.

In connection with Mr. Openshaw's second case, the President mentioned a large abdominal tumour which had existed more than six years without apparent increase or serious discomfort to the patient; he thought it was an adenoma of the suprarenal capsule, but had not been able to obtain a necropsy when the patient died of an intercurrent disease.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, METROPOLITAN BRANCH.

Tuesday, December 10th, 1895.

G. E. YARROW, M.D., in the Chair.

AN EPIDEMIC OF MILK TYPHOID.

Dr. SIDNEY DAVIES read a report of an epidemic of enteric fever at Plumstead distinctly traceable to a particular milk supply, although the actual source of the disease could not be discovered. The drains of the premises were very defective, the cowsheds dirty, and the business conducted in a slovenly manner. The water supply (that of the Kent Co.) was unimpeachable, but there was a filthy brick tank used for watering the cows and probably for washing the churns, since the same bacteria were found in it and in the milk, but the typhoid bacillus was not detected, and the cows were apparently healthy. But such negative evidence could not be set against the palpable fact that over 90 per cent. of the cases were proved to have used the milk of this dairy, and the proportion would probably have been even higher had there been any books kept, or better means for tracing the distribution. In the three preceding years the number of cases notified had been 22, 29, and 25, and 6 had been reported at intervals in the previous months of the present year, but in the week ending May 15th there were 25, and all but 1 having been traced to this dairy, an order for stopping the sale "within the district" under Sec. 71 of the Public Health (London) Act was obtained. The dairyman, however, defied and evaded the magistrate's order, sending his milk to the railway station, and alleging that he bought it there. A second conviction happily led to the breaking up his business, and the sale of

his stock, after which the epidemic began to decline, though caused probably of secondary origin continued to make their appearance up to the end of July. The weekly notifications from May 15th to June 30th were 25, 53, 39, 28, 19, 7, and 6; total, 177; besides 13 in July. Of the 177, no fewer than 159, or 90 per cent. were clearly connected with the same milk; 33 of these through a dairy in Woolwich, and there may have been many more among the customers in the latter district. Indeed, had the man been content to comply with the letter of the law and sent in his milk to places "out of the district" there is no knowing how far the mischief might have extended. Probably over 200 or 250 houses in Plumstead had the milk in question, but in 44 of 141 houses at which the carts called daily there were 65 cases. Of 49 houses in two streets supplied by this dairy 29 were invaded, but only 2 of the remaining 150, and these may have been casual consumers or secondarily infected. The occurrence within six weeks at a time when enteric fever is not usually prevalent of 177 cases, as against an annual average of 26, and over 90 per cent. of these being known to have been consumers of this particular milk leaves no room for doubt as to its cause. The lower case mortality of 15 per cent. as compared with that of 22 per cent. in previous years was probably due to the larger proportion of children attacked in an epidemic being supplied in a milk supply for that of persons under 20 years of age, and of those over 20 23.5 per cent. The second age and sex distribution, and mortality was as follows:

	Males	Females	Total	Deaths	Per cent. mortality
Under 5 years	15	11	26	2	7.0
5 to 10	15	26	41	4	10.0
10 to 20	20	34	54	5	9.0
20 to 40	18	29	45	9	20.0
Over 40	3	3	6	3	50.0
Totals	71	103	177	23	12.0

Of these, 64 were treated at home with 10 deaths, or 15 per cent., and 113 removed to hospitals with 13 deaths, or 11 per cent., a result doubtless owing to the greater care in diet, and contrasting with the higher hospital mortality observed in scarletina and diphtheria.

EDINBURGH OBSTETRICAL SOCIETY.

Wednesday, December 11th, 1895.

ALEXANDER BALLANTYNE, M.D., President, in the Chair.

SPECIMENS, ETC.

PROFESSOR A. R. SIMPSON showed Exomphalic and Anencephalic Fœtuses, also a Fœtus with irregular and defective development of the bones of the forearms.—Dr. FALKIN showed a new form of Safety-pin which locked by means of a simple mechanism.—Dr. F. W. N. HAULTAIN showed (1) Hematoma of the Ovary. (2) Hematosalpinx simulating Hydrocele of the Ovary.—Dr. J. W. BALLANTYNE showed photographs of a Dicephalic Fœtus, of a case of Congenital Elephantiasis, and of Spurious Hermaphroditism.

THE SO-CALLED "MITTELSCHMERZ."

Dr. HAULTAIN (for Dr. J. HALLIDAY CROOM) read a paper on this subject. The condition was first described by Valleix, and in our own country many years ago by Sir William Priestley, later by Fashender and Sorel. Dr. Croom gave notes of three cases that had come under his own care, in the first of which the intermenstrual pain began after a very severe attack of scarlet fever at the age of 14; in the second it began at the age of 30, was probably due to over-distension of the Fallopian tube with fluid, the pain being associated with the expulsion of that fluid; the third began about the age of 20, and appeared to be of the nature of intermittent hydrops tubæ profluentis, and was cured so far as known by removal of the appendages. The details of Priestley's four cases will be found in the BRITISH MEDICAL JOURNAL for 1872. The pre-

minent features were paroxysmal pain in the region of the ovary during the intermenstrual period, in some cases continuing up to the commencement of the flow, in others stopping before then. The normal menstrual flow was scanty, regular, and painless. Sorel's observations led him to state that *Mittelschmerz* bore a more definite relation to the commencement of the period which followed it than that which went before. Heinrich Fashender in 1876 gave full notes of a case in a woman of 24, where there was a midtime flow of mucus into the vagina; and gave as his view of causation a premature summation of nerve stimuli in the ovary, with the occurrence of ovulation. Anteflexion had been suggested as the cause of *Mittelschmerz*, but to this it had to be replied that anteflexion was not present in all cases, while if it were caused by anteflexion, *Mittelschmerz* would be much commoner than it was. The condition occurred under three different manifestations: (1) No external manifestation at all; (2) where the pain was associated with an escape of blood; (3) where the intermenstrual pain was associated with a clear discharge. In the first, probably ovulation and menstruation did not occur simultaneously, and thickening of the capsule of the ovary caused pain at dehiscence of the follicle. In the second group the slight flow was probably due to endometritis, and the pain to the passage of clots. In the third, the condition was almost certainly one of hydrops tubæ, reaching its full development at midtime. Some of course denied the existence of intermittent hydrops tubæ, and predicated a vaginal fistula communicating with the cyst. But either explanation was compatible with the view given.

The discussion which followed was taken part in by the PRESIDENT, Drs. A. R. SIMPSON and MILNE MURRAY (who gave particulars of two cases), Dr. J. W. BALLANTYNE, and others. All were agreed as to the importance and value of Dr. Croom's paper.

VIBURNUM PRUNIFOLIUM AND ITS VALUE IN THE TREATMENT OF DYSMENORRHOEA.

Dr. THEODORE SHERMAN read a paper on this subject. He detailed his investigations into the botany, chemistry, and pharmacology of the drug. He used the liquid extract evaporated down and given in capsules. This he had made by Mr. D. Middleton, of Edinburgh. The drug seemed to diminish reflex pain, to lower blood pressure, and to act as a uterine sedative. It was of great value in certain forms of dysmenorrhœa, in threatened abortions, etc.

Dr. WILLIAM CRAIG said he had for years maintained in his lectures its pre-eminent value in abortion, and had used it in his practice.

Professor A. R. SIMPSON said he had frequently used it with good effect in certain cases of early abortion, and in dysmenorrhœa of non-obstructive forms.

Dr. HAULTAIN thought it was a direct uterine sedative, and was of value in the first stage of labour, in after-pains, in dysmenorrhœa with clots, and in abortions where there was pain and a little hemorrhage.

The PRESIDENT and others also spoke, and Dr. SHERMAN replied.

A RARE FORM OF ABORTION: EXPULSION OF THE AMNIOTIC SAC, WITH RETENTION OF THE CHORION AND DECIDUA.

Dr. F. W. N. HAULTAIN, in his paper on this subject, showed three illustrative specimens. Case I. Amniotic sac of the size of a large orange, no embryo, cast off from a patient believed to be three months pregnant. The decidua and chorion were removed some days later for uterine hemorrhage. Case II. Amniotic sac of the size of a large goose-egg, containing embryo about the eighth week of development, granular *debris*, cast off from a patient supposed to be three and a half months pregnant; the decidua, with chorion attached, was removed seven weeks afterwards for symptoms of profuse constant watery discharge and irregular hemorrhages. Case III. Amniotic sac of the size of a turkey's egg, embryo about the eighth week of development, but he was unable to give a clinical history. These specimens were of interest on account of their want of description in popular midwifery works and the thus scanty knowledge of the possibility of the occurrence of such a form of abortion. The mechanism of production from the specimens shown undoubtedly pointed to: (1) Pre-existing disease and death of the embryo, with, in the first two cases, a continued increase

of liquor amnii. (2) Detachment of the amniotic sac from the chorion, thus forming an intrauterine foreign body, settling up uterine contraction by irritation. (3) Rupture of chorion with expulsion of the sac, the adherent chorion remaining attached to the still vascularised and healthy decidua. (4) Occasional continued growth of decidua lined by chorion. This when cast off forms a variety of the so-called carnosous mole, and accounts in many instances for the presumed absorption of the foetus so commonly met with in these moles. The condition was clinically interesting as showing how abortion might take place with a minimum of detachment of the decidua and thus a minimum of hemorrhage.

Professor A. R. SIMPSON, the President, Dr. J. W. BALLANTYNE, Dr. W. CHASE, and others took part in the discussion, and Dr. HAULTAIN briefly replied.

MIDLAND MEDICAL SOCIETY.

T. EDGAR UNDERHILL, M.D., President, in the Chair.

Wednesday, December 14th, 1895.

LEUCODERMIA.

Dr. MARRIS showed (for Dr. SIMON) a boy of 7, afflicted with leucoderma. He was one of ten children, and had always been weaker, mentally and physically, than the rest of the family. Twelve months ago his hair, which had been almost black, began to fall off in patches. As the hair grew again it was found to be pure white. At present the head was well covered with a growth of very soft white hair, except for a band about 2 inches broad reaching round the back of the head from ear to ear, which retained its original dark colour. Below this band the hair was again white. Scattered without symmetry over the body and limbs were patches of white skin, surrounded by a brown pigmentation fading gradually into the natural skin tint. The areas of white skin varied in size. The skin of the face was uniformly dark, contrasting markedly with the white hair. Under the microscope the hairs were seen to contain a few relics of the dark medulla. No deepening in colour of the nipples, and no pigmentation within the mouth.

SPECIMENS.

Mr. BARLING showed photographs of an unusual case of Syphiloderma, with hemorrhage centres to the individual patches.—Mr. HAMMOND SMITH showed a Knee-joint, with fracture of the outer head of the tibia extending into the joint. The cause was a fall of coal which produced a compound fracture of the leg, unconnected with that into the knee-joint. Large hemorrhage into the joint and indistinct crepitation led to the diagnosis of the outer fracture, and amputation through the lower part of the thigh.—Mr. BARLING showed a Sequestrum from a case of "Quiet Necrosis" in a man, aged 52, which in many ways simulated sarcoma of the femur. The necrosis followed double pneumonia some three months before, the swelling appearing during convalescence.—Dr. PEARSON showed a specimen illustrating Perforation of the After-coming head. The patient was a primipara, and when Dr. Pearson saw her attempts had been made, under chloroform, to deliver the head by traction on the body and by forceps. Pulsation in the cord had ceased some hours previously. The perforator was passed through the roof of the mouth, and after evacuation of the brain matter the head was delivered by traction on the body. Attention was drawn to the advantages offered by the roof of the mouth as a site for perforation of the after-coming head.—Dr. SNOW showed (1) the Gall Bladder and Ducts from a man aged 74 who died of senile asthenia. A few days before death jaundice set in with bilious urine; there was no pain, and the stools were dark in colour. After death the gall bladder was found full of gall stones, contracted, and fibrosed. The common bile duct was much dilated, and partially obstructed by a stone. The dilatation appeared of old date, but no history of any attack resembling hepatic colic could be obtained. (2) The stomach of a man aged 40 who, three years before death, had an extremely severe hæmatomesis, followed by pain but unaccompanied by signs of hepatic cirrhosis. The pain, at first paroxysmal and afterwards constant, persisted, and the case ran the clinical course of a pyloric cancer with dilated stomach, but no tumour was felt during life. He refused operative interference. At the necropsy a large flat ulcer, a crown piece in size, was found on the posterior

wall of the stomach, close to the pyloric aperture, which was narrowed by the hard raised edge of the ulcer. Microscopically no evidence of cancer could be found.—Dr. ROBERT showed a specimen of Dilated Duodenum from a case of peripheral neuritis.

EXHIBIT.

Mr. W. EDWIN BRADY showed a Portable Irrigator, the main feature of which was a bucket of sufficient size which was collapsible, in the manner of the well known drinking cup. The apparatus was very well made, there being absolutely no leakage, and the price was moderate.

VAGINAL CELLIOTOMY.

Mr. JOHN W. TAYLOR read a paper on Cases of Vaginal Celliotomy. A description was given of the operation, followed by a series of cases illustrating Mr. Taylor's experience of vaginal celliotomy as applied to vaginal fixation of the uterus, removal of the appendages, ignipuncture of the ovaries, and separation of pelvic adhesions. Mr. Taylor concluded his paper with a description of the part played by this operation in the practice of Professor Martin and Dr. Dührssen of Berlin, and drew attention to the important position which the operation was rapidly assuming, and to some of its more recent developments.

MANCHESTER MEDICAL SOCIETY.

F. A. SOUTHAM, M.B., F.R.C.S., President, in the Chair.

Wednesday, December 14th, 1895.

A CASE OF CHORDITIS TUBEROSA.

Dr. YONGE showed a case of "singers' nodes" of the vocal cords in a boy, aged 14, without history, and without symptoms except partial loss of the upper register in singing. The unusual features of the case were the absence of hoarseness or symptoms of laryngeal fatigue; the peculiar position of the nodes, which were situated about the centre of the cords instead of anterior to that point, and the absence of any history of laryngeal overstrain. The cords, in spite of being weighted, as it were, by the nodes, vibrated in a similar manner to healthy cords. This was proved by blowing indigo on to the cords, when the particles moved outwards in a curved line towards the ventricles during phonation, behaving in precisely the same manner in which, as Dr. Hodgkinson has shown, they do in the normal vibrating cord; the efficient vibration explained the absence of vocal impairment in the case.

PATHOGENESIS OF CANCER.

Mr. ROGER WILLIAMS remarked that for many years the microbic theory of cancer had been the order of the day. Inasmuch, however, as the cancer microbe had not yet been discovered, and as collateral indications of its existence were conspicuous only by their absence, he thought the time had now come for setting forth a rival theory, and that was the task to which he proposed to address himself. It was evident that out of the confusion of a transition period but two conceptions as to the origin of neoplasms had emerged, the one based on the cell theory and the other on the microbic theory. The question now was, Did cancers and other neoplasms arise, as J. Müller maintained, through a modification of the formative process, or were they the outcome of the inflammatory process, owing to the presence of microbes or other irritants *ab extra*? He inclined to the former alternative, and then discussed the various considerations favourable to this view, and the conclusion was reached that in most cases the outbreak of cancer was entirely spontaneous, and could not be attributed to the immediate action of any appreciable extrinsic cause whatever. In the genesis of neoplasms, as in the genesis of other organic structures, two factors had to be taken into consideration—the cells whence they originate, and the force that regulates the cellular activities. Lowly organised cells abounded in all parts growing and capable of growth, and these were the only real cancer and tumour germs. The essence of the neoplastic process was that certain cells of the affected part grew and multiplied more rapidly than their congeners, regardless of the requirements of the adjacent tissues and of the organism as a whole. The essential feature of malignancy was the persistence of this undue proliferative activity. The process by which cancers and

other neoplasms arose might be regarded as a kind of abnormal generation. Hence the genesis of cancer and other neoplasms was a phenomenon of the same order as discontinuous growth in general.

MALIGNANT ENDOCARDITIS.

Dr. DRACHFELD made a communication on the etiology of this disease. Of the organisms found some did not occur in other affections; others were well-known microbes, such as the staphylococci, streptococci, pneumococci. In some rare cases the typhoid bacillus, the bacillus of tuberculosis, the bacillus of diphtheria, and the gonococcus had been found. Of the predisposing causes, besides pyæmia and septicæmic diseases, the acute rymetic diseases, pneumonia, and chronic endocarditis. Dr. Drachfeld mentioned chorea, which in one case, without any previous endocarditis was associated with malignant endocarditis. A case was also referred to in which rupture of one of the aortic valves from overstrain was soon followed by malignant endocarditis. The season had also some influence on the occurrence of malignant endocarditis; several of the cases observed commenced during the months of September and October. Of the various clinical forms one was specially referred to in which the chief symptom besides the physical signs of endocarditis was an intermittent pyrexia, the temperature rising only a few degrees for several hours, and being soon succeeded by a normal temperature. The rise of temperature was ushered in by a sensation of cold or distinct chill and general malaise; during the afebrile period the patient felt comparatively well, and these cases often went on for months; they usually terminated fatally, but occasionally recovered. The examination of the blood during life, withdrawn by means of a syringe from a vein, often gave negative results on microscopic examination and on cultivation; occasionally, however, an organism—usually a streptococcus with virulent properties—was obtained. Large doses of quinine and the administration of arsenic appeared to give the best results. Several cases, with typical signs of malignant endocarditis—intermittent or remittent pyrexia, with evidences of embolism, etc.—recovered under this treatment.

TUBERCULOUS DISEASE OF THE MIDDLE EAR.

Dr. MILLIGAN commented on the insidious onset of tuberculous disease of the mucous membrane of the middle ear. The occurrence of a discharge from the mucous membrane of the middle ear, unaccompanied by pain or any of the usual symptoms of an acute ethenic inflammation, and the presence of a perforation in the centre of a pale, oedematous, and uninfamed membrana tympani, should always excite suspicion. The presence of enlarged cervical glands and the early appearance of facial paralysis were also important symptoms. Special reference was made to the occurrence of facial paralysis in these cases, and to its comparative rarity in non-tuberculous middle ear affections. In order definitely to establish the tuberculous nature of such cases, scrapings of portions of diseased bone, removed from the interior of the mastoid process, were taken and inoculated subcutaneously into guinea-pigs. In the course of from two to five weeks the animals were killed and scrapings from enlarged glands taken and examined for bacilli. Microscopic sections of liver and spleen were also made and examined. Of ten cases thus experimentally examined, eight proved to be tuberculous and two non-tuberculous. Great stress was laid upon ascertaining the essential character of the morbid affection, not only from the point of view of treatment, but also from that of prognosis. In tuberculous middle ear affections the prognosis was grave, and the younger the patient the graver the prognosis, thus differing very materially from simple inflammatory non-tuberculous cases when the prognosis was good. Free removal of all diseased foci of bone should be undertaken, and in general to effect this it would be found necessary to open the mastoid cells. Good food, tonics, and fresh air were essentials in the treatment. The paper was illustrated by lantern slides, microscopic sections, and dissections of guinea-pigs.

MEDICAL MAGISTRATES.—The names of Inspector Bames, R.N., of Harlesden, and Dr. J. S. Brockstedt, of Bessendbury, have been added to the Commission of the Peace for the county of Middlesex.

BRITISH GYNÆCOLOGICAL SOCIETY.—At a meeting on December 12th, Dr. CLEMENT GODSON, President, in the chair, Dr. SMYLY (Dublin) showed the following specimens: (1) Pyosalpinx removed by Vaginal Colpotomy; (2) three Myomatous Uteri removed *per vaginam* by morcellation; (3) Ectopic Gestation operated on at term. All the patients recovered. Dr. BANTOCK hoped that Dr. Smyly did not advocate colpotomy for all cases of pyosalpinx; in many it would be almost impossible to get good results by that method. In support of this statement Dr. Bantock related cases operated on by laparotomy where the complications could not have been dealt with *per vaginam*. With regard to the vaginal operation for fibroids, he did not think it was so good as the abdominal. He considered it most important that the integrity of the pelvic floor should be preserved, even if the uterus were represented only by the cervix. Compared to this, the prolongation of convalescence by one or two weeks was of little importance. Drs. HAYWOOD SMITH and ROUTH also discussed the question. Dr. SMYLY replied that the rule that had guided him was the selection of the operation which seemed best for the patient; he held it wrong to perform a new operation for any other consideration. Many cases of pyosalpinx were rendered unsuitable for colpotomy by fixation of the uterus, for it was most necessary for this operation that the uterus should be capable of being drawn down. Briefly the principal advantages of vaginal over abdominal operations were: First, the risk of hernia was obviated; secondly, convalescence was shorter; thirdly and chiefly, the shock of operation was much less, and results were proportionately more favourable.—Mr. WILLIAM ARMSTRONG, J.P., of Buxton, read a paper on Utero-Ovarian Irritation as a Factor in the Causation of Rheumatoid Arthritis, and the special treatment necessitated thereby. After some remarks by the President, Dr. LEITH NAPIER said Dr. Halliday Croom had pointed out some years ago the association of inherited rheumatism with a type of dysmenorrhœa, which he was the first to call rheumatic. It was possible for rheumatism to remain long latent, and to break out when uterine disturbance occurred, as in a case he had seen where the patient got an attack of acute rheumatism in two successive puerperal periods, remaining well in the interval. Dr. ELDER (Nottingham) said that all the facts mentioned by Mr. Armstrong were consistent with the view that rheumatoid arthritis was neither the cause nor the effect of uterine disorder, but that both were alike effects of a common cause. The paper was also discussed by Dr. ROUTH and Dr. FORTESCUE FOX; and Mr. ARMSTRONG replied.

SOUTH-WEST LONDON MEDICAL SOCIETY.—A clinical meeting of this Society was held at the Town Hall, Wandsworth, on December 11th, Dr. GILBERT RICHARDSON in the chair.—Mr. THOS. S. HOWELL read notes of a case of Hydronephrosis in which the obstruction in the ureter was believed to have originated in a strain at the age of 13; the patient died suddenly from hæmorrhage into the sac at the age of 41.—Mr. PERCY POPE read notes of (1) Five Cases of Lightning Stroke occurring simultaneously, and (2) a large quantity of Morphine taken subcutaneously with suicidal intent.—Mr. M. G. BRAGGS read notes of a case of Septic Pneumonia.—Mr. A. E. DONSON made some remarks on the Treatment of Incised Wounds, advocating the avoidance of the use of water in surgical incisions.—Mr. JOHN GAY showed a patient who had received a Gunshot Wound above the Right Elbow, causing extensive laceration of the tissues and severance of the musculo-spiral nerve. The healing of the wound was followed by complete loss of power in the forearm, which was entirely restored by a ten months' course of massage.—Dr. A. D. ROX showed a case of Mitral Disease in a boy.—Dr. M. MACINTOSH showed a case of Empyema in a boy, which had been entirely cured by one aspiration.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY (Clinical Evening).—At a meeting on Friday, December 6th, Dr. SYMONS ECOLLE, President, in the chair, Dr. RYEMOUR TAYLOR showed (1) a man, aged 30, with Symmetrical Prooping of the Pinna, which might, he suggested, be an instance of maternal impression, the mother having been frightened by a rat when four months pregnant. (2) A woman presenting the

classical signs of Myxœdema; the thyroid body was enlarged, though probably dystrophic. He believed that, as in the partial case of disease of the adrenals, any actual disorganization of the thyroid body would produce myxœdema. (3) A woman with the usual signs of Myxœdema, except that she was remarkably pallid, and was without the usual circumscribed bluish on the cheeks. He believed that there existed a distinct variety of pallid cases. In this case there was no albuminuria or evidence of cardio-vascular changes.—Dr. DOMOX remarked that in one of his cases there had been albuminuria, which disappeared under the thyroid treatment.—Mr. BIDWELL showed a case of Sclerosis of the Superior Maxilla in a woman, aged 52. A molar tooth was extracted, and since then the swelling had greatly decreased, thus showing that it was not an osteoma. There was no evidence of syphilis or acromegaly.—Mr. MCADAM ECCLES showed (for Mr. PAGET) a case of Resection of the Elbow for compound fracture of the humerus.—Mr. BIDWELL said that when possible resection should not be performed in these cases, since a stronger joint thus resulted.—Dr. PARDON showed (for Dr. GARNON) a case of White Spot on the Heart in a patient, aged 45, who had complained only of shortness of breath and pain in the chest. There was a loud systolic rub or *bruit*, most intense to the left of the sternum in the third intercostal space, heard faintly at the base, not conducted to the angle of the scapula, and varying with respiration. The area of cardiac dulness was not increased. There was no history of rheumatism, syphilis, or scarlatina, and the pulse was normal.—Mr. KENTLEY showed a boy on whom he had operated for Radical Cure of Hernia with Undescended Testis by bringing the organ into the scrotum and fixing it there by suture to the adjacent tissues of the thigh.—Mr. MCADAM ECCLES showed a girl, aged 13, with at least Twenty-three Exostoses. There was a history of rheumatism, but none of syphilis. The mental condition had not been noted. Dr. SHUTTLEWORTH quoted the case of a boy thus afflicted who was imbecile, and a girl who was mentally defective.—Dr. ALDERSON showed a case of Rodent or Epitheliomatous Ulcer on the Nose of a man, aged 60. There had first been a wart, which had been treated with caustics. He believed the ulcer to be epitheliomatous. Mr. BIDWELL concurred in the diagnosis, and advised operation under cocaine. Mr. MCADAM ECCLES thought it was rodent ulcer owing to its history, its slow growth, and the non-involvement of glands. He suggested ethyl chloride as a local anæsthetic. Mr. KENTLEY believed the case to be probably one of rodent ulcer. Dr. PORTER held that rodent ulcer was an early stage of epithelioma.

CARDIFF MEDICAL SOCIETY.—At an ordinary meeting on December 6th, Alderman EDGAR JONES, M.D., President, in the chair, Dr. PATERSON showed three cases of Graves's Disease, in none of which was there either exophthalmos or von Graefe's sign. Dr. C. T. VACHELL thought the slight thyroid enlargement was of a simple nature, and the accelerated pulse due to a neurotic temperament. Dr. JOHN WILLIAMS spoke, and Dr. PATERSON replied.—Mr. J. LYNN THOMAS showed (1) Scirrhus of Male Breast, the size of an orange. (2) Vermiform Appendix recently amputated after the seventh attack of typhilitis. Patient doing well. (3) Calculus *lævis* removed from the Left Kidney, the chief symptoms being hæmaturia and extreme irritability of the bladder, the location of the mischief being differentiated by the cystoscope. Eighteen months after the nephrolithotomy the patient's health and urine were normal. (4) Calculus weighing 6 drachms suprapubically removed from a girl aged 9 years. (5) Alternating Calculus weighing 6 ounces 6 drachms removed by the combined perineal and suprapubic methods. The combined method greatly facilitated the removal of the large stone. Dr. HERBERT VACHELL remarked on the rarity of scirrhus of male breast, he having seen only one in the practice of the late Dr. John Wood. Dr. COOK had seen a calculus in a young girl, and Mr. RUTH GRIFFITHS made remarks and showed two Calculi removed by lateral hysterotomy.—Dr. STAWART (Bridgend) read a paper on the Increase of General Paralysis in England and Wales. He treated the subject chiefly from the statistical standpoint, and showed in which grades of society and sex the increase

took place.—The library and the other rooms have recently been newly furnished at much expense. The membership numbers eighty.

REVIEWS.

THE PHYSIOLOGY OF THE CARBO-HYDRATES: AN EPICRITICISM. By F. W. PAVY, M.D., LL.D., F.R.S., F.R.C.P., Consulting Physician to Guy's Hospital, etc. London: J. and A. Churchill. 1895. (Cr. 8vo, pp. 162. 3s. 6d.)

It will be remembered that Dr. PAVY devoted his Croonian Lectures to the record of a series of experiments, extending over many years and involving a prodigious amount of work, as to the physiology of the carbo-hydrates and the exposition of certain conclusions to which he had been led by them on this subject. Subsequently his experiments and deductions were more fully stated and expounded in a volume entitled *The Physiology of the Carbo-hydrates*, published last year. His views, it will be remembered, were of a somewhat revolutionary kind, being directed to nothing less than the overthrow of the glyco-genic doctrine, which, since it was enunciated by Claude Bernard, has held undisputed sway in textbooks of physiology. The conclusions were of such fundamental importance, affecting not only the pathology of diabetes, but also the whole theory of nutrition, and were based upon a course of investigation so painstaking and elaborate, that we felt bound at the time to devote much space to laying them before our readers. It was to be expected, and, indeed, to be desired, that these views should be closely and thoroughly criticised both by physiologists and physicians. Dr. Noel Paton, in consequence of a statement contained in a paper by him published in the *Philosophical Transactions*, to the effect that Dr. Pavy's theory rested on an unsubstantial basis, and had been completely refuted by the work of Seegen and others, was under some obligation to take up the gauntlet which Dr. Pavy had thrown down. This he did in the *Edinburgh Medical Journal* for December, 1894, and some astonishment must have been felt by those who read this article at the extremely unsubstantial grounds on which Dr. Pavy's lifelong labours were curtly condemned as "unsubstantial." The volume before us is a very elaborate reply by Dr. Pavy. In it every point appears to have been taken up, and it will be admitted that Dr. Pavy makes out a very strong case. At any rate, he succeeds in showing that much of the evidence upon which Dr. Paton relies is not capable of supporting the very sweeping conclusions which he seeks to base upon it.

Dr. Pavy's main contention is, to quote his own words, "that the chemical changes taking place in connection with life result in building up on the one hand and breaking down on the other. The building up is effected by the synthesising power possessed by living protoplasm. Protoplasmic power is the term applied to it. The breaking down is a process effected by ferment action, and different ferments break down in different ways. For instance, as I have suggested, the proteid molecule built up by the synthesising influence of protoplasmic action from carbonhydrate and nitrogenous matter may be subsequently broken down by ferment action of different kinds, with the liberation it may be of glycogen, it may be of sugar, or it may be of fat. There is nothing chemically inconsistent, indeed on the contrary, with the proposition that carbonhydrate may enter the molecule and fat be cleaved off."

Dr. Paton himself says in one place that "it is now universally admitted, on the evidence of the formation of glycogen from proteids, that in the laboratory of living protoplasm carbo-hydrates may be formed from proteids," but he wishes Dr. Pavy's analytical evidence to be rejected mainly on the ground that Dr. Pavy has not given an elementary analysis. Dr. Pavy meets this by here producing the results of special analyses made for him by Mr. Ling, which fully confirm Dr. Pavy's contention founded on other analytical data. Sugar is present in the blood, but, according to Dr. Pavy, it is there as a constitutional ingredient just as it is present in other, and perhaps in all, the organs of the body. The quantity of sugar in the urine is for him an exact index of

the amount of sugar in the blood. The glycogenic doctrine requires that there should be a considerable portage of sugar by the blood from the liver, where it is said to be manufactured to the tissues, where it must be used to meet the functional requirements of the organs; of any such transfer the urine would give evidence, since the increase in the urinary sugar required by the theory does not take place the transfer, Dr. Pavy contends, cannot take place. The carbohydrate stuff is charioted by the blood not as such, but as a constituent part of a complex proteid molecule. Q.E.D.

There can be no doubt that Dr. Pavy's theory is very fascinating in its simplicity and completeness. We shall hope at an early date to have an opportunity of discussing some of its bearings more fully. Meanwhile, we have said enough to show that this *Espritisme* has intrinsic merits which render it worthy of perusal. Dr. Pavy is a vehement controversialist, and we cannot but regret some of the expressions of which, in the heat of a very natural indignation, he makes use. But we shall not dwell on this side of the question, nor shall we enter into a discussion of his complaint against the officials of the Royal Society, which is set out in a preface to this volume. We gather that it is admitted that an irregularity did occur in the manner in which Dr. Pavy's paper was accepted for insertion in the *Philosophical Transactions*, but the President and Council of the Society have expressed their regret that the statement to which we have referred at the beginning of this notice should have been published, and the matter may well be allowed to rest there, now that Dr. Pavy has taken steps to vindicate his views from the rather cavalier treatment which they met with at the hands of Dr. Paton.

LECTURES ON AUTO-INTOXICATION IN DISEASE, OR SELF-POISONING OF THE INDIVIDUAL. By CH. BOUCHARD, Professor of Pathology and Therapeutics, Member of the Academy of Medicine, and Physician to the Hospitals, Paris. Translated, with a Preface, by THOMAS OLIVER, M.A., M.D., F.R.C.P., Professor of Physiology, University of Durham; Physician to the Royal Infirmary, Newcastle-upon-Tyne; etc. Philadelphia: The F. A. Davis Co. London: F. J. Rehman. 1891. (Demy 8vo, pp. 318, 10s.).

DR. OLIVER is to be congratulated on introducing to the English-speaking medical profession Professor BOUCHARD'S *Lectures on Auto-Intoxication*. The busy general practitioner is, as a rule, unable to follow the rapid advances of medical science, partly, no doubt, because the researches are frequently too technical or are incomplete, and partly because, leading so practical a life, he is apt to subordinate everything to the acquisition of means of immediately relieving the patients under his charge. Professor Bouchard holds a distinguished place in medical science, and has, moreover, the faculty of expressing his views in language to be understood by everyone.

In the extremely able preface which Dr. Oliver has placed before the translation of the lectures under consideration, he shows in a succinct and very lucid manner the importance of the study of auto-intoxication. This term is perhaps not strictly scientific, since it includes two very different processes, or rather two processes which have not yet been sufficiently discussed to be classified together. One of these processes is the self-poisoning which may occur by means of the retention in the body of certain poisonous products of tissue change; and the other is the self-poisoning resulting from the bacterial decomposition of food in the gastro-intestinal tract. In the latter case the question is simply one of the absorption of poisons which are formed outside the tissues, that is, in the alimentary tract; in the former case the poisonous substances formed by the tissues are retained in the body.

It is not necessary to follow Professor Bouchard into all the details he has brought forward, perhaps somewhat egotistically; but no one who reads these lectures can but be struck by the fact of the great practical importance of the subject with which they deal. The part of the work which deals with the toxicity of urine and with the toxic condition

known as uræmia, is one in which, as Dr. Oliver says in his preface, Professor Bouchard is at his best; and although, from the experimental point of view, the account is incomplete, the suggestiveness of the lectures is to be highly commended. With uræmia every practical medical man has to deal, and our knowledge of it is so deficient that the clear statement of fact to be found in Bouchard's work is of great value. But little need be said concerning auto-intoxication from the gastro-intestinal tract: the subject is treated in the same manner as that of uræmia, and with highly suggestive conclusions, since the great need of disinfection of the intestine in many conditions is clearly shown. Professor Bouchard's lectures, excellent as they are, deal only partially with a wide subject; but they are worthy of study by everyone interested in practical medicine.

As knowledge progresses the question of auto-intoxication will have to be considered in its relation to that of the "internal secretion" of the normal glands of the body, a subject which was clearly dealt with by Professor Schöler in his address before the Association at the annual meeting; and it may, in the future, be decided how far many cases of "auto-intoxication" are really cases of the stoppage of a normal internal secretion which is essential to the well-being of the body.

In conclusion, Dr. Oliver's translation of Professor Bouchard's work is to be heartily recommended to the medical public.

FONCTIONNEMENT DE LA MAISON D'ACCOUCHEMENTS PAU-LOGUE ANNÉE 1894. [Report of the Baudelocque Lying-in Hospital for the year 1894.] Paris: G. Steinheil. 1895. (4to, pp. 100).

In the preface to the annual report for 1894 of the Baudelocque Clinic, Professor Pinard states that since 1872 the mortality of lying-in cases under his care has constantly diminished until in the year 1894 the total mortality was 7 out of 2,117 women who were delivered or miscarried (34 cases). Under natural labour, with a normal pelvis and presentation of the vertex, there were delivered 732 primiparæ and 1,014 multiparæ. Two of the children of the primiparæ died during the act of birth, but none of the children of the multiparæ. After the birth, 20 children of primiparæ and 21 of multiparæ succumbed. Under spontaneous labour with contracted pelvis (that is, diagonal conjugate of 11 inches or less) and head presentation, 21 primiparæ and 49 multiparæ were delivered, and the 70 children all left the institution alive with the exception of 1 multiparæ which died on the second day of double meningeal hemorrhage. Presentation of the face was met with 4 times (2 multiparæ, 2 primiparæ); all the mothers recovered, 1 child died (fracture of skull by forceps).

Breech or footling presentation occurred in 42 cases (21 primiparæ, 21 multiparæ); of these, 6 cases had contracted pelvis, and two of these children succumbed; 35 (27 had normal pelvis, and 2 of the children died; all the mothers recovered).

There were 8 cases of presentation of the shoulder, with 3 dead children (1 macerated, 1 from basiotripsy, and 1 died during extraction); all the mothers recovered.

The forceps was used in cases of normal pelvis 20 times in primiparæ, with the result of the death of one child; 4 times in multiparæ, with the result of 3 living children. The forceps appears to have been employed in no case of contracted pelvis, symphysiotomy having taken its place. During the year there were 21 symphysiotomies (12 primiparæ with 1 maternal and 1 fetal death, 9 multiparæ with 1 maternal and 1 fetal death).

Basiotripsy was performed 7 times (always on dead children and with success as to mothers). There was 1 case of Perro's operation for contracted pelvis, successful to mother and child. Premature labour was induced in 3 cases, with recovery of the mothers and of 2 children. The indications were in one case hemorrhage and in the other two a grave cardiac condition in the mother; the operation was not performed for contracted pelvis. There were 4 cases of extrauterine gestation: 1 of these died before operation, the other 3 were operated upon with success (1 by vaginal section, 2 by abdominal section and "marsupialisation").

Artificial delivery of the placenta (that is, introduction of the hand into the uterus to remove the placenta, whether separated or not) occurred in 34 cases (19 primiparae, 15 multiparae); of these women 1 died. The indication for the artificial delivery of the placenta was usually hemorrhage; 4 cases only required it on account of failure of the placenta to separate.

Twenty-two women (9 primiparae, 13 multiparae) were delivered of twins; amongst these was an interesting case of both twins presenting by the face. Eleven fetuses were deformed. Ophthalmia occurred in 38 cases; this was treated in the first three-quarters of the year by irrigation with solution of carbolic acid and emulsion with nitrate of silver; in the last quarter of the year by solution of permanganate of potash; in no case did corneal opacity occur. Nine patients (8 primiparae, 1 multipara) suffered from eclampsia. Of these, 1 who was attacked during pregnancy recovered; of 5 in whom the attack occurred during labour, 1 died; both of the patients attacked after labour recovered. Six of the children survived. The treatment employed was the administration of chloroform and ether, inhalation of oxygen, and injection of artificial serum where there was a tendency to anæmia.

The report ends with a full account of the fatal cases and with statistical tables, including one of the gynecological operations performed in the clinic; of these there were 36, with 3 deaths.

THE SCHOTT METHODS OF TREATMENT OF CHRONIC DISEASES OF THE HEART. Illustrated. By W. BRILL THORNE, M.D., M.R.C.P. London: J. and A. Churchill, 1895. (Roy. 8vo, pp. 79. 5s.)

This book contains an account of the physical treatment of cardiac disease introduced by the brothers Schott, of Nauheim, which has recently been the subject of a long correspondence in our columns. The first and second chapters are devoted to a short description of Nauheim and its baths. In the third chapter the results of the therapeutic movements on the pulse and heart are given and an attempt made to explain them. The exercises are limited in the Schott treatment to movements against resistance, this resistance being interposed by the "operator," or in some instances by the patient himself. The next chapter is an important one, since it deals with the special conditions for which the Schott treatment is available. As regards heart disease, all chronic cases are subjected to the treatment except those with marked disease of the endocardium or advanced disease of vessels. Diseases due to the uric acid diathesis, asthma, etc., also, it is stated, derive benefit. In Chapter v the series of regular exercises are described, with illustrations. These exercises are never pushed to the extent of producing dyspnoea, palpitation, or fatigue. The last chapter contains illustrations of the benefits obtained.

There can be no question that if the Schott treatment can accomplish all that is claimed for it, it should become one of the recognised modes of treatment; at all events, it deserves a more extended trial than it has yet obtained. One of the striking facts is, according to those who recommend this treatment, the diminution of the cardiac dulness produced by it. It is admitted that the whole of the gain is not permanent, but the dulness does not relapse to its former dimensions. This is one of the subjects raised by many of those who took part in the recent correspondence in the *JOURNAL*, and as will have been seen no explanation which is entirely satisfactory can be given. This book explains in a lucid fashion the main features of the Schott treatment so as to enable the reader to carry it out for himself.

STATISTIK DER INFECTIÖSEN ERKRANKUNGEN IN DEN JAHREN 1881-1891, UND UNTERSUCHUNG DES EINFLUSSES DER WETTERUNG. [Statistics of Infectious Diseases in the Years 1881-1891, and an Examination of the Influence of the Weather.] Von JOSEF KÖRÖSI, Director des Communal-Sanitäts-Bureau (Buda-Pesth). Berlin: Pottkammer und Mühlbrecht, (8vo, pp. 141; 5 tables. 4½ M.)

STATISTICS OF THE MORTALITY FROM INFECTIOUS DISEASES IN ANY locality, if founded upon the returns from a sufficiently large

population, are always valuable, and in the hands of such a man as M. Körösi may be trusted. In spite of the evil reputation for mendacity which statistics have earned, to give some instructive information. Since June 1st, 1891, compulsory notification has been in force in Buda-Pesth for small-pox, scarlatina, croup, diphtheria, measles, typhoid fever, cholera, and cholerae. The notification regulations require particulars to be given as to the number of other residents in the house in which the patient was attacked, the number of children, whether the patient, if a child, attended school, and if so what school, and the number of other children in the house of school age, and the school they attended. The first striking fact brought out is the enormous increase in the number of notifications of diphtheria, which rose from 53 in 1885 to 2,439 in 1891. Increased accuracy in diagnosis cannot be invoked to explain this increase, since the number of notifications of croup rose in the same period from 126 to 422. Even when some allowance is made for a greater thoroughness of the operations of the notification law, the figures appear to prove conclusively that Buda-Pesth has been no exception to the rule that during recent years diphtheria has become increasingly prevalent, especially among town populations. Epidemics of measles and scarlet fever recurred at irregular intervals, and there was no distinct evidence of any diminution in their extent and severity; but small-pox has been almost abolished, and the number of cases of typhoid fever as well as their mortality has shown a decided tendency to diminish. The marked diminution in the number of cases and deaths from small-pox M. Körösi attributes to the increased efficiency of vaccination, dating from 1887. In the previous year there had been a considerable epidemic. The mortality from measles was per 10,000 living—in 1881-83, 7.0; in 1884-86, 13.7; in 1887-89, 2.7; in 1890-92, 0.0.

It would be impossible to follow M. Körösi through all the interesting disquisitions of the statistics, but we may remark that he gives some very striking figures to show that measles is a "school disease." In nine out of the eleven years under consideration a measles epidemic broke out, or was very largely increased, soon after the opening of the schools, and in every one of the eleven years measles ceased to prevail shortly after the closing of the schools. A minute examination of the dates of opening, which varied in certain years, is held very strongly to confirm this conclusion that school conditions favoured the spread of measles. The long incubation period of measles renders it necessary to make special allowances at the beginning of the school term before drawing final conclusions; but even the gross figures are sufficiently striking. Adding together the figures for the eleven years, M. Körösi finds that during the last school quarter 3,664 cases of measles were noticed; in the first school quarter, 11,865; in the second school quarter, 13,263; and in the third school quarter, 13,147.

NOTES ON BOOKS.

The Bacteriological Test of the Purity of Water.—By R. H. HANKIN, M.A. (Agra: Star Press Artillery Bazaar, 1895. Demy 8vo, pp. 22. 8 annas.)—This is a pamphlet urging the small utility of chemical tests of the purity of water, and giving very simple and complete directions for applying what may be called the quantitative bacteriological test. The directions will prove invaluable to those who have only a limited knowledge of manipulation, and are sufficient to enable any waterworks engineer to safely take the necessary sample and sow his tubes. The chief value of the publication is, however, in the incidental expression of those opinions, which the author's unusually minute experience of water examination has led him to adopt. Professor Hankin emphasises the extreme delicacy of the slime film on which the efficiency of waterworks sand filtration depends, and demands the separate examination of the water from each filter bed, a precaution which it is not laborious to take, and one which adds greatly to the value of the *primæ faciæ* quantitative test. He also deduces the conclusion, already well established by independent research, that the use of sand and similar material in domestic filters is at the best worth-

less, and mentions instances in which it has led to the actual contamination of otherwise pure water by serving as a breeding ground for microbes. The Pasteur Chamberland filter will, if introduced into barracks, jails, and other establishments in India, do much to remedy this evil. The pamphlet does not deal with the qualitative examination of organisms, which is of course desirable as soon as the appearance of an epidemic or the quantitative test has thrown suspicion on any water supply.

A Textbook on the Science and Art of Bread Making, including the Chemistry and Analytical and Practical Testing of Wheat, Flour, and other Materials employed in Baking. By WILLIAM JAGO, F.I.C., F.C.S. (London: Simpkin, Marshall, Hamilton, Kent, and Co., Limited. 1895.)—In this book the scientific as well as the mechanical aspect of bread making is fully considered, and the author gives, in addition to his own researches, the views held by other recognised authorities. The latter part of the book, consisting of seven chapters, contains a useful description of a thoroughly practical character of the analytical processes for the commercial testing of wheats and flours, the estimation of the constituents of bread, and the detection of adulteration. The whole book is very clearly arranged, and is illustrated with fourteen large plates and a number of woodcuts. It should not only prove of value to those directly engaged in bread making, but is likely to be useful, partly on account of the many tabulated results of investigation, to any who have to deal with the scientific side of the subject.

REPORTS AND ANALYSES

AND

DESCRIPTIONS OF NEW INVENTIONS

IN MEDICINE, SURGERY, DIETETICS, AND THE ALLIED SCIENCES.

THE ANTITOXIN TREATMENT OF DIPHTHERIA.

Messrs. BURROUGHS AND WELLCOME (Snow Hill Buildings, London, E.C.) issue a chart for recording on a uniform system the results of the treatment of diphtheria with antitoxic serum. It is issued in two sizes, the larger being 14 inches long and 6 inches wide. Space is afforded for noting the important points in the patient's condition before and for four days after injection. There is also a temperature chart and space for notes as to complications. The smaller chart is constructed on the same plan. Messrs. Burroughs and Wellcome ask us to state that in order to minimise the difficulty of adjusting the dose in various cases and at various ages they have adopted the Behring unit system of estimation, and the serum is now supplied by them, either dry or liquid, in phials or tubes containing an adult therapeutic dose of exactly 600 units.

A TWO-HEADED MONSTER (PLEUROPAGUS).

On February 25th, 1894, Dr. Griffiths, of Carlton, Melbourne, was called to attend a poor woman in labour. The pains were feeble, and the patient was nervous and anxious. A foot was felt and brought down with gentle traction, and presently the second foot was caught, and very quickly the pelvis and lower half of the child was delivered. Up to this time everything pointed to the swift and safe delivery of a living child at full term. The arms were delivered folded across the chest, and Dr. Griffiths then endeavoured to find the mouth with his finger, but failed, owing to the firm contraction of the uterus.

Assistance was now obtained and chloroform administered, but the difficulty of delivering still continued. With very great trouble a hand was forced in between the head and neck and tightly contracted uterus. Chloroform was now suspended, for though the woman lost no blood she was in a very alarming condition of prostration and weakness. Another medical man was now called in, but before his arrival at 6.30 p.m., the woman became collapsed and expired unde-

livered, the legs of the fetus dangling between the thighs of the mother.

Permission being obtained from the husband, Dr. Griffiths made a post-mortem examination. He found that the child had two perfectly-formed heads and necks springing from the one thorax.

The child was a female, and the body below perfectly formed in every respect. The heads were perfectly symmetrical and well shaped, and, as can be seen by the photographs, which were taken by Mr. Herbert Hewlett, the head on the right side is more in the mid-line. The chest is wider than usual, and there are two spinal columns converging at the sacrum. The photographs will explain the cause of the impossible delivery, for the greater the pull downwards the more the heads became impacted at the brim. The mother was a healthy, industrious woman, and had previously given birth to seven children.

Mr. Hamilton Russell, F.R.C.S., undertook the dissection of the fetus, but had to discontinue it owing to objections made by the father. As far as the examination went, he found two oesophagi opening into one stomach, from which one duodenum led away. The rest of the canal was normal. Two aortae were found leading away from one left ventricle, but the distribution of the branches and the terminations of the main trunk were not ascertained.

A case very similar to this is reported by Dr. Tinley in the BRITISH MEDICAL JOURNAL of February 2nd, 1889, page 240 (illustrated).

The obstetrical aspect of Dr. Griffiths's case is interesting. Large monsters often cause great anxiety to the medical attendant, especially when the labour proceeds easily at first. In arrested head after a footling presentation the odds that a second head causes the difficulty are so small that the possibility of the existence of monstrosity is very naturally overlooked. When one head presents, as in Dr. Tinley's case, the true state of affairs is detected much earlier and with little difficulty.

Teratologically Dr. Griffiths's monster was most probably a

"pleuropagus" or "dicephalus bispinalis." As Mr. Lowne classifies the variety in the College of Surgeons' Catalogue, pleuropagus is distinguished by having "two axes adherent side by side. Such abnormal twins have hitherto been called dicephalus, from their external resemblance to dichotomous conditions of the anterior extremity of the axis.

In these forms, however, the whole axis is double. They are transitional between anterior dichotomy—bifurcation of the axis at the anterior (in animals) or upper (in man) extremity, double head and shoulders, in fact—"and emprothozygosis" (union face to face above the umbilicus, the well-known "xiphopagus" and "thoracopagus," according to degree of union). "The median limbs are frequently fused together, and are sometimes reduced to mere tubercles."

In Dr. Griffiths's case there were "two spinal columns converging at the sacrum," which was probably more or less double. The upper and lower extremities on the median aspect were suppressed—a feature in true pleuropagus. In Dr. Tinley's case one fetus had an arm on the median axis, as the first illustration in his report will show. It was probably another example of pleuropagus. In dicephalus proper the axis is more completely double down to the point of union of the two vertical columns. Pleuropagus is the usual, if not constant, variety of two-headed monster in man, whilst dicephalus is common in cattle. In the same way scordiacus ascephalus, or headless twin, is common in man, whilst pteroccephalus, or single fetus with the head not developed, seems unknown in man, though not rare in calves.

PRESENTATION.—Mr. John Band, F.R.C.S., of Dulwich, has been presented by his friends and patients with his portrait, as a mark of their appreciation and esteem, on the occasion of his retirement from practice.

A new children's hospital, with accommodation for sixty patients, has recently been opened in St. Petersburg. The hospital, which owes its creation largely to the initiative of Madame E. von Wahl, wife of the mayor of the Russian capital, is intended for the reception of chronic cases.

REPORTS

ON

THE NURSING AND ADMINISTRATION OF IRISH WORKHOUSES AND INFIRMARIES.

SPECIAL COMMISSION OF THE "BRITISH MEDICAL JOURNAL."

XII.—OMAGH WORKHOUSE INFIRMARY, CO. TYRONE.

OUR visit to this house was, unfortunately, made during the absence of the medical officer (Dr. Fleming), but the master and matron courteously gave us every assistance for the purposes of this inquiry. The house is of medium size, standing at a little distance from the town. As we entered the gates it was pleasant to see an old man enjoying a rest on a sheltered seat in the drive. This is the first time that such an indulgence has come before us.

THE HOSPITAL DEPARTMENT

has overflowed into the house, where a male and a female ward on the first floor in the infirm wings have been set apart for the use of the chronic cases. The male ward had 9 patients, and the female ward 12. Some of these appeared to be feeble minded, but not of the lunatic class. In the hospital the 34 beds are generally full. The hospital wards occupied the two floors, the nurses' quarters being in the middle of the block. Besides the adult wards there is a small room for children, holding 8 beds; here we found three little ones, all out of bed, under the care of a wardswoman. They were retained in this division on account of delicacy, which unfitted them for the rougher life of the schoolroom. The lying-in ward is on the first floor, holding 8 beds, which were empty. We were struck with the cleanliness of the room.

IN THE WARDS

there is a painted wooden dado, except in the male ward on the first floor; the top of this dado forms a shelf, and there are besides bracket shelves between the beds, on which we saw fancy mugs and cups, evidently personal property. Most of the beds are the "harrow" frames with straw pillows and ticks; there are a few wire-wove mattresses scattered about the wards. The merits of straw as bedding are an open question; much may be said for and against it, and a good deal depends on how the tick is filled and how often the straw is changed; but there can be no doubt as to the unsuitability of narrow wooden frames (2 feet 3 inches by 6 feet), without sides, for use in a hospital ward. The windows are on one side only, the north, and there are small slits in the opposite wall. Some of the bed heads were across the window, and in winter the imperfect frames admit more weather than is suitable for a sick ward. As the grates, one to each ward, are of the old style, the wards in winter must be cold and draughty. There are no day rooms, and the wards were decidedly crowded. We saw no bed cards. The flags on the ground floor wards are covered with coconut matting; a strip of the same material is laid down the middle of the upper wards, and also on the landings.

THE LUNATICS

are placed as usual at each end of the hospital block; their quarters are decidedly superior to those provided in many other houses; the cells have been entirely removed; the ceilings are boarded; one room is used as a day room and the other as a dormitory. The walls are coloured, and there is an endeavour by means of pictures and such adornments to make the surroundings cheerful. The patients looked clean and had a brighter aspect than many we have seen. There is an attendant on each side, not trained, or paid, except by rations and extras. There were seven men and eleven women in these divisions.

SYSTEM OF NURSING.

There is one nurse to take charge of six wards in the hospital and two large wards in the body of the house, these

latter being in a distinct building at some distance from the hospital. This nurse is not trained, and her assistants on the female side are the unfortunate women detained with their children in the house; and on the male side, the nearest approach to a decent able-bodied pauper who can be found in the house. As Dr. Fleming says in his report, the selection "has to be made from material damaged mentally, morally, physically, or in all three ways combined." There is no night nurse, nor are there any bells placing the wards in communication with the officials.

IN JUSTICE TO THE NURSE

we would note that her wards were clean, her patients and their bedding appeared to be clean, and certain slight details betokened respectability for the patients; mugs and cups showed individual possession; the crenelery for the service was not only pretty but bright and clean. In the absence of Dr. Fleming, we asked no questions as to the various diseases of the patients under treatment; several, perhaps about half, were in bed; among these were the chronic and helpless cases and feeble patients; winter increases the number of admissions and the severity of the cases. It is therefore evident that though the nurse is capable her hands are overfull, and hence the nursing is not as good as it might be. At this point we cannot do better than refer our readers to Dr. Fleming's exhaustive report published in the *Tyrene Standard* of September 21st, 1895.

THE INFIRM WINGS

having been invaded by the patients from the hospital, the infirm class are placed not only in one of the ground-floor wards, but some of the women are on the second floor, these wards holding 27 and 22 beds respectively. We saw some of these old women in bed, the matron telling us that she did not enforce the rising of the old people every day if they seemed unfit for the exertion. The old men and women looked clean and neat in their persons and clothing, and the wards also were clean and tidy. The only light came from a window at either end; stoves were used for heating the wards; there was need of more armchairs for the use of the old people. The beds are the harrow frame, with straw ticks and pillows. A wider frame would make these beds much more comfortable. The men have a day room; that for the women is taken for

THE NURSERY.

This room is of the same size and shape as the infirm ward; the long low-pitched room, with a window at each end, one fireplace, and a door leading into the female infirm ward, is difficult to warm in winter, and rarely bright and sunny in summer. This department has successfully resisted the civilising influences brought to bear on the other parts of the house. There were six dirty, untidy, uncared-for infants with their mothers; the air was close, the cradles filled with straw contributing their unsavoury odour to the atmosphere. We saw no apparatus for washing or bathing the infants, nothing but the slatternly women with their dirty children. An inmate may have been responsible, but she was evidently unable to exercise control. The house has made

NO ADVANCE IN SANITATION.

The sick wards, infirm wards, lunatic wards have no indoor conveniences; pails and buckets placed in the wards are all the provision made, which is neither decent nor sanitary; these must remain in the locked wards all night. There is no service of water in the hospital, and therefore no baths or means of giving such. We saw a washstand and basin in each ward of the hospital, and also in the infirm wards, but these offer a poor substitute for the generous supply of hot and cold water in a properly constructed lavatory, and for the bath.

RECOMMENDATIONS.

There were many points in the management of this house which betokened humane and enlightened care for the inmates on the part of the guardians and their officials, but no amount of thoughtfulness will correct the evils of an antiquated building, or supplement the services of an overworked nurse, and it is to these two points that we would direct the attention of the guardians. The nursing of the sick is carried out under the disadvantage of the patients

being located in widely separated wards; and when we add that the only nurse has only pauper assistance of a doubtful kind, it is clear that the work cannot be done efficiently. Then the sanitary arrangements add to instead of saving the labour of the staff, and, worked at their best, are unsatisfactory from all points of view. We most heartily endorse every word of the report which Dr. Fleming has placed before his Board, and we would add our suggestions that the nursing staff be increased by at least a second nurse by day and by a trained nurse by night; that bells or some other means of communication from the hospital and wards be contrived with the lodge and the master's quarters; that the whole of the sanitary system be overhauled with the intention of bringing it up to date. It would be found a more satisfactory method of working to place all the sick under one roof. Lastly, the infants should be placed under the charge of one nurse, the mothers having access to them at stated hours.

THE MODE OF ELECTION OF POOR-LAW OFFICIALS.

DR. RICHARD H. LESPER (Rathfriland, co. Wicklow) writes: "The attention of the public being now directed to the Irish workhouses—mainly through your active endeavours to improve these institutions—I venture to think the present moment not an inopportune time in stating some of my ideas with regard to the working of the Poor Law in this country."

First, I wish to ask any who really understand the Poor-law system if they consider that system can ever be made perfect in its working so long as the present mode of election of officials to Poor-law appointments is adhered to. I say it cannot. From the election of a medical officer or clerk of a union to that of the most subordinate of officials, is not the open canvassing, the modes of voting, and the election generally too often but a scene of envy, hatred, and malice, and all uncharitableness, undignified and unbecoming to our profession, alike to electors and elected, and most hurtful to the efficient working of the Poor-law system? If information is needed by the unlearned in these proceedings, let such a one attend a Poor-law election, or read the *Carmincham* prize essay, written by Dr. Lushan some years ago, which truthfully describes these matters. The writer clearly and with no sparing hand exposes this foul usage; but alas! the Legislature and the public seem too careless or too unwilling to apply the sorely-needed canter of reformation to effect its cure.

Improve a workhouse as you will so that you can improve no more. Allow the existing staff to be perfect and the working of the institution be without fault. Now suppose a vacancy to occur in the staff, supposing an unsuitable person be elected, will not such a man appointment undo all your good work for years? A drunken master or immoral matron, or untrained and unsympathetic nurse of course might be elected under the most perfect of election systems, but is not such an appointment far more likely to be made when an election is a mere party affair, a political trick, or a job to oblige a friend of some enemy? Why cannot the candidate for election to a Poor-law appointment enter the service by examination, with some hope held out to him of advancement when once there? When will experience, knowledge, and ability be the means by which men hope to gain these appointments? Take for example the post of sub-station officer. Would will these posts be filled by reason of the applicants' knowledge of the rudiments of sanitation and the laws of public health and not by reason of the knowledge by the local guardians, their feelings, politics, or religion? The microbes of disease have no politics, and their religion is the destruction of men.

In improving the workhouses we are opposed by guardians on grounds of expense. "It is all a matter of money," we are told. "Have the guardians ever thought how much money is yearly wasted by their own carelessness? How many paupers are now in Irish workhouses whose families could be made to pay for their maintenance, or at least contribute towards it? How many lunatics are in Irish asylums whose relations (often well-to-do farmers) place them in pauper asylums where they are 'kept for nothing.' I myself know of many such a case, and am of opinion that if the guardians were to carefully sift every case in their unions much relief would be given to the rates. And even a money saved which might profitably be expended in modernising the union infirmaries and rendering them suitable for their purpose. Lastly, when we have night nursing, proper cooking, and well-managed institutions, we shall still want good sound legislation to enable us to prevent the children of the vagrant being reared as vagrants. We shall want authority to send the dangerous lunatics to asylums, an authority which is now denied us by law. We shall want a law to enable us to drive out from our workhouses the idle and professional pauper who uses the union as a tourist does a hotel."

OVERCROWDING IN LONDON.—In spite of the provisions made in the Public Health (London) Act, 1891, respecting overcrowding, there is still much overcrowding in the more central districts of London. The best and most natural cure for the evil is that workmen should live farther from the centre, but before this can take place to any great extent there must be cheap means of locomotion from the central districts where the work is done to less crowded neighbourhoods. Efforts are again to be made to obtain improved services of cheap workmen's trains, and to see that the Cheap Trains Act, 1883, is more effectually enforced. The Government will also be asked to deal with the matter.

BRITISH MEDICAL ASSOCIATION. SUBSCRIPTIONS FOR 1895.

Subscriptions to the Association for 1895 became due on January 1st; and notice is hereby given, in accordance with By-law 5, that Branch Secretaries' subscription accounts close on October 31st, and all unpaid subscriptions must be forwarded after that date to the General Secretary, 429, Strand, London. Post-office orders should be made payable at the General Post Office, London.

British Medical Journal.

SATURDAY, DECEMBER 21st, 1895.

WANTED, A PILOT.

MEANS, we understand, are being taken to convince the Lord President of the Council of the extreme weakness of the arguments on which he relies to defend his policy of doing nothing in the matter of a University for London. Whether they will meet with much success we greatly doubt. Seldom in our experience has a great subject been dealt with by a responsible statesman in so cavalier a manner as the Duke of Devonshire dealt with this question in his interview with Professor Ramsay's Committee on November 28th. The agencies of higher education disorganised and stunted in the centre of the British Empire; the training of English medical men being driven from England to the sister kingdoms; the greatest city the world has ever seen without the intellectual advantages which a dozen petty capitals in Germany possess—these were the topics tendered for his Grace's consideration. They were topics which might have been expected to move the most phlegmatic of Ministers to interest; they were topics which at least merited sympathetic consideration of the means proposed as remedies. But the Duke of Devonshire apparently cares for none of these things. Scarcely a word does he vouchsafe to the real merits of the question. The University of London itself, the London medical schools for whose purposes it was originally founded, every important educational interest in the locality from which it takes its name, desire a change in its constitution. The Duke replies that there are persons holding degrees of the University who object to the reform. It is pointed out that the authorised Convocation of Graduates has twice deliberated on and approved the proposed reorganisation; the Duke retorts that the members who have not deliberated seem not to be convinced on the point. Men of European distinction urge that the objections of such members have been weighed by a Royal Commission of singular strength and ability, and found to be baseless. His Grace in return quotes from an anonymous paper which, he says, some unnamed person has placed in his hands, and which he gravely proceeds to commend to the consideration of the leading educational authorities of the metropolis. It is needless to argue; there are some country graduates who object; *res locution, causa finita*. Rudderless London must wait, tossing helplessly on the sea; the pilot declines to put forth in the face of an expected storm.

But if any thing could excuse the attitude taken up by the Lord President, it would be the singular ineptitude of the

manner in which this great question was brought before him. The lack of *savoir faire* which characterised the London University movement from the outset unhappily attended it still. If the Duke failed to understand that a great public question was awaiting his action, it is fair to say that his petitioners had taken but little trouble to convince him of the fact; if he treated the matter as one of institutional and sectional interests mainly, it is but just to point out that hardly any but institutional and sectional interests were represented before him.

Eleven years of failure seem to have taught the movers in this question no lesson in the conduct of public business. It is not in the interests of London colleges and their teachers that we should ask for the reorganisation of this State Examining Board as a real university, but for the benefit of the people of London for whom these colleges were founded. It is not for the profit of the medical schools of London that we must ask Parliament to ignore, if necessary, the obstructive privileges of Convocation, but for the good of the profession that is to be trained in them and the advantage of the public for whom the profession exists. But where in the deputation of last month was the profession of medicine, apart from the colleges and schools, and where was the public of London? Where was the Lord Lieutenant? Where the Lord Mayor? Where the Chairman of the County Council? and where the metropolitan members? Where—it is not purposeless to ask—was the British Medical Association?

It is vain in these democratic days to expect statesmen to legislate at the voice of the "superior person," unless some broadly felt public need be at the same time shown them as justification; but for all that appeared in the deputation headed by Lord Kelvin, neither the London public nor the medical profession might ever even have heard of the matter at issue.

We are not writing for the sake of blaming, but in the earnest hope that the persons and institutions concerned in this business will at last learn an elementary lesson in public affairs, and will understand, when next an approach is made to Government in the matter, that if they wish to succeed they must treat public questions as matters of public interest, and go with an assured and obvious body of public opinion at their back. We say "when next an approach is made," for on one thing all are agreed, that matters cannot be left as they stand at present.

That Professor Ramsay's Committee will succeed in inducing the Lord President to change his attitude to Lord Cowper's scheme, as we have said above, we greatly doubt; nor do we build much on the prospect held out of an arrangement with the recalcitrant members of Convocation. But on the other hand we have never shared either in the extravagant admiration expressed in some quarters for Lord Cowper's scheme, or in the counsels of despair heard in others which represented it as a sort of Hobson's choice for despised London to take or leave, without hope of any alternative. If the labours of the Graham Commission are after all to go for nothing, the time has clearly come to revive in some modified and improved form the original Graham project for a genuine metropolitan university by the side of the titular University of London. The Government which declines to take in hand the Royal Commissioners' scheme cannot in circumstances refuse a charter to carry out the only

alternative solution of the question; and to such an alternative, indeed, the Duke of Devonshire's remarks seemed, albeit obscurely, to point.

MEDICINE AND SOCIETY.

We can scarcely congratulate Dr. Burney Yeo upon the article which he has contributed to the current *Nineteenth Century* on the above subject. It seems an unwise thing to publish such matter in a lay journal unless the contents be far more thoroughly digested and more lucidly presented than in the article before us. We are by no means too rigorous in our demands. We are far from saying that medical men shall never write on medical matters for the public; but we think that such communications should fall within two categories: either the articles should deal with matter which has reached a certain stage of definition in the eyes of those best able to judge—as in the case, let us say, of protective inoculations, or of serum therapeutics, which have reached a point of definition that enables us to set them before the layman greatly to his interest; or again with matter which pertains to the domain of individual opinion. But when, as in the latter case, a medical man betakes himself to the public, with views of his own, he enters upon a serious affair, and he is bound to present the subject in a manner which if it do not silence the learned reader, shall command his respect.

Now Dr. Yeo's article seems to us to lay itself open to much dissent, both in respect of matter and form. It seems to us loose both in style and in thought. To prove this judgment in this place would take up more room than we can spare. Some points of dissent, however, we will indicate. Dr. Yeo utters, with less than ordinary point, some of the stock arguments against "extreme specialisation." When we enter upon the context we find that Dr. Yeo does not mean by these words that which they express, but rather that the specialist, however "extreme," should keep himself abreast with the general knowledge of his subject—surely a very different proposition. Anyone who has thought carefully on modern scientific progress has satisfied himself that this progress depends upon "extreme specialisation," or what, in our dislike of such an ugly word, we should call accurate research.

That society is beginning to "resent the increased costliness of medical and surgical help," if true, is not Dr. Yeo's fault, unless, indeed, he encourage an ungrateful public. We are happy to think, however, that as compared with the law for instance, the leaders of public opinion regard the members of our profession as kindly and moderate in their demands. Many reasonable people think, indeed, that the fees of leading physicians are too low to secure good work from men so busy. That some adventurers prey upon the public is true; it has always been true; yet we are disposed to say, if these persons be as rapacious as ever, that they are not so ignorant and mischievous as in former times. Nevertheless, they are adventurers still, and not to be taken as examples of our ranks.

Dr. Yeo is very oracular on the subject of medical etiquette. Now, we are not sure that we disagree with him in some of his words on this head; that is, if we were ever sure of his meaning, or that he had thought out what he would say. But when Dr. Yeo proclaims that medical

etiquette is "common sense, good faith, gentlemanlike feeling," and so forth, we think he is confounding the raw material with the finished product. If we were all agreed about such qualities, and agreed to act accordingly, medical etiquette would be unnecessary, and indeed many of the laws on the statute book likewise. Dr. Yeo's methods would make our relations to each other a matter of individual taste. All laws, whether of professions or of nations, leave plenty of room for common sense and good taste. For instance, in the story of Dr. Yeo's letter, written to the medical attendant of a patient without that patient's knowledge, we conceive that the indignant patient was right, not because Dr. Yeo wrote to his doctor, but because he did so without the patient's permission, and even without his knowledge.

Dr. Yeo compares our too reticent manners and customs with those of the Bar, whose members permit and desire the publication of their names in the journals. The Bar may take care of itself; meanwhile we deny the parallel. The advocate succeeds or fails absolutely in the face of the world; from his public form there is no appeal. That advocate is the best who wins his case, or who makes a good fight for it, under the control of certain well-understood rules. There is no appeal from the obvious results. Is this so with our profession? Surely it is rather the reverse. Our successes are known only to our brethren and to our advanced pupils, our loyalties to others only to ourselves; the estimate of the public, except in a very remote sense, is worth little. Again Dr. Yeo, taunting us with inconsistency, says that we are keen enough in advertising after our own fashion, and that our fashion is "intraprofessional advertising," a process the author denounces as much the same thing as public advertising.

That medical men write books, some bad and some good, for their own advantage with professional readers is true; but it is mere paradox to say that books written for skilled critics, who can judge with more or less certainty of the value of their contents, are in the same position as such books or other publications addressed to the general public. It is a droll thing to compare us to our disadvantage in this respect with the Bar, seeing that in the latter profession the custom of writing a book or books for the edification of the solicitor is almost invariable among men who would rise; books, that is, which are never supposed to pay directly, and are written avowedly, as with us, to show what the author is made of: no improper purpose, perhaps, in either profession. The thing surely is in a nutshell: in most callings a man advertises that which can be more or less immediately tested, and bad wares or blundering and ignorant counsel, if not found out at once, can be recognised in no long time.

In medicine the tests are far more difficult, while unfortunately the issues are far graver; not one patient only, but a generation of patients, may be fleeced, maimed, or killed, and their medical attendants stabbed in the back, before the world can discover the incompetence or bad faith of the pretender. Hence it is that our profession is the paradise of the quack and the unscrupulous practitioner, and will always be so; and hence it is that we must present a stern countenance to all semblance of selfishness, even if, in the sight of thoughtless people, we appear prudish and self-righteous. If the "tact" which Dr. Yeo wishes to see in us is to result in the kind of canning which gives the

point to some of his illustrative anecdotes, we earnestly hope the time is far off when such "tact" is to take the place not only of self-respect, but also of "etiquette."

THE PERILS OF RIGHT DOING.

We have long felt, and have oftentimes expressed, the need for a total change in the organisation of our system of appointments of medical officers of health. It has now for a long time been held that the system whereby a local health body can appoint and reappoint again and again at will any properly qualified medical man for one year and for one year only is wrong in principle; yet the matter continues to-day in precisely the same position as it has now for so many years occupied. No sanitary authority is in the position of being forced to appoint their health officer for a longer period than one year. Granted that many have done so, even to the extent of making the appointment one for life, yet these are a comparatively small minority; and we may safely assume that such appointments have been made for districts that have some pretension to advancement in the direction of sanitary completeness. This is precisely the main difficulty. Were it those districts which can boast of a desire, borne out by results, to benefit by the best advice of their medical adviser, which had elected to abide by an annually repeated election, the system might be defended; but when we see districts wherein sanitation is of the crudest, and where even the elements of sanitation have been ignored, when we see these localities clinging to the antiquated form of annual appointments for their health officers, then it is that we see also the danger that threatens the officer who dares to confront his Council with the true state of the district under his care.

In illustration of our point, we may say that we have received from Dr. Churchouse, the late medical officer of health of the Daventry rural district, a copy of the correspondence which he has recently had with the Local Government Board on the subject of his supersession in his post by the election recently of another medical man in his place. Dr. Churchouse has held the post for ten years, having been elected annually without opposition. But he has had to report very strongly on the insanitary condition of two of the twenty-seven parishes in his district—namely, Long Buckby and Weedon. These two places seem to be without the simple elements of sewerage and adequate and wholesome water supply. The state of the wells in the former place is specially deplorable, that of the public wells being equally bad with those of a private nature, as shown recently by the results of the analyses by Professor Atfield. This notion, says Dr. Churchouse, has incurred the odium of several of his councillors, and he has been ousted from his position. Thus is sanitary rectitude repaid. Yet here are 7,500 people living under conditions of gross insanitation, with absence of proper sewerage, with cesspools leaky and foul, with no system for the disposal without nuisance of their excrement, and with a condemned water supply which may at any moment give rise to disease. Indeed, Dr. Churchouse shows typhoid fever to have been during several years past unusually prevalent, and of the 367 notifications under the compulsory system in the whole of the twenty-seven parishes in the period 1890-94, no many as 111 have been in Long Buckby alone. We are further told that one of the medical inspectors of the Local Government Board

found grave fault with the state of the two parishes in question in 1893; and yet in these circumstances the local authority got rid of their health officer after ten years' faithful service.

If the circumstances be as here stated, we sincerely hope that the matter may receive reconsideration, and that the year of office of the present holder may merely be a break in the otherwise permanent tenure by Dr. Churchouse of the office of medical officer of health. People on all hands nowadays say a good deal concerning the benefits of decentralisation, but we have ever felt that no sanitary official is safe so long as his tenure of office depends on the caprice of a few councillors, or the packing of a committee, or the desire of a health authority to see a minimum of real commensurate with the nominal sum doled out as a salary. What we contend for is that sanitary officers shall be appointed by, and hold office subject to the control of, a responsible but not local body, a body that is free from the prejudices and narrowness of a purely district council. Not until we see the sanitary staff of our country placed on a permanent basis, free from the trammels of local petty government, and independent enough to be in a position to give advice founded on true statement—not until then shall we see that progress in matters sanitary in England which is needed in only too many of its areas of local jurisdiction.

The Albert Lévy prize, of the value of £2,000 sterling, has been awarded by the Academy of Medicine to Dr. Behring, of Berlin, and Roux, Sub-Director of the Pasteur Institute in Paris, for their discovery of the means of curing diphtheria.

Dr. L. A. A. DE VERTEUIL, the President of the Trinidad and Tobago Branch of the British Medical Association, has been created a K.C.M.G. Dr. Verteuil is about 85 years of age, and has practised his profession in the town of Port of Spain for over fifty years. He was an unofficial member of the Legislative Council for nearly thirty years, and only resigned this year on account of old age. He is an M.D. of Paris.

ANTI-CHOLERA INOCULATIONS IN CALCUTTA.

We learn with satisfaction that the Calcutta Municipality has, with wise liberality, decided that Dr. Haffkine's anti-cholera inoculation experiments are to be continued there for another year, and have assigned a grant of 7,500 rupees for the purpose.

THE PURIFICATION OF SEWAGE.

At a sessional meeting of the Sanitary Institute held at the Parkes Museum, Margaret Street, W., on Wednesday, December 11th, Sir Benjamin Baker, K.C.M.G., LL.D., F.R.S., in the chair, Sir Douglas Galton, K.C.B., LL.D., F.R.S., read a paper on The Lessons to be Learned from the Experimental Investigations by the State Board of Health of Massachusetts upon the Purification of Sewage. After dealing with the various systems of sewage filtration, he described the systems devised for the aeration of the filters, dealing more particularly with experiments made by Colonel Waring at Newport. He summed up the conclusions to which the various experiments lead as follows: (1) The suspended matters of sewers (sludge) can be mechanically withheld by straining slowly through suitable material. (2) The filth accumulated by this straining material can be destroyed, and the straining medium restored to a clean condition by mere aeration. (3) The successive alternate operations of fouling and cleansing

can be carried on indefinitely without renewal of the straining material. (4) The purification obtained by this straining process practically equals that accomplished by chemical precipitation, and is sufficient to admit of discharge into any considerable body of water not used as a source of domestic supply or for manufacturing purposes requiring great purity. (5) Such filters can be maintained in constant and efficient operation by suitable abrasion. (6) The erection of a plant capable of purifying large volumes of sewage upon a relatively small area calls for no costly construction. Repairs and renewals are merely nominal. The attendance required is but slight. There is no outlay for chemicals, etc. The only expense of mechanical operation is the driving of the blower or air compressor. (7) The process admits of wide variation in the selection of filtering material, and nearly every community can find, in its local resources, something suitable for the purpose.

RABIES.

THE Board of Agriculture has, for some time now, been busying itself in regard to stopping the increase of rabies round about London. The counties of Middlesex and Surrey, and the boroughs of Richmond, Kingston, and Guildford have passed muzzling orders, and London has likewise been asked to do so. Upon careful inquiries it is found that, although the cases in 1895 show a great increase on the figures of the years 1890-94, they are less than one-half the number in 1889, when all dogs in London had to be muzzled. Measures are being taken to watch the progress of the disease, and instructions have been given that the carcasses of all dogs slaughtered as suspected of rabies, except those certified by the veterinary inspectors not to have been rabid, are to be sent to the Brown Institution for investigation. Until it is found to be greatly on the increase the London County Council will not reimpose the muzzling regulations, which, by the way, have been altered by the order issued last February. The provisions of the new order include the examination of rabid or suspected dogs, the isolation of suspected dogs, the slaughter of rabid dogs and the destruction of their carcasses, and the disinfection of premises on which they have been kept. In addition, it gives power to local authorities to make regulations (a) for the muzzling of dogs, and (b) for the seizure, detention, and disposal of unmuzzled dogs. London dogs may therefore rejoice in perfect freedom on their walks, at all events, for a while longer.

PHOTOGRAPHY OF RETINAL IMPRESSIONS.

AN article of much interest, by Mr. W. Inglis Rogers, appeared in the *Amateur Photographer* of November 22nd, 1895, under the startling heading "Psychography or Photography without a Camera. The Dawn of a New Science." Although written in a style which savours more of cheap sensation than science, with a profusion of italics and capitals, the article is one which deserves careful study, and is in many respects suggestive. The essential part of it is the record of experiments by the author, the first more or less accidental, the succeeding two premeditated and deliberate. By psychography, the writer means an impression upon a sensitive plate of an image formed upon the human retina and thence projected on to the gelatine surface. His endeavours to supply a theory which will explain the phenomena he has observed have led him beyond his depth in the sea of cerebral physiology and chemistry. This portion of the article is however of minor importance. The record of the experiments is briefly as follows: The first deliberate experiment was performed in his own "dark room," and without assistance; the next took place at the house of a friend, a medical man, and in the presence and with the help of the medical man and two other gentlemen. A small object, in one case a shilling, in the other a postage stamp, was placed in a good light before the writer, who gazed fixedly at it for one minute; the light was then shut off, and the test object re-

placed by a rapid photographic plate, at which the author looked steadily for a period (in the second experiment) of twenty minutes, concentrating his thoughts meanwhile wholly upon the image of the object he had been previously fixing. During the substitution of the plate for the last object, the observer's eyes were closed. The plate was then developed in the ordinary way, and reproductions of the psychograms are given in the journal. In the first case, in which a shilling was the test object, the print shows an ill-defined circle on the plate, and in the second, when a postage stamp was employed (and a larger plate used than before) "two impressions were obtained, one from each eye, and at respectively the same distance from each other as the eyes." These impressions (in the reproduction) bear a distinct resemblance to a postage stamp; more than this we cannot at present admit. These experiments, or similar experiments, can be carried out by anyone with a little assistance. The subject is one which merits most careful and thorough investigation, and by such research alone can we determine whether or no Mr. Rogers's sanguine expectations in regard to his discovery are likely to be realised. When his observations have been confirmed it will be time enough to formulate an hypothesis in explanation of the phenomena described by him. Those who are interested in the subject from the psychological, physiological, or photographic side should read Mr. Rogers's account of his experiments, the *bona fide* character of which has been vouched for by the three gentlemen who witnessed them.

STATUE TO A GERMAN DOCTOR IN TOKIO.

THE ceremony of unveiling a statue of the late Dr. Müller in the grounds of the Imperial University took place recently. Dr. Müller was the first German Professor at the Tokio Medical College, the embryo of the present College of Medicine in the Imperial University. He came to Japan in 1871, when few even among the Japanese Professors of the College could speak German. In spite of serious difficulties he patiently laboured to impart his knowledge to his students, and thus laid the foundation of modern medicine in Japan. Hearing of his death in January, 1891, his former pupils—including Surgeon-General Dr. Ishiguro, Professors Miyake, Taguchi, and Aldachi, and a large number of well-known Japanese—decided to erect a bronze statue of their esteemed master in the compound of the University. The work has been executed by Mr. Fujita Bunzo, the sculptor who earned a reputation by casting the statue of Dr. Aoyama. The statue represents the German Professor in his military uniform.

THE SOCIETY OF MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE Committee of the Society of Members of the Royal College of Surgeons of England has put out a very ably written and moderately worded paper, containing a statement of the propositions made by the Society of Members for the amendment of the charters of the College. The first proposition is that no alterations in the constitution and external relations of the College should be effected without the consent of the corporation convened to discuss such alterations. The second proposition is to the effect that a statutory annual meeting should be held to which the Council should present a report and an audited financial statement, the report to be submitted to the approval of the meeting and formally adopted by it. The remaining proposition deals with the admission of members to the Council. It is proposed that the number of the Council should be raised to thirty-two, eight of the members of Council to be Members of the College, and elected by the Members. The Society has dropped the proposal that those Members who were also Fellows should be ineligible to be elected to represent the Members on the Council, and the proviso that no Member should be eligible until he has attained twenty years' standing is retained. The Society

points to the fact that a petition embodying similar proposals was in 1888 signed by nearly 5,000 Members proves that its proposals have met with substantial support among the Members, though at the same time it is admitted that there is much apathy and want of interest among Members in all matters relating to the College, owing, as the Society believe, to the past attitude of the Council towards the Members. The Society urges further that if the Council still have any doubt as to the sentiments of the Members it should take steps to ascertain the facts by a direct communication addressed to every Member. The point to which most weight is attached by the Society is the proposal to provide for the direct representation of the Members on the Council. Were it adopted the Council would be rendered representative of the whole body. This wider basis would increase the authority with which the Council could act in all matters affecting the Members, especially in ethical questions. "We hope," the Committee write, "to see in the near future not only increased activity in dealing with 'infamous conduct' in our own body, but that powers will be obtained by the College to suppress unqualified practice in surgery, these powers having been sadly needed for many years." The honorary secretary of the Society is Mr. W. G. Dakin, M.R.C.S., Southfields, S.W.

M.D.U.S.A.

Mr. FERNAND, of King's Road, Chelsea, whose conviction under the Medical Act we reported last week, has lodged an appeal to the next General Quarter Sessions of the Peace to be holden at Clerkenwell, and has entered into the required sureties. We shall watch the result with interest.

WATERBORNE TYPHOID AT DUNBAR.

THE epidemic of waterborne typhoid fever at Dunbar and in its immediate neighbourhood shows little sign of abatement. There are stated to be no fewer than eighty cases, and there have been a good many deaths. The Shore Hall and the Bath Hospital are both full of patients, and on application to the military authorities the New Inn Barracks Hospital has been placed at the disposal of the local authority. The opinion grows that the Pathhead cases and the consequent contamination of one of the sources of the water supply are the most probable causes of the epidemic. We are unable to say why the result of the water analysis should so long remain a mystery. Mysteries and delays in such matters as public health tend to no good end. It is said that the fierce light of public criticism may tend to cause a panic, but even if this were true publicity is invaluable later as compelling a greater alertness on the part of the local authorities. In many country districts it must be freely admitted that the policy is mainly one of indolent drift, to be interrupted only in the presence of grave catastrophe.

THE FEVER HOSPITAL DIFFICULTY.

HARDLY a morning passes without our table being littered over with complaints about the conduct of the Metropolitan Asylums Board. Yet we find their officials working well, we find no shirking of work, we certainly find no hesitation in spending money, and the more one sees of the work which is being done at Norfolk House every day the more is one convinced that it is not the officials who are to blame, but the system. The fact is the Metropolitan Asylums Board have never been able to throw off the taint of their pauper origin, and although they are doing great things for the value the public have no rights in the matter. Nevertheless, we can hardly doubt that if the Metropolitan Asylums Board had not existed the metropolitan sanitary authorities would long ago have been driven to provide hospital accommodation for their ratepayers. Where to look for a way out of the impasse it is difficult to say. What is certain is that the real root of the trouble lies in the divorce which has taken place between the work of the sani-

tary authorities and the management of the infectious diseases of the metropolis. In the meantime grave questions arise as to how far the point of view from which the Asylums Board regard the treatment of their patients is the right one. We have every admiration for what we may term a counsel of perfection, and if on the one hand there were plenty of beds, and if on the other London was not stuffed full of infection, we would gladly see patients kept in hospital even for a very long time so as to be quite free from infection on their return home, but under existing circumstances we doubt whether any sanitary authority which had thrown upon it the whole responsibility of dealing to the best of its power with an epidemic of scarlet fever, would, in presence of the present lack of beds, keep its patients in hospital so long as the Asylums Board do theirs, namely, on an average ten weeks, for during half of this period, while they are running about practically well, they are still occupying beds, to the exclusion of other children, who are being refused admission every day although acutely ill, and often actually dying for want of hospital treatment. The Asylums Board is concerned for the credit of the hospital system, but the public not unnaturally demands that the greatest good should be done to the greatest number. It is to be noted, moreover, that this aiming at perfection for the few seems not only to be a characteristic of the whole Board, but to affect the different committees. It is not easy otherwise to explain the reluctance of the Board to open the Gore Farm Hospital for the use of scarlet fever convalescents. Evidently, even within the Board, there is a strong feeling in favour of such a step, which would at once put over 700 beds at their disposal for the use of fever cases, and one can only imagine that the small-pox interest, if one may so call it, is sufficiently strong to keep these beds to itself in view of a possible extension of small-pox in London. Again we do not say that they are wrong from their point of view, but this point of view does not seem to be the practical one which would be adopted by any single sanitary authority trying to use its limited means to the best advantage in defending itself against the onslaughts of epidemic disease.

LECTURES AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE Arris and Gale Lectures before the Royal College of Surgeons of England by Dr. E. H. Starling on the Physiological Factors involved in the causation of Dropsy will be delivered on February 17th, 19th, and 21st. Mr. Leonard K. Hill's lectures on Cerebral Pressure and the Cerebral Circulation will be delivered on February 24th, 26th, and 28th. The course of lectures by Professor Charles Stewart on the Integumentary System, its Structure and Functions, will be delivered on March 2nd, 4th, 6th, 8th, 11th, and 13th. The Erasmus Wilson Lectures on the General Pathology of Bone will be given by Mr. W. G. Spencer, F.R.C.S., on March 16th, 18th, and 20th. The lectures by Dr. J. A. Condit on Infantile Syphilis will be given on March 23rd, 25th, and 27th. All the lectures will commence at 5 p.m. on the days mentioned.

LEITH V. EDINBURGH.

THE Leith Dean of Guild Court, on December 16th, gave judgment dismissing the petition by the Edinburgh Corporation for warrant to erect a temporary hospital on ground belonging to them as governors of Trinity Hospital, at Quarryholes, Easter Road. To this interlocutor there is appended a note, extending to the length of a column of an ordinary newspaper, explanatory of the judgment. The "note" may be excellent in law, but, from an extra-legal point of view, one may fitly quote Omar Khayyam, and say: "I heard great argument about it and about, but evermore came out by the same door wherein I went." The Town Clerk stated that the Court desired him to say that this judgment was drawn entirely by Mr. Salvesen, a Scotch barrister,

who sat as assessor at the hearing of the case, but that the Court entirely concurred in it. It will be observed that the respondents, or some of them, in whose favour the judgment is drawn were the judges who tried the case and issued the judgment. At a meeting of the Edinburgh Town Council, the convenor of the Public Health Committee on the following day said that as the Quarryholes Hospital was proposed to be erected in connection with the order of the Local Government Board that the city might be prepared for the possibility of an invasion of cholera, they had proposed the site in question as nearest the probable point of attack. They thought they had only to ask their friends in Leith for formal permission, since Leith had, without asking leave, erected a hospital on ground belonging to the City of Edinburgh. He did not think they could or ought to accept without higher authority the decision of the Leith Dean of Guild Court. He therefore moved that the Council do now instruct the Clerk to intimate an appeal from the decision. The Lord Dean of Guild seconded, and the motion was passed unanimously.

THE "INDEX MEDICUS."

We are glad to learn that the number of subscriptions from Great Britain to the *Index Medicus* is larger than would appear from the list published a short time ago in America. In addition to the institutions mentioned last week we now learn by a letter from Sir Henry Acland, published in another column, that the Radcliffe Library, Oxford, has subscribed, and that the Medico-Psychological Association of Great Britain and Ireland is also to be numbered among the new subscribers. Dr. Karl Grossman, the Honorary Librarian of the Liverpool Medical Institution, informs us that that Institution has been a subscriber to the *Index Medicus* for the past sixteen years, and will continue its subscription.

CORONERS AND DIPHTHERIA.

THE Borough Coroner for Ipswich has followed a rather unusual course in holding an inquest upon a fatal case of diphtheria, but the evidence elicited, as reported in the *East Anglian Daily Times*, was such as to suggest that the example is deserving of occasional imitation, if only as a means of stimulating the local authority, and at the same time of strengthening their hands against the opposition which the most necessary improvements in sanitary matters are pretty certain to meet with among a section of the rate-payers. There had been four deaths from diphtheria in the same family within a week, and this in a house with only two bedrooms, occupied by a family of seven children. The parents would not agree to removal to hospital, but it transpired afterwards that there was no room there, even if consent had been given. The drainage was about as bad as it could be, and the water supply was derived from a contaminated well. School influence, and the effluvia from sewer gratings also came into question. Indeed, in the course of the inquiry nearly every point connected with the etiology of diphtheria seems to have been put before the jury and the public in a very clear way, with a practical application to the duties of the sanitary authority in matters of water supply, drainage, and sewerage, inspection and abatement of nuisances. In the end the jury made some very sensible recommendations with regard to the systematic inspection of houses of this class, particularly as to drainage and water supply. The publicity thus given to such a terribly tragic object lesson can scarcely fail to do good, and we shall not be sorry to hear of other coroners trying to throw light in an equally efficient way upon preventable deaths that have not been prevented.

THE ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

At the annual dinner of this Society, which was held in the Medico-Chirurgical Hall on December 14th, the chair was taken by Professor Stephenson, and Dr. Ogilvie Will acted as orator. After the usual loyal toasts had been duly

honoured, that of the "Navy, Army, and Reserve Forces" was given by the Chairman, and acknowledged by Fleet-Surgeon Kirker for the Navy, by Brigade-Surgeons Maconachie and Mackie for the army, and by Dr. Angus Fraser for the reserve forces. The toast of the "Medico-Chirurgical Society" was also given by the Chairman. That of the "University and Medical School," given by Brigade-Surgeon Maconachie, was acknowledged by Dr. Angus Fraser. The toast of the "Medical Charities" was proposed by Dr. Ogilvie Will, and acknowledged by Dr. Gordon. The toast of the "Founders" was then given by Dr. Edmond, who also responded to the toast of the "Health of the Retiring President," which was proposed by the Chairman. The health of the "President" was proposed by Dr. Beveridge and suitably acknowledged by Professor Stephenson. Finally the health of the "Guests" was given by Dr. Thomas Milne, and acknowledged by Mr. J. P. Cumine, advocate. The company was the largest which had ever assembled on this annual occasion, and a most enjoyable evening was spent, the speeches being diversified by music and story.

THE DIRECT REPRESENTATION OF IRISH PRACTITIONERS.

In another column we publish with some reluctance a letter from a correspondent in Ireland discussing the future of the direct representation of the profession in Ireland on the General Medical Council. We learn from various sources that since it became known that the illness of Dr. Kidd, the direct representative of Irish medical practitioners on the General Medical Council, was of a serious character, canvassing has taken place for the seat which it is thought may become vacant. Should the seat be vacated several candidates are ready to come forward, among others Mr. Wm. Thomson and Dr. Jacob of Dublin, Dr. Hercules MacDonnell of Dundalk, and Dr. King of Castlepollard. When the vacancy is declared, there will, we understand, be other candidates who feel a delicacy in coming forward at the present time, and it would appear to be from many points of view undesirable, as it is unbecoming, for some one or more of the possible candidates to invite voters to give pledges at the present moment.

THE CASE OF DR. LIONEL SMITH.

THE wrongs which Dr. Lionel Smith has suffered at the hands of the West Australian Government are familiar to our readers, and it is also well known to them that after fighting against his oppressors for eight years he at last received from the highest Court of Appeal, instead of redress, only that *summum jus* which is proverbially *summa injuria*. We are sure that our readers will be pleased to learn that Mr. Chamberlain, partly at the instance of the Parliamentary Bills Committee, has offered Dr. Smith the appointment of District Surgeon of Zuluand. The salary is, small and the prospects of private practice somewhat doubtful, but it may be hoped that as the Secretary to the Colonies, to whom the Chairman of the Parliamentary Bills Committee not long ago addressed a letter strongly supporting Dr. Smith's claim for compensation, has shown himself disposed to do what is in him to repair the wrong which Dr. Smith has suffered, the appointment will be a stepping stone to something better. Mr. Chamberlain has also, we understand, suggested to the Governor of Western Australia the propriety of that colony paying Dr. Lionel Smith the damages awarded by the jury before which the case was first tried on appeal, together with the costs of the action, amounting in all, we believe, to some £500. In the meantime, Dr. Smith's pecuniary position, owing to the drain on his resources caused by his long struggle against injustice, is so unsatisfactory that unless the profession come forward to help him it will hardly be possible for him to accept the appointment offered to him. We ven-

ture to express a hope that the appeal by Drs. De Havilland Hall and Goodhart, which we publish in another column, will meet with a prompt and liberal response. Dr. Smith has been fighting not his own battle only, but that of all medical men holding appointments in the civil service of the Crown.

THE SICK POOR IN IRISH WORKHOUSES: OMAGH.

At Omagh, as at Ballyshannon, our Commissioner found the difficulties inherent in obsolete structures and an antiquated and rigid system largely overcome by more enlightened guardians, seconded by humane and able officials. Here the dreary tale of dirt and squalour gives place to the description of clean wards and careful attendance; those little indulgences are permitted which do so much to lighten the pitiful lot of the aged; the nurse, though untrained, clearly does her best for the comfort of the sick. She is, however, single-handed but for pauper help, selected, as the medical officer says, from material "damaged mentally, morally, or physically, or in all three ways combined." And her patients are not only in the thirty-four beds of the hospital (usually all filled) but in the wings of the body of the house, some distance away. An increase of the nursing staff is therefore urgently needed. There is no nursing of any kind at night. Then the nursery "has successfully resisted the civilising influences brought to bear on the other departments." The infants in charge of their ignorant and too often degraded mothers are dirty and untended. It is misplaced sentiment to leave these unhappy babies entirely in their mothers' hands. If these women come on the rates and their children are brought up at the expense of the State, the State is in duty bound to see that the poor infants have as good a start in life as it is possible to give them, to lift, if possible, the new generation out of the slough of pauperism. The sanitary arrangements are still on the old lines, neither decent nor wholesome. We trust that the guardians will shortly turn their attention to these matters.

DEATH AT THE INSTITUT PASTEUR.

On October 13th a little girl, E. W., aged 3, was bitten in the eyelid by a mad dog, and was placed under the care of Dr. Murphy, of Twickenham. He at once took advice of those best able to give it, and the child was sent by her parents three days later to the Pasteur Institute in Paris. The treatment was begun the same day; it was finished on November 6th, and she was to return home at the end of that week. On November 8th she was seized with hydrophobia, and, though further inoculations were made in rapid succession, she died two days later. That the dog was mad has been proved for certain by investigations made at the Brown Institute. Those who know the especial fatality of bites on the face, and, above all, of bites about the eyelid can hardly be surprised at her death or at the shortness of the period of incubation. The mortality after face bites not treated by Pasteur's method is estimated by Leblanc at 80 per cent.; the statistics of the Comité d'Hygiène for 1862-72, giving 50 cases of face bites not treated by Pasteur's method, give a mortality of 88 per cent. These figures are, for different reasons, too high to be accurate, but they serve to show the frightful mortality of these bites on the face. In the Pasteur Institute in 1887 the total number of patients inoculated was 1,778; the total mortality was 1.94 per cent., but 145 of them were bitten in the face and head, and the mortality of these was 7.61 per cent. In 1888 the total number of patients inoculated was 1,625; the total mortality was 1.16 per cent., but 123 of them were bitten in the face and head, and the mortality of these was 7.33 per cent. The lowest mortality of people bitten by rabid animals and not inoculated, if we take bites of all parts of the body, and not only of the head and face, is 15 per cent. at least. The period of incubation after face bites is, on the average, 48 days, but in many cases it is far short of this;

and it is fairly certain that after a bite of any part of the body the period of incubation is shorter in a child than in an adult. Such are the facts of the case; it was a bad case to begin with; the only possible treatment was followed, and that without loss of time, and there is not the very faintest shadow of reason for thinking that the child's death was in any way due to the treatment. The *Star*, however, has made some statements concerning it so outrageous that they go beyond anything it has yet done in its shameful hunt for horrors. It speaks of "vile experimentation, reckless experimentation of a cruel and odious quackery, merciless experimenters, a pitiable story of reckless experiment, the patient agonised with the injected poison;" it employs gross flaring headlines, and every possible trick to raise a sensation, and to feed a coarse lust for reading of pain and death. It asks, "Did Dr. Murphy know that only one person in six, of those who actually have hydrophobia, dies of it? Did he know that the chances of the child's getting hydrophobia were almost incalculable?" These questions are as libellous as they are absurd. A further publicity has been given to the case by a statement made by a girl aged 16, who alone accompanied the child to Paris, that the poor child's body "was hurried into her grave like a dog, without service of any kind, because she was a Protestant." We have independent written evidence before us that flowers were placed on the coffin, and that a service was duly read over the body in the mortuary by a Protestant clergyman. There are doubtless differences of custom and of thought regarding these things between one country and another; nor are we here concerned with this matter; still it may be worth while to note that care was taken to fulfil the wishes of those who have lost their child. Such are the facts of the case. It is evident that Dr. Murphy did everything that could possibly be done, and lost no time over it. We offer him our sincere sympathy that his name has been dragged into publicity by such disgraceful methods, and we assure him that he has the sympathy and approval of all reasonable and honest men.

A NATIONAL SYSTEM OF NOTIFICATION AND REGISTRATION OF SICKNESS.

At a meeting of the Royal Statistical Society on December 17th, Dr. Arthur Newsholme strongly advocated an extension of the present system of notification of diseases as a means towards a more complete and accurate knowledge of the natural history of these diseases, and ultimately of their prevention. A modified system of weekly returns for all but the more urgent diseases was recommended. Dr. Newsholme pointed out that if medical practitioners were required to make such returns gratuitously, this must go along with much more efficient protection of them in the discharge of their skilled work. A system of sickness registration already existed in Germany and in the Scandinavian countries, the value of which for epidemiological purposes was very great. Dr. Newsholme added that such a system to be satisfactory must include tuberculous and respiratory diseases, alcoholism, insanity, and many others; every disease that flesh is heir to, he said, except old age, falls within the scope of preventive medicine. He formulated the following proposals: (1) That all cases occurring among the parochial poor should be periodically reported to the medical officer of health, and tabulated statements of them forwarded by him to a central office in London. (2) All cases of sickness in all hospitals and public dispensaries should be similarly reported and utilised. The importance of these hospital statistics was especially emphasised. (3) All friendly and allied societies should be required to furnish periodical returns of new cases of sickness in their care to the medical officer of health, and a yearly statement of the total number of members classified according to age. (4) An attempt should be made to obtain

accurate returns of sickness in the great industries. The present state of the law on this subject was stated, and strong exception taken to Section 29 of the Factory Act of 1895, which requires notification of certain diseases direct by the medical man to the chief inspector of factories. (5) The schedule of notifiable diseases under the Infectious Diseases (Notification) Act should be widely extended, and a modified system of weekly notification of certain diseases introduced. (6) A central office in London should be organised for the reception, tabulation, and publication of the preceding sickness returns, which would have all in the first instance been sent to the medical officer of health for utilisation in each district.

THE CHILDREN OF THE ALIEN POOR.

A COMMITTEE appointed by "the Committee of Ministers and others visiting among the Jewish poor in the East End of London," has presented a report on infant mortality. It would appear that the mortality among Jewish infants in the East End is very high, though the available statistics do not render it possible to say whether it is higher than that of the population among whom they live. The main causes of the infant mortality would seem to be diseases of the respiratory and of the digestive system. As to the latter class, disease seems in most cases to be produced rather through ignorance of the proper way of feeding infants by hand, than through neglect. The large number of deaths due to the former are probably to be attributed to deficient ventilation. As to this the report says: "Dwelling rooms are frequently converted into workshops. Rooms in which children are placed to sleep at night are frequently used in the daytime, and till late in the evening, for trades such as tailoring or bootmaking, which require heating stoves, gas light, etc. Coke is generally used for fires even for purely domestic purposes. Overcrowding takes place, the atmosphere becomes vitiated, and the children are deprived of healthful rest at the proper time." The Committee believe that the Jewish poor are "singularly free from those vices which are referred to by recent writers as causing infant mortality, such as wilful neglect of children in order to obtain policy money; drunkenness resulting in overlying; immorality, resulting in illegitimacy; syphilitic diseases, etc. This, however, all tends to show that the actual causes of mortality must have a very much greater effect on the Jewish population than upon the general community." As tuberculous diseases also are thought to be very little prevalent it seems clear that the other causes mentioned must be affecting the Jewish child population more severely than the general child population. The Committee recommend that the staff of nurses working among the Jewish poor should be increased; that all visitors should be instructed to explain the rules of health as to ventilation, cleanliness, etc.; and that the use of public baths and washhouses should in particular be advocated. Further, it is thought that special steps should be taken to prevent rooms used by day as workrooms from being used at night as sleeping rooms for young children. For this purpose the assistance of the factory inspectors and sanitary officials should be enlisted. The circulation of simple rules in English and Yiddish to married women giving instructions as to the management of their health during pregnancy, and as to the up-bringing of their infants, would also, it is believed, be advantageous. Every day experience in the East End shows that the foreign Jews and their children are, on the average, more dirty in their persons than even the poorest of the English population, which is saying much; and that while showing no little affection towards their offspring, and perhaps too much anxiety, they are more incompetent to feed and nurse them. Home nursing by trained women will do much to ameliorate the present lamentable condition of affairs; but, to work this system to the best advantage, all the medical men practising in the district and all the hospitals and dispensaries should be supplied with

forms for transmission to the nursing headquarters giving the name and the address of the child and the nature of the disease for which it is being treated. The fate of an infant or young child attacked by acute disease of the respiratory or digestive organs is commonly sealed within the first forty-eight hours, and unless efficient nursing and instruction are obtained within that time good results can hardly be hoped for. The communication between the medical man and the nursing staff should be direct and speedy.

RATE-SUPPORTED HOSPITALS.

In reference to the proposal that hospitals should be supported out of the rates, a correspondent in the *Daily Chronicle* writes that it is already carried out in some of our colonies. In South Australia and in New Zealand not only hospitals, but all duly authorised charitable institutions send in an annual statement to the central department (called in South Australia the Destitute Poor Department) as to the funds they are likely to require during the coming year. The Board then orders contributions from the various localities proportional to the value of property in each district, the Government contributing an equal amount, besides also making grants to supplement voluntary donations. Thus every town or district contributes to charity in proportion to its wealth—surely a better plan than that in vogue among ourselves, where the main burden of support falls upon the shoulders of a comparatively small number of philanthropic individuals. In South Australia the State makes itself largely responsible, not only for the support of charities but for their administration. Their expenditure on relief is believed to be barely one-sixth of that so spent here.

EPIDEMIC PNEUMONIA AND SCORIA DUST.

It may be remembered that in 1888 an epidemic outbreak of acute pneumonia which occurred in Middlesbrough was most carefully investigated in all its features by Dr. Edward Ballard, then one of the medical staff of the Local Government Board. So thoroughly did he execute his commission that his conclusions have ever since been accepted, at least in Great Britain. Dr. Attivant, of Nantes, however, has revived the hypothesis that the epidemic at Middlesbrough was simply due to the dust of scoria produced by the pulverisation of the slag of iron furnaces where the Gilchrist-Thomas process is resorted to for the dephosphorisation of iron. Dr. Attivant, from an examination of the scoria dust and its effects upon persons exposed to it at Nantes, has arrived at the conclusion that this dust is the true cause of the acute croupous pneumonia that prevails; and this opinion seems shared by other physicians in Germany and France, where the process of dephosphorising iron and of grinding of the resultant slag is carried on. From his general statement of his pathological observations and arguments, we gather that he relies especially upon the fact that the production and prevalence of the pneumonia stand in direct relation to the extent of exposure of sufferers, represented by the amount of floating dust, and the duration of exposure to it. Or, to state the fact in reverse order, that ventilation and whatever reduces the amount of dust are attended by a reduction in the number and severity of the cases attacked. He states that the dust is highly irritating to the respiratory passages and sets up acute bronchitis. The variations observed in the frequency and severity of attacks he attributes, not to atmospheric conditions, but primarily to the greater or less activity of trade as affecting the amount of dust generated in the mills. In individual sensitiveness and the circumstance of usage and habit he sees causes of variations in the symptoms and course of the pneumonia. Relapses are common, and scoria workers suffer in a higher ratio than others, and at times are the only persons attacked in an epidemic. This notion possessed the public mind when Dr. Ballard entered upon his

researches; but when these were completed it at once had to be given up, and a cause admitted to reside in certain insanitary conditions connected with the existence of a contagious agent in the shape of a particular bacillus named *bacillus pneumoniae*. This bacillus differs in vital characteristics from the bacillus of Friedlaender and also from the diplococcus of Fraenkel. In studying these bacteriological points Dr. Ballard had Dr. Klein as a distinguished coadjutor. Dr. Attivant does not seem to have made investigations of external conditions and surroundings, and of the dietary of the workpeople, as Dr. Ballard did. Before he closed his inquiry he traced out the entire history of the epidemic, and fathomed the collateral conditions associated with the outbreak. This complete inquiry dispelled the theory that the epidemic was owing simply to the dust of the scoria. He showed that pneumonia attacked individuals of all sorts and classes in no way exposed to the dust, and that it prevailed in the town workhouse at such a distance from the factories that no such heavy dust would reach its inmates. At the same time, he was ready to admit that the irritant dust was an assisting cause of the malady, but not its *vera causa*. The essential agent required to lend the property of epidemicity to the dust is the presence of a specific bacillus in connection with it, and with surrounding insanitary conditions found in food and in sewage gases and fluids. The frequent concurrence of acute inflammation of the bronchi, no necessary concomitant of pneumonic fever—must be accepted as an indication of the peculiarly irritating qualities of the scoria dust when in contact with pulmonary mucous membranes.

THE PREVENTION OF CHOLERA: DR. HAFKINE'S WORK IN INDIA.

We publish in another column the very able address given by Dr. Hafkine, of the Pasteur Institute, by invitation, at the Examination Hall of the Royal Colleges of Physicians and Surgeons, explaining the results of the work which he has done during the last two years and a-half in India in carrying out the practice of his method of vaccination as a preventive of cholera in India. Dr. Hafkine's work is of the highest scientific value and promises to confer a great boon on our Indian Empire. It has been carried out under circumstances of the most remarkable self-sacrifice and devotion to the interests of humanity and of science. He has given many of the best years of his life to this research, and has with unwearied industry and transparent sincerity worked out in India all the details which can test the value of this new gift to science to life-saving purposes without fee or reward other than his own conscience, his love to humanity, and his ardent devotion. Dr. Hafkine has with steady diligence and unquestionable enthusiasm braved every danger, and endured the extremes of climate and of unhealthy seasons. He has listened to the appeals from every direction regardless of personal risk and unmindful of his own health, which has suffered greatly. He returns to Europe greatly debilitated by the continuous trials of his arduous labours. In India he earned the respect and affection of all with whom he came in contact. His unaffected simplicity of character, his undeviating search for the truth regardless of any other object than that of the largest possible application and the most rigorous tests of his method have won for him universal esteem. It is fitting that his first great public reception should have been in this country, for it is in our Indian Empire that his discovery and his invention will find its largest field of usefulness, and while the boon which he has conferred on humanity is one which all the world must recognise, and by which all will be benefited indirectly, even where not directly, still it is especially in the Indian endemic home of cholera that the application of his method will find a most useful field. It may be hoped that with the larger views on sanitation which the Indian Government

are now adopting and carrying out, and with the universal recognition in India and the unspeakable importance of recognising the waterborne theory of the causation of cholera, the necessity for the application of Dr. Hafkine's method will become narrowed within diminishing limits. Dr. Hafkine concluded his address by a touching, eloquent, and deeply-felt tribute to the memory of his illustrious master, Pasteur, from whom he derived his inspiration, and who gave, it should be remembered, the most generous financial help, as well as his scientific aid and encouragement, to this great enterprise of Dr. Hafkine. The adoption of the Pasteur filter throughout India, where it is now being extensively introduced, will in its own way tend probably almost as largely to prevent the development of cholera as Dr. Hafkine's vaccination will limit its extension within the areas of its prevalence. Thus Pasteur's name will be doubly connected with the crusade against this terrible plague, which annually slays hundreds of thousands in our Indian empire, and thus extends its ravages from time to time to European countries. The Pasteur filter and the Hafkine-Pasteur vaccinations will go hand in hand in rendering this great service to humanity. The tribute which Dr. Hafkine paid to the memory of his great master comes at a timely moment, and everyone who reads his luminous and convincing address will feel that his concluding words are not the least interesting part of it. We trust that the Indian Government may see its way to some just and adequate recognition of the unstinting services which Dr. Hafkine has rendered to our great Indian dominions, and that his unexampled devotion and self-sacrifice will not pass without due official recognition.

THE RISING OF THE CREAM.

THE explanation urged by the defence in a recent milk prosecution, that the sample was taken late in the day, when the cream having risen to the surface had been unreasonably removed with the milk dealt out to the previous customers as it was ladled out from the vessel on the counter, is not an unreasonable one. It is easy to say that in dipping the vendor ought to have stirred and mixed it better, but negligence of this kind does not amount to wilful fraud. The difficulty arises also when milk is drawn from a tap at the bottom of the churns or cans in which it is carried through the streets for serving customers at their own houses, and which are securely locked to prevent tampering with it. As time passes the cream rises, until the last drawn off consists of little else, the drawings immediately preceding being proportionately impoverished. To check this separation and to equalise so far as possible the distribution of the cream Mr. O. Bolle, a dairyman, of Berlin, has adopted a very simple contrivance in the form of an inverted cone of finely perforated tin plate, the open base of which rests on the bottom of the churn. While the fat globules in the milk outside rise to the surface, those within the cone adhere to the inner surface of the upper portion, from which they are detached as the level of the milk sinks below its apex, and the cream that had floated in the outer space is sucked back through the perforations, assisting in the loosening of that within, and with it mixing with the general mass of milk without the necessity for agitating the contents of the cans. Numerous examinations of milk drawn off at intervals from the first filling to the time when the last is exhausted, and in hot and cold weather alike, have shown by the almost inappreciable differences in their composition that the apparatus, simple as it is, works most satisfactorily.

DR. HAMILTON J. BOGAN, of Arthurstown, has recently been sworn in a Justice of the Peace for the county of Wick.

THE *Journal of Medicine* of Leipzig states that MRS. CHLOE HOPPER, of Leipzig, has taken the degree of Doctor of Medicine in the University of that city, obtaining also the special diploma in gynecology with the highest honours.

THE ASHANTI EXPEDITION.

THE HEALTH PROSPECTS OF THE EXPEDITION.

[FROM OUR WAR CORRESPONDENT.]

The Base Hospitals and the Hospitals on the Lines of Communication.—The Route from Prahu.—The Weather to be Expected.—The Diseases Likely to Occur.—The Pocket Pasteur Filters.—Dress.—The Health Statistics of the Last War.

The medical arrangements for this expedition are now fully completed. The disposition of the officers and men, as regards numbers, etc., has not yet been announced. The Base Hospital at Cape Coast Castle will consist of 75 beds, and 35 miles on the road another hospital of 60 beds will be established at Mansu, and a third of 75 beds at Prahu, which is 74 miles, or exactly half way to Kumassi. Between these stations there will also be placed small sections, which will be useful in giving aid, and where a short rest can be made and the hammock bearers changed. A medical officer will be at each, under control from Prahu or Mansu, and will be ready to accompany the convoy if necessary.

After leaving Prahu, the route will be through dense bush and forest, and no permanent posts except the ordinary halting places can be utilised for medical purposes. Sick or wounded will have to receive the best available attention, and then be formed into a convoy and brought down to Prahu.

It seems to be generally accepted by the colonial officials that King Prempeh is fully determined to resist to the best of his power. As regards climate, there is no probability of any severe rain falling during the expedition. The wet season lasts from April to September inclusive. During the months of December, January, and February, the Harmattan blows; it is a dry breeze coming from the north-west, and when this wind is not blowing, southerly and westerly winds prevail. Tornadoes do not generally occur during this period. The mean maximum shade temperature varies between 82° F. and 87° F. Owing to the great dampness of the climate, chilliness is a common sensation, and thicker clothing must be worn than might be expected in a country so near the equator. Decomposition aided by the extreme dampness of the atmosphere is so rapid that its products hang over particular places like clouds, and poison those who are exposed to their influence. In the way of diseases likely to be encountered in the expedition, waterborne disease will, it is hoped, be largely obviated by the use of the Pasteur-Chamberland filters. Many officers have provided themselves at their own cost with a new pattern of Pasteur pocket filters; it was much to be desired that the men also were provided. However, malarial fever naturally takes the first place—all degrees from the slight "seasoning" to those grave varieties with albed and adynamic symptoms. In fact on the west coast these latter or bilious remittents closely resemble ordinary endemic yellow fever. Dysentery has also to be reckoned as a formidable factor; during the last expedition of 1873 it was remarkably prevalent; amongst the residents it is comparatively rare, and its presence must be regarded as the result of the conditions of military life. Small-pox occurs as an epidemic at intervals, and though the precaution of ordering the troops to be vaccinated is advisable, the occurrence of a single case may be regarded as unlikely. It is a tradition amongst the white residents, perhaps totally unwarranted, that the small pox amongst the natives does not attack Europeans.

The dress of the men will consist of serge clothing, flannel vest, and flannel shirt; nothing has been spared to make the kit serviceable and adapted to the requirements of the climate.

To conclude, as a guide the statistics of the last Ashanti war may be quoted. The European troops landed were 1 578 strong and remained between 50 and 60 days ashore. During this time there was 71 per cent. of sickness; 59 per cent. of this due to fever (malarial), 13 per cent. to dysentery, 23 per cent. to other causes. The mortality, including men killed in action, was 1 per cent., and 43 per cent. were invalided home. In the present campaign the total European troops actually engaged will be between 600 and 700, and, without in any degree being too sanguine, it is anticipated that no such

large proportion of sickness will be met with. As long as excessive fatigue is avoided, rapid movement to the front is the surest stimulant to the soldier's courage and health.

THE STRENGTH AND CONSTITUTION OF THE EXPEDITIONS IN 1874 AND 1895.

It is difficult to arrive at anything approaching accurate figures as to the numbers of the force to be employed. If we analyse the actual strength of corps we find the number mounting up to 1,900. Thus: 800 European troops from England, consisting of (a) 300 picked infantry, (b) artillery, (c) engineers, (d) Army Service Corps, (e) Medical Staff Corps, 400 men 2nd Battalion West Yorkshire Regiment stopped at Gibraltar en route home from India. The native troops number 700 Houssa Military Police and 500 West India Regiment. The numbers of the West India Regiment have varied from 400 to 600 in the different reports. Thirty specially selected officers proceed with the troops from England. The bulk of the force being native reduces transport and expense generally. The West Indian troops are said to be acclimatised, well disciplined, brave, and moderately good shots. There will, in addition to the troops aforementioned, be available, if not actually employed, a naval brigade from the men of war stationed at Cape Coast Castle. In the last Ashanti war the number that actually marched into Kumassi, according to the *Broad Arrow*, was only about 1,500 Europeans with some 200 levies. The force employed was far smaller than generally supposed, and the total European strength did not exceed 2,400. The proper complement of officers for the various troops in the present expedition will have to be added to the thirty specially selected officers.

The medical department consists of twenty-three officers, of which number Brigade-Surgeon-Lieutenant-Colonel Townsend and Surgeon-Majors R. Porter and J. R. Dodd are detailed for the hospital ship, the others being employed in base and field hospitals and regimental duty. In the Gold Coast service there are some nine officers—three surgeon-majors and six surgeon-captains whose services can be utilised.

The men of the Medical Staff Corps who have been detailed form a provisional company eighty-four strong, under Surgeon-Major W. O. Wolsley and Surgeon-Captain O'Callaghan. Orders have been issued for the Medical Staff Corps and Ordnance Store Corps, with their respective stores, to march towards the front on December 26th. On the same date the Special Service Corps and the 2nd Battalion West Yorkshire Regiment may be expected to arrive at Cape Coast Castle. It is probable, therefore, that by the close of the first week in January the rearmost troops will have closed up to the Prahu. On December 11th seventy Houssas from Elmina began their march to the front.

The following is we believe a complete list of the medical officers serving with the present expedition: Surgeon-Colonel W. Taylor, P.M.O., Brigade-Surgeon-Lieutenant-Colonel Townsend, Surgeon-Lieutenant-Colonel Elenorhassett, Surgeon-Major Hughes, Wolsley, Dodd, Porter, Wilson, Beatty, J. Stevenson, Bentlett, Hickman; Surgeons-Captain Wilson, Beaver, Maher, Jussling, Burke, Eckeraley, O'Callaghan, Cummings, Coreoran, Hilliard; Surgeon-Lieutenant Spencer.

The number of medical officers who went to the West Coast of Africa in 1873-74 would appear to have been 80, namely: One deputy Surgeon-General, local, 19 Surgeon-Majors, 60 Surgeons; but we doubt whether more than 50 were actually employed at one time on shore. The Principal Medical Officer was Sir Anthony Horne, who, falling sick, was succeeded by Surgeon-General Woolfreyes, who in turn was succeeded by Sir W. A. Mackinnon, now the Director-General Army Medical Department.

THE INEBRIETY OF ADOLESCENCE.—A young woman, aged 19, was sent to prison last week by Mr. Denman at Westminster Police-court for being drunk and disorderly. She had been apprehended on the same day she had been discharged after having been a month in prison for a similar offence. She had a total record of twenty-three former convictions.

CHELSEA HOSPITAL FOR WOMEN.

A SPECIAL meeting of governors of this hospital was held on Wednesday for the purpose of considering "the propriety of the governors dispensing with the services of a member of the honorary medical staff, and to pass a resolution thereon." Lord GLENESK, Chairman of the hospital, presided. There was a very large attendance.

At the commencement of the proceedings Mr. O'CALLAGHAN applied for the attendance of Mr. Russell as his legal friend. After some discussion this was agreed to.

The CHAIRMAN said the governors had been called together to decide upon the conduct of the Council in a matter affecting the hospital. Rumours had got abroad respecting the condition of the patients, but the fact was that the hospital was never in such good circumstances as it was at the present moment. From January 1st to December 18th the percentage of mortality on the total number of operations performed had been only 2.2, and on the total number of patients 2.5, which would compare favourably with the statistics of any hospital in London. Mr. O'Callaghan was appointed in November, 1894, as honorary surgeon to the out-patients; and of his skill from that day to this no one ever had the slightest doubt. In a pamphlet issued by Mr. O'Callaghan he represented himself as being a victim, alleging no motive except that he was a reformer, and had met the usual fate of a reformer—namely, martyrdom. His reform consisted in interfering with the general law of the hospital in a case where he suddenly forbade the resident medical officer to interfere with his patient. This being brought before the Board, Mr. O'Callaghan was requested to comply with the rules of the hospital. He subsequently saw Mr. O'Callaghan, and told him that any suggested reforms should have been brought before the Board, and that if they were desirable they would have been carried out. In this particular case a patient on whom Mr. O'Callaghan had performed an operation died, and in his statement written in the hospital book Mr. O'Callaghan virtually attributed the death to a secondary shock received from the action of the resident medical officer in interfering with the dressings. This was a very serious imputation, and necessitated an inquiry. The result was that Mr. O'Callaghan was informed on July 3rd that he had lost the confidence of the Board. He did not at once resign as might have been expected, and on the 15th a report was received from the medical staff, in which, for reasons given, they intimated that they could not possibly go on with Mr. O'Callaghan. The Chairman then read a number of letters which passed, and from which it appeared that the Council declining to rescind their resolution, it was suggested that the matter should be inquired into by two medical men of high standing appointed by the Colleges of Physicians and Surgeons, and Dr. Black and Mr. Bryant were appointed for the purpose. Mr. O'Callaghan did not attend the inquiry, and those gentlemen accordingly reported that the inquiry could not be proceeded with in his absence. In conclusion, the Chairman stated that the Council, at some eighteen meetings, had carefully considered the whole matter. "Arbitration" was asked for, but there was nothing at all to arbitrate. It was a matter of discipline and a matter of etiquette. As representatives of the governors, the Council had done their best to maintain discipline and etiquette. They thought Mr. O'Callaghan had acted entirely wrongly towards his colleagues, and, under the whole circumstances, if their action was not confirmed, the Council would feel it their duty to place their resignation in the hands of the governors.

Mr. RUSSELL complained of the last statement made by the Chairman as tending to prejudice the case. He explained that Mr. O'Callaghan objected to the arbitrators or consultants appointed, because they had already had an interview with the Chairman in Mr. O'Callaghan's absence. He claimed, however, that the case should be fairly decided by properly appointed arbitrators, who would be in a position to deal fairly with the whole matter. In the particular case before them the patient was admitted on May 30th, and after consultation with other medical officers an operation was decided upon, and Dr. Granville Bantock who saw the operation performed by Mr. O'Callaghan, was of opinion that it was the proper operation. After it was performed at 11 o'clock at

night, the resident medical officer came in and removed the bandages and put on new ones, and in that action he did interfere when Mr. O'Callaghan could easily have been sent for. No doubt he acted in perfect good faith, but at the same time Mr. O'Callaghan had very grave reasons to complain of his conduct, and did speak severely to him. The house surgeon reported him and the Board without hearing Mr. O'Callaghan censured him. He said Mr. O'Callaghan sought for arbitration in the matter, and asked that the charges against him might be definitely stated and dealt with.

Dr. DUNCAN said that the resident medical officer had placed a statement in his hands denying that any instructions had been given him by Mr. O'Callaghan with regard to the dressings, or to send a wire or cab for him in case the patient required immediate attention. As a fact in this case the whole of the dressings were not changed, but only the superficial ones. Speaking for the medical staff, Dr. Duncan said the pamphlet issued by Mr. O'Callaghan teemed with inaccuracies. As to the order to the resident medical officer not to interfere with dressings in serious cases, it was the invariable rule in every hospital where there was a resident medical officer that he, and he alone, in the absence of the physician or surgeon, was solely responsible for the treatment and care of patients. In the case of hemorrhage coming on, if Mr. O'Callaghan's order was carried out, and he had to be sent for to attend to the case, living as he did three miles away, the patient might easily have bled to death before he could arrive. All the facts of this case and the evidence given before the Council were referred by them to the medical staff for consideration and advice. They met, with the exception of Mr. O'Callaghan, and after very careful consideration came to the unanimous conclusion that the death of the patient was in no way contributed to by the action of the resident medical officer, and this was conclusively proved by the post-mortem examination, which showed that the death was the result of a kink obstruction. The medical staff entirely endorsed the action of the Council.

A long discussion followed, in which Mr. BUNNETT COURIS urged that the only fair means of arriving at a solution of this difficulty was by arbitration.

Mr. FERGUSON, *per contra*, said there was nothing to arbitrate. The whole question was as to the infringement of the existing rules.

Mr. LANGHAM moved as an amendment to the Board's resolution that the whole matter should be referred to arbitration. This having been seconded was put to the vote and a ballot taken, with the result that 17 votes were recorded for the amendment and 106 against.

The resolution on behalf of the Board, which was seconded by Mr. DYER EDWARDS,

That the Council after full investigation and consideration, being of opinion that the continuance of Mr. O'Callaghan as a member of the medical staff would be incompatible with the maintenance of the proper discipline of the hospital and injurious to its interests, and all the other members of the honorary medical staff having in a formal manner, distinctly refused to co-operate with him in the discharge of their professional duties in the hospital, resolved that Mr. O'Callaghan be and he is hereby relieved of his duties as honorary medical officer of the hospital,

was put to the meeting and carried by show of hands.

ROYAL COLLEGE OF SURGEONS.

An ordinary Council was held at the College on December 12th, Mr. CHRISTOPHER HEATH, President, in the chair. The minutes of the last meeting were read and confirmed.

The following resolution was received from the Board of Examiners in Dental Surgery, and was referred to a committee of the Council for consideration and report:

The Board of Examiners in Dental Surgery have fully considered the letter from the National Dental Hospital as well as other questions arising out of it and whilst they do not recommend that an examination in mechanical dentistry be instituted "for dental students previous to their commencing their surgical training," yet they are of opinion that the time has now come when it is desirable that the examination for the license should be divided into two parts, and should include chemistry and physics and metallurgy. The importance of these subjects to the dental practitioner cannot be questioned, and it is generally felt that

under the present system candidates do not obtain a proper knowledge of them, doubtless owing to the fact that there is no definite examination in chemistry and metallurgy.

Dr. Arthur Pearson Luff, of St. Mary's Hospital, was elected an examiner for Part I of the examination in Public Health.

A report was received from the Discipline Committee dealing with two cases which were referred to them for consideration.

Mr. N. O. Macnamara, who delivered the Bradshaw lecture on December 5th, received the best thanks of the Council, and was requested to publish the same.

A letter was read from Mr. Frank Marshall, Honorary Secretary of the Newcastle-on-Tyne Dental Hospital, applying for the recognition of that institution by the College for the purpose of teaching. The matter was referred to the Board of Examiners in Dental Surgery for consideration and report.

A letter was read from Mrs. Garrett Anderson, acknowledging the receipt of the letter informing her of the reply of the Council to the memorial from the London School of Medicine for Women, and expressing the belief that the memorialists, while much regretting the decision, will greatly value the assurance contained in the resolution of the Council that, had the matter rested solely with them, the prayer of the memorialists would have been granted.

It was announced that the Royal College of Physicians had adopted the report of the delegates on the arrangements of the Examinations under the Five Years' Curriculum with the following rider:

That the College of Surgeons be informed that this College would consider it an improvement if pharmacology were placed with therapeutics under the head of medicine, instead of being accorded a distinct position as a subject separate from medicine, surgery, and midwifery.

The proposal was accepted by the Council.

INDIAN SANITATION: ARMY CHOLERA REGULATIONS.

Is this, as in some other important matters, it is satisfactory to see that the outspoken criticisms of Mr. Ernest Hart in his address in India and the last meeting of the British Medical Association have been productive of early and decisive effect. In pointing out the antiquated character of the cholera regulations still in force for the army in India, Mr. Hart spoke of it in strong language as a discreditable document, and one which ought to be withdrawn. We are now informed that the Government of India have approved of a Committee assembling in Calcutta in January next to revise the present cholera rules for the forces, of which Mr. Hart spoke as inadequate and discreditable. The Committee will be composed of the Quartermaster-General in India, the Principal Medical Officers R.M. Forces in India, and the Sanitary Commissioner with the Government, associated with Mr. Hankin, the bacteriologist.

ASSOCIATION OF FELLOWS OF THE ROYAL COLLEGE OF SURGEONS, ENGLAND.

The annual general meeting of this Association was held on December 11th. The chair was taken by Mr. GEORGE POLLOCK, President, who stated that his address practically embodied the report of the work done by the Association for the past year, of which the following is a summary. The first business of importance was the appointment of a Subcommittee to meet and confer with a Subcommittee of the Society of Fellows with respect to the election of the President of the College and other matters. As the result of this conference (on November 7th, 1894) the Society of Fellows undertook a canvass of the Fellows upon the subject of the mode of selection of the President. The Association had, however, adopted a resolution asking the Council of the College of Surgeons to agree to a conjoint Committee of the Council and the Fellows for the purpose of considering what alterations should be made in the existing charters of the College. This resolution was brought before the Fellows' meeting in January last.

Upon several occasions, both officially and unofficially, communications bearing upon College politics have been received from the Society of Members; but the Committee of the Association had in all cases declined to pledge itself to any definite policy in this regard, leaving it to the members of the Association to act in their official capacity as they might deem fit. A deputation of the Association had met a Committee of the Council of the Royal College of Surgeons on June 10th, 1895, to discuss the proposed amendments of the charters and by-laws. Documents were subsequently submitted, and the matters were still under the consideration of a Committee. The mode of conducting the proceedings at the half-yearly meetings of the Fellows had claimed attention from the Committee, and certain resolutions had been forwarded to the Council of the College. The Council of the College replied to the effect that the proceedings had been conducted in accordance with the regulations. But in answer to some further resolutions for the amendment of these regulations, the Council had sent merely a formal acknowledgement. It is still hoped that the action of the Committee will bear fruit, but if not, it may be necessary to take further steps in the matter.

Mr. A. T. NORRIS read the auditor's report for the past year, and added that he would have great pleasure in rendering all the assistance that he could in keeping the books of the Association. The report was unanimously adopted and a vote of thanks was passed to Mr. Norton.

The following is the list of officers elected for the year 1895-96:—President: Mr. GEORGE POLLOCK. Vice-Presidents: Mr. T. HOLMES and Mr. W. RIVINGTON. Treasurer: Mr. TWEEDY. Auditor: Mr. A. T. NORRIS. Honorary Secretary: Mr. PERCY DUNN. Committee: Mr. W. ALLINGHAM, Mr. HERBERT ALLINGHAM, Dr. ROBERT BARNES, Mr. WICKHAM BARNES, Mr. BRUCE CLARKE, Mr. JOHN COOPER, Dr. WARD COUSINS, Mr. GANT, Mr. VICTOR HORSLEY, Mr. JORDAN LLOYD, Mr. MAYO ROBSON, Mr. MANLEY SIMS, Dr. C. STEELE, Mr. GEORGE JACKSON, Mr. GEORGE HELM, Mr. C. B. B. KEETLEY, Mr. MANSELL MOULLIN, Mr. VINCENT BELL, and Mr. J. J. PARNELL.

The meeting unanimously approved of the action of the Committee in regard to the case of Mr. R. B. ANDERSON.

Mr. POLLOCK, Mr. HOLMES, and Mr. PERCY DUNN were appointed representatives of the Association on the Civil Rights Defence Committee. The following resolution was then unanimously passed:

That this Association adopts the reports of its Committee and of the Civil Rights Defence Committee on the case of Mr. R. B. ANDERSON, and desires to express its thanks to the Right Honourable the Earl of STAMFORD as president, and the public men and bodies constituting the Defence Committee who have stood forward in resistance to illegality, oppression, and persecution, and its appreciation of the action of the Council of the College in uniting in defence of the rights of its Fellows and Members.

Further, Mr. HOLMES undertook to give notice of the following resolution for the half-yearly meeting of Fellows at the College in January next, namely:

That this meeting learns with pleasure that the Council of the College are represented on the Civil Rights Defence Committee in the case of Mr. R. B. ANDERSON, and pledges itself to take every possible step to promote the objects of that Committee.

CYCLING FOR WOMEN.

A CORRESPONDENT writes to us: "One is frequently asked if cycling is good for women. I should be very glad if you would, through the columns of the BRITISH MEDICAL JOURNAL, answer this question fully, giving the *pros* and *cons*, and pointing out the considerations which should weigh in giving a reply to such a question. I have seen nothing in the JOURNAL to help much in this direction so far. One reads a good deal of the 'permanent injuries' which women may incur through bicycling. I should like to know what is the pathology of such injuries and why they need permanently disable. I have never met with a case directly or indirectly, but I am anxious to acquire a more precise knowledge of the results in injudicious cycling, in view of the great popularity it has now attained to. I am not seeking information as to the effects of overexertion on the system generally, but as it applies to women and their sexual systems."

We have requested opinions on this subject from several

physicians likely to have good opportunities to furnish information on the subject.

Dr. W. S. Playfair writes: With reference to the inquiry as to whether cycling is good for women, I may say that I have never come across a single case, with one exception, in which I had the least reason to think that cycling had been in any way injurious. That case was a very trivial ecchymosis of the external labia produced by the pressure of a badly fitting saddle, which might readily have been produced by riding on horseback or by any similar pressure. I do not see any reason why cycling should be hurtful, excluding, of course, falls and the like. The pedal movement of the limbs is accompanied by general exercise of all the muscles of the trunk and upper extremities; and it is practised in the open air, so that it is quite different from that of the sewing machine. Of course if there is any marked uterine or ovarian lesion, cycling, like other forms of exercise, should be prohibited, and it should not be practised during menstruation. I know of one lady who has tender swollen ovaries who cannot take carriage exercise, who tells me she is able to cycle without any bad results. On the other hand, I have recommended cycling in several cases of anaemia and chlorosis in girls with very beneficial results. It is a form of exercise which interests and amuses them, and which they can therefore be induced to take, while more general advice to exercise would be useless. If young ladies at school were taken out for a good bicycle ride, instead of for the usual perfunctory walk in couples, I feel sure it would be a very good thing.

Dr. Herman writes: The popularity of cycling as an outdoor exercise for both sexes gives importance to the question which is often asked, Is bicycling good for women? For women as well as men, who are free from disease, outdoor exercise is good, especially such as takes them into pure air and sunshine. For both alike the good effect is counterbalanced by the harm if the exercise is pushed to the point of excessive fatigue. Excessive fatigue we may define as that which is not renewed by rest and food. For certain persons of both sexes, owing to peculiar conformation of the body, which permit protrusions of parts which ought to be internal, exercise short of fatigue may do harm if it produces hernias, prolapse, etc. These ill-effects are common to both sexes, and are not peculiar to cycling, but they nevertheless require to be borne in mind when advising patients with regard to the special influence of cycling on women. The bad effects are mainly two. If the pedals are too far from the seat, the rider cannot make her feet follow the pedals without inclining the pelvis. Such side to side movement of the pelvis produces unnecessary strain on the muscles of the back and loins, and also friction against the sensitive external genitals. If the saddle is badly shaped, the friction thus produced may lead to bruising, even to excoriations, and short of this, in women of certain temperament, to other effects on the sexual system, which we need not particularise. Medical men who are consulted by ladies as to whether they may cycle should qualify their assent by insistence on the points that the pedals should be of the right length from the saddle, and the saddle of proper shape. There are many saddles in the market, each claiming special advantages, and the ingenuity of the makers is constantly being exercised to devise improvements. We cannot therefore attempt to adjudicate between the rival merits of the different productions. All we need say is that a saddle which causes friction against the sensitive structures at the anterior part of the vulva is one to be condemned.

MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE SOCIETY.

The last usual monthly meeting of the Executive Committee of this Society was recently held at 420, Strand. There were present the CHAIRMAN (Dr. de Havilland Hall), the Treasurer (Dr. G. E. Herman), and Mr. H. H. Clutton, Dr. J. B. Hall, Mr. F. Swinford Edwards, Mr. W. J. Stephens, Dr. Walter Smith, Dr. Major Greenwood, Dr. J. Pickett, Dr. F. J. Allan, Dr. W. Knowsley Sibley, Mr. R. S. Charsley, and Dr. Alfred S. Gubb.

The accounts presented showed that an unusually large number of new members had joined the Society during the preceding month. This is mainly owing to the fact that the meeting of the British Medical Association was held this year in London, and the Medical Assurance Society was in consequence enabled to bring the advantages of its membership under the notice of the large number of members of the profession who attended that meeting.

The Committee, as usual, carefully considered the list of outstanding sickness claims. As the Society gets older this list naturally increases both in extent and interest, and in particular in the winter and spring, shows the Society to be doing a large and useful work. Thanks to the care taken in the examination of new applicants, the sickness experience of the Society has so far been well under the expectation, but as time passes the results of sickness slowly but surely die away, and the experienced sickness has a tendency to approximate to the expected.

During the twelve years the Society has been in operation it has paid more than £30,000 in sickness benefit in respect of some thousands of claims. The claim register contains full particulars of all these cases, and when the time arrives for grouping and analysing the mass of information here collected some interesting and useful results may be anticipated.

Prospectuses and all information may be obtained on application to Mr. F. Addison, Secretary, Medical Assurance Society, 33, Chancery Lane, London, W.C.

ABORTION AND CHILD MURDER.

THE collapse of the charge of libel brought against a representative of the *Sun* in reference to allegations made in the course of a series of articles published in that newspaper under the heading "Massacre of the Innocents" sets us free to comment upon the remarkable revelations there made as to the modern practice of abortion and child murder as now carried on amongst us. First of all, however, we must give expression to the feeling that in laying bare the details of these hideous crimes the *Sun* has done good service to humanity, and to the hope that these revelations will speedily have the effect of, at the least, making the perpetration of such misdeeds as dangerous as it now appears to be easy and free from risk.

Last week we published a comment on the immoral advertisements which so often appear in presumably respectable newspapers, and we pointed out that although in many cases the nostrums advertised for "removing obstructions" and "preventing large families" were mere swindles, containing nothing of any efficacy for the purpose, the mere fact of their extensive publication was an incentive both to immorality and crime.

There is, however, much reason to believe that such advertisements are but the introduction to much worse things, and that in too many cases those who are led into the trap by the hope of getting rid of their "trouble" by a few pills are, by the introduction so given, induced to discuss and entertain questions of criminal abortion and even of murder. There would seem to be three principal ways by which the "girl in trouble" (often, by the by, anything but a girl in knowledge) is brought into communication with the abortion monger and the child murderer: (1) by the advertisements of quack medicines; (2) by advertisements of lying-in houses; and (3) by the advertisements of baby farmers. Whether it is the man or the mother who wants to have the difficulty arranged, it is from the newspaper that information is sought, and there is no blinking the fact that these three classes of advertisement are intimately allied with each other, both as to their more or less veiled meaning and as to the class to which they appeal; and that in each case it is by the managers of newspapers that the associates in the contemplated crime are introduced to one another.

It is idle to deny that such deeds are done or to maintain that they are only exceptional and rare results of the constantly repeated advertisements, to the nature and evils of which we have so frequently drawn attention. The *Sun* has but focused, and made certain with names and dates, what has long been known to be going on. There is no smoke without a fire; and it has long been recognised that adver-

tisements for children for adoption were but a cloak for more or less slow murder. The Infant Life Protection Act, 1872, was an attempt to deal with this evil, but it still continues, and it is now apparent that "adoption," "baby farming," starvation, and child murder, are but the smoke showing the existence of another crime smouldering still deeper in modern society, and are but the efforts to get rid of what one may call the failures of the abortion monger—children born alive and viable, sometimes from delay on the mother's part, sometimes from the fear of the consequences, or perhaps from some trace of humanity holding the employer back from giving the fatal order, often, it is to be feared, because "adoption" is cheaper in ready cash than murder during birth, which, as we are informed by the *Sim*, runs to £40 or £50.

A careful consideration of the facts recently made public, in the light of all that has for long been well enough known by those who took the trouble to dive into such matters, is sufficient to show that for the abolition of this abominable traffic action must be taken in four separate directions.

It is of the first importance that the disposal of the body of a stillborn child should be made as difficult as possible, and for this purpose the registration of all stillbirths, whether premature or not, should be made compulsory. The reckless indifference to child life which leaves stillborn children to be buried in the back garden or cast out upon the dust heap, and their births left unregistered is purely English, and would not be tolerated in any other civilised country.

Then it is absolutely necessary to extend the provisions of the Infant Life Protection Act to all cases in which children are removed from their parents, even when only one is taken in at a time. Such an extension can do no harm to honest people, at the worst nothing more than inconvenience can be caused, and that only here and there, while as things are it is open to any woman to receive child after child and to "do for" as many as she likes, so that she only takes in one at a time.

The registration and inspection of all lying-in houses would be a useful measure, although there might be many difficulties in the way of efficient inspection without which mere registration would not do much. None of these measures, however, will put a stop to the trade of the abortion monger. They will increase the risk of the process, and by driving it to earlier months, before the expectant mother has been brought to terror regarding her condition, the number of those who are willing to submit to "operation" will be much diminished, but no stop will be put to this abominable trade so long as facilities are offered by the press for introducing men who hate the idea of paternity, and young girls terrified at the thought of motherhood and shame, to secondhands who are willing for a fee to break the law. It is the filthy advertisement columns which lie on every breakfast table that form the first link in the chain, and it is the suppression of such advertisements which would itself do most to suppress the evil about which we write, and without which it may be doubted whether any other steps will be of much avail.

THE BATTLE OF THE CLUBS.

CORK.

We understand that a meeting of the medical profession in Cork will be held on December 27th for the purpose of considering the desirability of establishing in Cork a medical club or dispensary under the control of the medical profession. A set of rules will be submitted, and, should they be approved, the new organisation will probably be started with the new year.

INVERNESS.

We are informed that the following letter is sent to applicants for the post of medical officer to the clubs and societies under the circumstances described in Dr. Munro Moir's letter published in the *BRITISH MEDICAL JOURNAL* of December 7th, p. 1461. If anything could recall to a sense of their duty to the medical profession those who may be disposed to become candidates for the post, it would be a perusal of this letter, especially the several sections of Paragraph III. Let them consider what it would mean to attend 600 men in the railway works for £25 a year, just 10d. a head; a foundry com-

pany with about 180 hands for 10 guineas; a juvenile lodge of 45 members for 60s. a year, and so on!

[COPY.]

Inverness, December 21st, 1895.

DEAR SIR,—Annexed find particulars re benefit societies' advertisement for medical officer:

I. Reasons for advertisement. The medical association here are increasing their charges to higher figures than some of the societies can pay.

II. All the societies have agreed to combine for the purpose of getting a new medical man to Inverness, who would act as their medical officer. Societies would also support him in general practice.

III. There are four registered societies and two not registered, who presently pay as follows

1. Oddfellows, 280 members, at 2s. 6d. per member, without medicine.

2. Shepherds, 58 members, at 2s. 6d., without medicine, and 1s. for examination of infirming members.

3. Rechabites, 25 members, at 2s. 6d., without medicine.

4. "Legal Friendly" Medical Aid Branch, about £16 per annum.

5. Railway works, about 600, present £25 per annum.

6. Foundry company, about 180, present £10 10s. per annum.

7. Juvenile Lodge of Oddfellows, 45 members, about £5 per annum.

IV. Each Lodge responsible for its own payment, half-yearly, except railway works, yearly at present.

V. Foundry company's medical officer's term does not expire till May, 1896.

VI. Medical officer would require to be here in January, 1896, owing to short notice of alterations given to us by the Medical Association.

VII. There are twelve practitioners in the Association.

Address—
Wm. Munro, Bookseller,
Eastgate, Inverness.

OLD MEMBERS AND NEW RULES.

A correspondent states that the medical officers of certain clubs in his neighbourhood have unanimously passed resolutions to the effect that in future female members shall not be taken for a less annual fee than 6s. 6d., nor male members for less than 5s. At present the members of the societies are attended for 4s. 4d. a year, and our correspondent asks whether the resolution can justly be put in force in the case of present members. The medical officer's tenure of office is not, we are told, in any way secured, and we are of opinion that the change in the rate of payment will equally affect both old and new members, the only question is, When can it take effect? This will depend on the conditions under which the medical officers to the societies hold office; if their appointment be at the "pleasure of the society," the new rule will take effect as soon as promulgated; if a certain period of notice has to be given on either side, then the new rule cannot be enforced till after the period has expired. Of course, in any case, the insisting on this increased payment is equivalent to a notice of vacating the appointments in question in event of the payment being repudiated by the members; so that if the latter elect to retain the services of the medical officers after they have made these demands, it obviously implies that they accept the altered conditions.

LITERARY NOTES.

THE last three numbers of the *Phonographic Record of Clinical Teaching and Medical Science*, issued by the Society of Medical Phonographers (London, Sir I. Pitman and Sons, 1875, 6d., by post 6½d.) contain some excellent contributions in well-lithographed shorthand. In the October number a member of the Society contributes his notes of a lecture by Mr. Treves on abdominal section in private practice; Dr. Fletcher Bouch discusses the causation of sporadic cretinism and its treatment by thyroid extract, whilst the notes of the bedside teaching of Mr. Davies-Colley, taken by another member of the Society, show to what excellent use shorthand can be put at the bedside. In the November number, Dr. Gowers relates the case of a young man who, after being at a swimming bath, was seized with headache, culminating, after pyrexia, swelling of the eyelids, and protrusion of the eyeball, in unconsciousness, slight convulsive attacks, and general convulsions. Dr. Gowers gives the reasoning by which he arrived at the conclusion that the case was one of rheumatic inflammation of the cellular and fibrous structures of the orbit. Mr. Roger Williams, in the December number, declares against the germ theory of cancer. There are also papers dealing with the administration of gas and ether; recovery from melancholia of long duration; and desquamation after scarlet fever.

* Nearly half the members being married.

† Th. so might, e slightly in raised.

ASSOCIATION INTELLIGENCE.

NOTICE OF QUARTERLY MEETINGS FOR 1896.
ELECTION OF MEMBERS.

MEETINGS of the Council will be held on January 15th, April 15th, July 8th, and October 21st, 1896. Candidates for election by the Council of the Association must send in their forms of application to the General Secretary not later than twenty-one days before each meeting—namely, December 26th, 1895, March 26th, June 18th, and October 1st, 1896.

Any qualified medical practitioner, not disqualified by any by-law of the Association, who shall be recommended as eligible by any three members, may be elected a member by the Council or by any recognised Branch Council.

Candidates seeking election by a Branch Council should apply to the Secretary of the Branch. No members can be elected by a Branch Council unless their names have been inserted in the circular summoning the meeting at which they seek election.

FRANCIS FOWKE, *General Secretary.*

LIBRARY OF THE BRITISH MEDICAL ASSOCIATION.

MEMBERS are reminded that the Library and Writing Rooms of the Association are fitted up for the accommodation of the members in commodious apartments, at the offices of the Association, 429, Strand. The rooms are open from 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 2 P.M. Members can have their letters addressed to them at the Office.

BRANCH MEETING TO BE HELD.

LANCASHIRE AND CHESHIRE BRANCH.—The adjourned meeting of this Branch will be held in the Medical Institution, Liverpool, on Wednesday, January 8th, 1896. Agenda: Report of the Council of the Branch on the Midwifery Nurses Registration Bill as drafted by a Subcommittee of the Parliamentary Bills Committee and amended by a Committee of the Branch Council. Report of the Committee of the Branch appointed March 9th, 1895 "to watch the progress and to oppose any proposed legislation for the registration of midwives." Mr. H. H. Preston will move and Dr. G. H. Broadbent will second, "That a Vigilance Committee of the members of the Branch be at once elected, with power to add to their number, to watch the progress of any legislation for the registration of unqualified persons to practise medicine, surgery, or midwifery without the supervision of those already registered under the Medical Act." Mr. Walter Whitehead will move a resolution standing in his name as to the present system of government of the British Medical Association. Mr. Collin Campbell will move and Dr. J. Brassey Brierley will second, "That this Branch contribute £50 to the fund which is being raised to repay Dr. R. K. Reuter his expenses incurred in defeating the first and second Midwives Registration Bills." All notices of motion and amendments for the meeting, and applications for membership of the Association and the Branch, should at once be sent to the Honorary Secretary, JAMES BARR, M.D., 72, Rodney Street, Liverpool.

BIRMINGHAM AND MIDLAND COUNTIES BRANCH.

THE third ordinary meeting of this Branch was held in the library of the Medical Institute, Edmund Street, on Thursday, December 12th. The chair was taken by the President, Dr. CARTER, seventy-six members and visitors being present.

Ethical Committee.—A report was received from the Council on the formation of an Ethical Committee. The report was considered paragraph by paragraph, and slightly amended to read as follows: "1. The Committee shall consist of seven members of the Branch, of whom the President of the Branch shall be one, and not less than four shall be engaged in general practice, the same to be elected annually by ballot after previous nomination. Three shall form a quorum. 2. The Committee shall appoint from their number a Chairman and an Honorary Secretary, whose names shall be printed upon the list of the officers of the Branch. All correspondence relating to the work of the Committee shall be conducted through the Honorary Secretary. 3. The general object of the Committee shall be to promote fair and honourable practice, to exercise judicious supervision of matters touching medical interests, and to use their influence to prevent abuses in the profession. 4. The duties of the Committee shall be: (a) To arbitrate and adjudicate upon any professional disputes which may be voluntarily submitted to them by both parties as occurring between members of the Branch, or between a member of the Branch and any person or persons other than members of the Branch. (b) To hear

professional complaints or grievances of any member or members of the Branch, and to advise them thereon if so requested. (c) To make recommendations or suggestions to the Council of the Branch when corporate action appears to be desirable for the promotion of professional interests. (d) To co-operate with the Ethical Committee of the Council of the Association by obtaining information, or in such other ways as may from time to time be required. 5. The Committee shall be called together from time to time by the Chairman at his discretion, or at the request of three members of the Committee, but at least one meeting shall be held annually for the purpose of drawing up a report to be presented to the Branch at its annual general meeting. 6. The formation of this Committee shall be notified in writing to the Secretary of the Association, together with the name and address of the Honorary Secretary. Resolved:

That the report as amended be approved and entered on the minutes, and that steps be taken to give effect to the recommendations thereon.

The following members were elected to serve on the Committee: The President, Sir Walter Foster, Mr. Priestley Smith, Mr. Langley Browne, Mr. M. A. Messiter, Mr. Vincent Jackson, and Mr. J. St. S. Wilders.

The Treatment of Typhoid Fever.—A discussion on this subject was opened by Dr. SIMON. The following members took part in the discussion: The President, DR. RICHARDS, SAUNDY, FOXWELL, and STACY WILSON.

METROPOLITAN COUNTIES BRANCH: NORTH LONDON DISTRICT.

A MEETING of this District was held on Tuesday, December 17th, at the Highgate Infirmary, Dartmouth Park Hill, N. Dr. CLEVELAND presided.

Paper.—Mr. D'ARCY POWER read an instructive paper on the Differential Diagnosis and the Treatment of Cystic Lymphangiomas in Children, showing a child from whom he had successfully removed a large growth of the above nature. Several members spoke on the subject, and Mr. D'ARCY POWER replied.

Clinical Cases.—Dr. CHILCOTT and other members of the staff showed several interesting cases in the wards of the infirmary.

Votes of Thanks.—Votes of thanks were passed to Mr. D'ARCY POWER for his paper, and to the guardians and the superintendent and staff of the infirmary for their kind hospitality.

SOUTHERN BRANCH: SOUTH EAST HANTS DISTRICT.

An ordinary meeting of this Branch was held November 1st, 1895, at the Medical Library, 5, Pembroke Road, Portsmouth.

Cases.—Dr. WATSON exhibited a boy practically cured of Pityriasis Rubra under thyroid treatment, which seemed to have affected his general health beneficially.—Dr. CARLING exhibited an infant aged 19 months having nearly all the characteristic appearances of Cretinism—the arrested development, dumpy growth, weakness, listlessness, placid expression, sallow aspect, face swollen, with the waxy transparent appearance of oedema, thick lips, large tongue, dribbling of saliva dry and rough skin, hair scanty, dry, and coarse, absence of sweating, hands broad and thick, fingers short, feet flattened out, extremities cold and blue, abdomen large and pendulous. A course of mercury had produced no improvement. Dr. Carling now proposed to give thyroid extract.—Dr. CLAREMONT showed a boy suffering from Pharyngo-mycosis. The membrane contained leptothrix, yeast cells, and coeli. Cultures yielded a luxuriant growth of staphylococci and some yeast cells. Microscopic sections were also shown.

Exhibit.—Surgeon-Major General J. DAVIS showed a sample of a preparation of Iron which he recommended as compatible with both acids and alkalies. It was made by mixing golden syrup $\frac{3}{4}$ iv with liq. ferri perchl. fort. (1) and adding liq. ammoniac fort. in slight excess (about $\frac{1}{2}$ v) and water to $\frac{1}{2}$ viij. Dose about xxx.

Specimens.—Dr. G. A. O'B. RAID showed (1) the Skull of an Australian aboriginal from Hobbs Bay, Western Australia, and compared it with a Maori skull and a European skull. The Australian skull was of remarkably low type. It was

highly dolichocephalic. The face bones were almost entirely in front of, not below, the brain case. The anterior nasal opening was nearly round but with the anterior nasal spine well developed, though it was absent from a specimen from the same locality now in the Edinburgh University Museum. The angle of the mandible was unusually wide; there were thirty-two perfectly developed teeth. Dr. Reid proposed to present the specimen to the Edinburgh University Museum. (2) A Dermoid Horn from the wrist of an elderly woman.—Dr. Kellie showed the Horn from a fatal case of carbolic acid poisoning.—Dr. CLARKE showed microscopic sections of a case of Epithelioma of the Clasp-organ. He had shown the sections at a meeting of this Society on November 17th, 1892, and it was referred to in the report of that meeting at p. 1173 vol. II, 1892 of the BRITISH MEDICAL JOURNAL, as a case of apparently simple ulceration. The sections, made by the Clinical Research Association, showed that the case was one of epithelioma in which the ulceration had kept pace with the new growth.—Dr. J. R. ROBERTSON read a paper on the Influence of Large Doses of Arsenic in Cholera, quoting a series of cases showing its favourable effect. A discussion followed, in which Drs. WATSON, OWEN, OXFORD, CLARKE, and Messrs. Goss, WILLMER-PHILLIPS, COUNSELL, and Surgeon-Major General DAVIS took part.

Paper.—Mr. H. E. COUNSELL read a paper on a Few Important Details in Aseptic Surgery.

SPECIAL MEETING.

Registration of Midwives.—A special meeting was held on November 20th, when the following resolutions were passed:

1. That this meeting cordially endorses the vote passed by the annual meeting, 1894, in support of Mr. Lawson Tait's amendment, namely: That we, the members of the British Medical Association, while anxious to improve the training and supervision, and if need be, to support a practical scheme for the registration of medical, surgery, and midwifery nurses, emphatically condemn any proposal which has for its object the formation of a class of medical, or surgical, or midwifery practitioners other than those recognised by the Medical Act of 1858 as now existing.

2. That it is to the interest of the public and of the medical profession that the Council of the British Medical Association should take power and authority to protect both the individual and collective interests of the medical profession, and that the Council be requested to take such steps as may be necessary to enable it to actively undertake these duties, and to devote a portion of the income and funds of the Association for these purposes.

HALIFAX, NOVA SCOTIA, BRANCH.

A LARGELY attended meeting was held on November 29th at Halifax; the President (Dr. Trenaman) in the chair.

Discussion on Scarlet Fever.—Dr. MAHER read notes of 145 cases of scarlet fever, with special reference to the complications.—Dr. D. A. CAMPBELL reported three cases of hyperpyrexia during scarlet fever.—A prolonged discussion on scarlet fever then followed, in which the following took part: Surgeon-Colonel O'DWYER, Drs. FARRELL, CUNNINGHAM, WALSH, CHISHOLME, ALMON, RUID, and CARLETON JONES.

SPECIAL CORRESPONDENCE.

PARIS.

The Paris Medical Faculty for Frenchmen only.—An Operation by an *Interne* and its Consequence.—Treatment of Tuberculosis at Cannes.—Surgeon's Fees on Transport Company's Boats.—Medical Men Inheriting from Patients.—Sanitation; its Effects on Typhoid Fever at Toulon and St. Ouen.—General News.

In order to keep the Paris Medical Faculty for born and bred Frenchmen, foreign students with foreign matriculation certificates are accorded an "equivalence," which gives them the right of studying in the provincial faculties only; the dearth of subjects in the dissecting room and the overcrowding of students has led to the passing of this measure. The Paris Faculty is organised to give medical education to 3,000 pupils; 6,300 were last year within its gates. This new regulation will benefit the provincial medical faculties, and the

students likewise if they choose wisely, inasmuch as in many provincial faculties the first two or three years of the medical curriculum are more profitably passed than at the Paris Medical Faculty, where order and method in the programme of the medical students, judging by the dissatisfaction expressed, are far from perfect. Dr. Lataud proposes in the *Journal de Médecine* what he considers to be a sovereign remedy to prevent the plethora of medical men in France, which is no other than to allow foreign medical students to take their degree in the Paris Medical Faculty, but to withhold from them the permission of practising in France.

There is at the present time great excitement among the house-surgeons at the Lariboisière Hospital. M. Villiers, in M. Périer's service, operated on two patients suffering from hernia in the absence of his chief, giving as a reason that these patients had waited too long. M. Périer, interviewed by the *Temps*, gives another account, and states that on the morning of the same day he had seen all the patients with his *interne*, and decided that there was no case in his wards needing immediate surgical treatment. In case such an occurrence happened, he gave directions to his *interne* as to the surgeon to whom he should apply for assistance in case of need, as he had to go to a distance from Paris to perform an important operation. M. Villiers neglected these directions, and, aided by another *interne*, performed the operation. M. Villiers has been suspended from his official duties. The *interne* who helped him has claimed the right to share the same punishment; this has been accorded. The affair will be judged in a few days by the Conseil de Surveillance of the Assistance Publique.

At a recent meeting of the Academy of Medicine M. de Valcourt dwelt on the good effects of open-air life at Cannes on tuberculous patients who continue to take sea baths in winter; good results in winter are more rapid than in summer. This fact has already been noted by Dr. Cazin, and confirmed by further observations in sanatoria for the treatment of pulmonary phthisis.

According to the *Bulletin* of the syndicate of the medical men of the Seine, the fees of the medical men attached to different seafaring companies are as follows: The Messageries Maritimes, £7 4s. a month. After several years of service, £8 and £12 a month. The maximum is £20 a month after six years' service. In the General Transatlantic Company on the New York and West Indies line, £12 a month; on the Mediterranean line, £6 the first three months, afterwards £8. In the Fraissinet Company for the Levant and Asia Minor, £8 a month; for Brazil and La Plata, £12 a month. In the Chargeurs Réunis, £20 for the journey to La Plata and back, which takes about three months.

At a recent meeting of the Société de Médecine Légale the report of Maître Decori, an eminent barrister, on a nice point of law and medicine, was read: Whether medical men, *officiers de santé*, and dispensing chemists who have treated a patient during the illness followed by death, can inherit from the said patient by a will made during the last illness. The decision arrived at by Maître Decori, in the name of the Commission appointed to study the question, permits medical men to inherit under such circumstances; and he points out that an adverse interpretation of the Article 909 is neither necessary nor logical. A case at the beginning of the year in which it was applied induced the Société de Médecine Légale to take up the question.

Dr. Cartier, in a pamphlet on Toulon, states that in that town the deaths are a third more than the births. For the last twenty years there have been yearly 33 deaths and 24 births per 1,000. A third of the deaths may be imputed to bad sanitation. The sewerage system is of the most primitive and dangerous kind. The water supply, under such circumstances, is evidently contaminated. There are at Toulon 1,800 wells situated in contaminated soil. This water is the principal factor in the 20,000 cases of typhoid fever and the 3,500 deaths which have occurred among the lay, military, and marine population of Toulon in the course of twenty years. All the contaminated wells ought to be filled up. In a short time 130 litres of water will be supplied daily to every inhabitant. In this quantity, from 60 to 65 will be potable. Throughout France the average number of deaths from typhoid fever is 51 per 100,000 inhabitants. At Toulon, among the lay population, it is 84, and during certain epi-

deaths 142 per 100,000. The proportion would be greatly increased if the military and marine typhoid statistics were added. In twenty years 1,651 deaths from typhoid fever occurred among the soldiers and sailors. Alcoholism and syphilis are two other scourges which devastate the Toulon population. Twenty years ago the average yearly consumption of alcohol was 2.16 litres a head; it is now 6.83 litres. In 1873 there were 236 wine shops; in 1894, 830. From 1883 to 1888 there were constant cases of typhoid fever at St. Ouen. In 1888 the contaminated wells were closed, and the fever disappeared. Dr. Dubouquet Laborde and Dr. Léon Pons, in their report on the St. Ouen typhoid fever epidemic declare that the water supply was the principal factor in these outbreaks. Sand filters were established, which ensured a pure water supply.

The Council General applied to the State some time back for help from it to defray the expenses of medical inspection in departmental schools. This demand has been made repeatedly, but without success, because the budget neglected this item. Now, things are changed. The omission is corrected and the Minister of Public Instruction informs the Prefect of the Seine that £622 will be paid by Government towards the expenses of medical inspection in departmental schools. This is about half the total expense.

The Municipal Council, at the request of M. Albert Robin, has ordered that the therapeutical laboratory annexed to the late M. Dujardin-Beaumetz's service at the Cochin Hospital be attached to M. Robin's service at the Pitié Hospital. All the instruments, etc., at the Cochin Hospital laboratory will be transferred to the Pitié Hospital laboratory, which will be in receipt of the £30 a year granted to the therapeutical laboratory formerly at the Cochin Hospital.

In accordance with M. Berchelet's report the General Council has voted £2,164 for the municipal laboratory.

A scheme of removing household refuse by means of an underground system is being considered by the Municipal Council; carts are to remove the refuse from the sewers to boats, which will carry it away. Thus it is hoped the public health will be protected and agriculture advanced.

In accordance with the report drawn up by M. Dubois, the Municipal Council has voted that a service of isolation for diphtheria points be organised; also that dwellings be constructed for the nurses of the Necker Hospital and of the Children's Hospital. The expenses are estimated to be £17,168. These will be defrayed by the £20,000 the *Pari Mutuel* pays yearly to the *Assistance Publique*. It is also proposed to establish services in different hospitals similar to that organised at the Maternity Hospital for the purpose of treating chorea.

M. Lamy Bonafant states that civilisation with its results of education and comfortable living weakens the prolific power of nations. The degree of civilisation attained by a nation can be estimated by studying its birth rate. Italy is the only exception to this rule; the percentage of births does not decrease in that country, it is 37 per mille. The antidote to this evil is furnished by the fact that civilisation brings with it better sanitation; the mortality is less and the average span of life is greater.

A chemist and druggist who indulged in invectives against a medical man has been condemned by a provincial law court to pay £12 indemnity to the injured doctor, whose practice was threatened; £50 was demanded. The tenth Chamber has condemned a chemist and druggist to pay a fine of £30 for having made up a prescription illegibly signed by a charlatan proceeding without a diploma.

CORRESPONDENCE.

THE GENERAL MEDICAL COUNCIL AND DIRECT REPRESENTATION.

SIR—I approach this subject with great reluctance, as the present representative for Ireland is a near and beloved relative of my own and is very ill, so ill that two metropolitan consultants have already put themselves forward as candidates for the position still held by Dr. Kidd on the General Medical Council. This premature action on the part of the metropolitan candidates forces the "provincials" into the field

before the time selected ordinarily by the dictates of good taste.

I hope to awaken the provincial medical men to a consideration of their own interests, and ask them to vote for a provincial general practitioner instead of a Dublin consultant, who will simply be a second representative of whatever teaching school he belongs to.

The Council is composed of thirty members, twenty of whom are sent from the various medical corporations, five nominated by the Crown, and five are "elected representatives." The corporations have thus double the voting power of any possible combination of the remainder. To quote from the *BRITISH MEDICAL JOURNAL*: "Direct representation is powerless against the interests of the corporations, bodies which the Council was created to control, and which nevertheless have the exceptional advantage of raising the Council, and receiving through their members the larger share of the funds to which they contribute nothing." Registered practitioners contribute all the income of the General Medical Council by which the Acts are administered, while the twenty corporations represented contribute nothing.

Of the six Irish members on the Council, five are sent from the schools; in their selection the great body of the profession have no voice, as they are nominated by the Senates or Councils, whose election is further narrowed to those holding the higher honour degrees. Indeed, so jealous are the "metropolitans" of their monopolies that a provincial "Fellow" can have a seat on their Councils.

In the face of such an intolerable state of affairs, are we provincials to extinguish what little influence we have in the administration of our profession by voting for metropolitan candidates who are members of the Councils of the corporations? No, vote for a man who will support as asked for at the annual meeting in London this year an extension of the principle of direct representation, a man who will vote for enlarging the sphere of action of the Council by obtaining from Parliament the necessary authority to make it what it ought to be—penal and protective to the profession and a majority of its members "elective."

There are 800 Poor-law medical officers in Ireland. What influence or voice have they on the Council? But they have the influence and power to turn the election in favour of a provincial candidate, and they should realise that twice has the Council used its majority to reject the reasonable request made to it to apply to the Privy Council, as provided for in the Medical Act of 1886, for power to increase its number by an addition of elected representatives.

Dr. MacDonnell, of Dundalk, who has done good work on the Council of the Irish Medical Association for the Poor-law medical officers, will stand if assured of support, or if a stronger man is nominated he will retire in his favour. If the provincial vote is split it is useless to expect success.

In this county we have formed a society, one of whose objects is to obtain "increased representation for general practitioners on the General Medical Council and for medical men in Parliament." If other districts throughout the country would do likewise, and eventually become affiliated to the Incorporated Society of General Practitioners (the Irish Medical Association as at present constituted is useless), the provincial profession would have the machinery ready to work and carry the election of their nominees, and to further their interests in many ways at present impossible.

We have also made an effort to get Belfast, Cork, and Derry into line by appealing to the medical societies in those cities to adopt concerted action, and put our man at the head of the poll.

As Dr. Greene pointedly says in his letter to the *Irish Times*, November 18th: Let no man hold back for want of a personal knowledge of the candidate, or because he comes from any particular part of the country, or thinking that one vote will not make any difference. Every vote is wanted, and whoever is nominated by the "delegates" must be heartily supported. There should be a meeting of representative men from all parts of the country, and a suitable candidate chosen. We must begin without a moment's delay to combine and organise; at present the 800 Poor-law medical officers are powerless to help themselves.—I am, etc.

L. KERR, M.D.

Enniskillen, Dec. 18th.

Hon. Sec. Fermanagh Medical Association.

MIDWIFERY ENGAGEMENTS.

SIR.—In the *BRITISH MEDICAL JOURNAL* of November 16th you kindly answered my query about a midwifery engagement in which another medical man was called in. I submitted a copy of the *JOURNAL* to the county court judge's notice, and am pleased to tell you that he has to-day given judgment (with costs) in my favour, although he only assessed my damages at £1 1s., or one-half the fee that was originally agreed upon between defendant and myself.—I am, etc.,

December 17th.

T. A.

THE INDEX MEDICUS.

SIR.—With reference to your remark in the *BRITISH MEDICAL JOURNAL*, December 14th, 1895, that Oxford have not subscribed for the renewal of the *Index Medicus*, I have to inform you that this Library subscribed immediately on learning that it was to be revived.—I am, etc.,

HENRY W. ACLAND.

Radcliffe Library, Museum, Oxford, Dec. 14th.

MEDICAL AID ASSOCIATIONS.

SIR.—Permit me in reference to the above subject to direct attention to the *modus operandi* of what is known as "The National Medical Aid Company, Limited."

Recently an advertisement appeared in the *Daily Telegraph* for a medical officer to a club. In response I made application and received the following reply:

THE NATIONAL MEDICAL AID COMPANY, LIMITED.

Chief Office:

20 and 21A, Fleet Street, London, E.C.

December 9th, 1895.

DEAR SIR.—With reference to your application we beg to inform you that the vacancy advertised by us which was at Rugby is now filled. We have one of a similar nature at Leith, N.B., the guaranteed salary for first year being about the same as at Rugby (£250), midwifery and surgical cases extra.

From what I have been able to ascertain there appears to be a good chance of working up a good private practice.

Yours faithfully,

E. T. HARWOOD,

Secretary.

Upon seeing the nature of the business, I acted upon the sentiments of the *BRITISH MEDICAL JOURNAL*, and at once wrote as follows:

December 10th, 1895.

DEAR SIR.—When replying to your advertisement I had no idea that the club for which a medical practitioner was required was carried out under the auspices of the Medical Aid Company. Since your letter has apprised me of this fact I emphatically withdraw my candidature, and at the same time express astonishment that any qualified man with self-respect could be found to lend himself to such professional prostitution as employment in a so-called Medical Aid Company.

Faithfully yours,

My object in sending these particulars is to show that self-respect in the junior members of the profession is not yet dead, and I am sure that if the senior practitioners treated their assistants in a more liberal spirit and as brothers in the same profession, instead of masters, the assistants and junior practitioners would not be so hasty in accepting offices under the patronage of the "National Medical Aid Company, Limited."

If this crisis in the profession is the means of directing attention to the root of the malady, namely, the intolerable position of many qualified assistants, good may yet come out of evil.—I am, etc.,

December 11th.

ERINENSIS.

THE AERIAL CONVECTION OF SMALL-POX.

SIR.—The article which appears in the *Public Health Department of the BRITISH MEDICAL JOURNAL* of December 7th is, by itself, so much calculated to discourage effort by sanitary authorities to limit the epidemic diffusion of small-pox, partly by means of "isolation" at hospitals, situate outside the centres of population, that I trust you will allow me to comment thereon.

Inasmuch as, for official reasons, I do not desire to refer specially to the particular case under notice, I would prefer to write at present from the standpoint of one who for several years has had the responsibility of teaching the subjects relating to public health administration at one of the principal medical schools.

The article speaks of "a distinct danger to a locality from a

small-pox hospital by reason of atmospheric spread of small-pox therefrom," and further on, in connection with the establishment of hospitals outside centres of population it speaks of "the potency for harm of small-pox hospitals." Now are we in the existing state of medical knowledge justified in the use of such expressions? I certainly think not.

In my yearly course of lectures, after describing fully the ordinary means of epidemic diffusion, as given in the standard works on medicine and in the reports of medical officers of health, I have always given an account of the circumstances of the extraordinary outbreak of small-pox which took place round the Fulham Hospital in 1881, which was reported on with scientific care and precision by Mr. W. H. Power, and which was subsequently inquired into by a Royal Commission.

I have endeavoured to do this impartially, not omitting any of the essential points in a case which has been held to be so important as proof of the aerial convection of small-pox from hospitals or houses for distances of a mile or more. This description has been coupled with the statement, which I think will be considered only fair, namely, that from my experience, and that of many others, the possibility of infection in the ordinary way (that is, personally or by fomites) in the majority of cases cannot, from the circumstances of town life, be excluded.

I hold that this teaching is what might be expected with our present day knowledge, although it differs from that which appears to meet with the approval of some high authorities.

The article on which I now comment begins by asking "What is proof?" I need not remind your readers that constant reiteration of expressions such as those quoted above does not constitute "proof," although they may give the "impression" of a distinct danger to a great many; the result being costly actions at law such as that which furnishes the subject of the article, and which tend to prevent the establishment of isolation hospitals as part of the system of defence against small-pox in this country.

As to the comparative value or signification of "positive" rather than "negative evidence" referred to in the article, is there not a great distinction between the signification of evidence as applied to questions of possibility apart from probability? Negative evidence, chiefly irrelevant on the question of possibility, becomes all-important in the estimation of probability, or, in other words, indicating the extent or proportions of a risk or danger.

I offer these remarks because it seems to me clear that a good system of notification and hospital isolation has proved to be efficacious in controlling the epidemic diffusion of small-pox. Small-pox hospitals situate outside the centres of population may therefore be a boon to the public by providing a means of checking epidemic diffusion which, in its power, is second only to vaccination.

I purposely refrain from comment on the case now under notice, in which I was not subpoenaed.—I am, etc.,

December 12th.

EDWARD SEATON,

Lecturer on Public Health St. Thomas's Hospital.

THE REAL MEANING OF MIDWIVES' REGISTRATION.

SIR.—The following circular letter has been forwarded to every Board of Guardians in England and Wales:

Union Offices, Peterborough, November 12th, 1895.

SIR.—I am directed by the guardians of this union to forward to you copy of a resolution passed at their meeting held on the 11th instant, and at which meeting it was resolved that the various Boards of Guardians throughout the country be invited to co-operate with the guardians of this union by adopting a similar resolution, and forwarding a copy thereof to the Local Government Board.

I am requested to ask that you will be good enough to bring the matter under the consideration of your guardians, and shall feel obliged if you will let me know their decision in relation thereto.—Your obedient servant,

WILLIAM PETTIT, Clerk.

[COPY OF RESOLUTION.]

That the members of this Board are of opinion that it is desirable that Boards of Guardians should have the discretionary power of appointing duly qualified midwives for attendance at childbirth in place of the district medical officer (subject to the condition as laid down in the Poor-law Board's Official Circular, No. 55).

I have applied to the Local Government Board, and am informed that there is no such circular No. 88; the circular referred to is No. 57, 1858, and it is as follows:

VII.—MEDICAL OFFICER.

"1. Fee in case of child-birth, where a midwife attends. Article 2 of the General Prohibitory Order. June 6th, 1887.

"Clark of Bromsgrove Union.—It frequently happens that able-bodied men on the occasion of the confinement of their wives apply to the guardians for temporary assistance. The women are attended by midwives, and go on well, not requiring the assistance of a medical officer, who, if called upon by the relieving officer or guardians to attend to certify the sickness in such cases, claims the fee allowed under Article 182 of the General Prohibitory Order. Requested, that the Board would, in these cases, sanctioned a departure from the rule laid down in Article 2 of the General Prohibitory Order.

"Answer.—The Board think that it must have escaped the notice of the guardians that Article 2 of the General Prohibitory Order only applies to cases in which a medical officer or some other medical practitioner has attended, and therefore does not extend to such cases as these to which your letter refers. At the same time the Board think that in cases of child-birth the practice of employing only female midwives in place of the medical officer is one which, if adopted by the guardians, should be exercised with due caution; and they rely on the guardians directing their officers in all cases of difficulty or danger to at once authorise the attendance of the medical officer.

I have obtained a copy of Article 2 of the General Prohibitory Order, and it is as follows: "In every case in which outdoor relief shall be given on account of sickness, accident, or infirmity to any able-bodied male person resident within any of the said unions, or to any member of the family of any able-bodied male person, an extract from the medical officer's weekly report (if any such officer shall have attended the case), stating the nature of such sickness, accident, or infirmity, shall be specially entered in the minutes of the proceedings of the Board of Guardians of the day on which the relief is ordered or subsequently allowed. But if the Board of Guardians shall think fit, a certificate under the hand of a medical officer of the union, or of the medical practitioner in attendance on the party, shall be laid before the Board, stating the nature of the sickness, accident, or infirmity, and a copy of the same shall be in like manner entered in the minutes."

I would earnestly call the attention of all Poor-law medical officers to the above. Articles 181 and 182 of the Poor-law Commissioners, 1847, provide that a confinement fee of from 10s. to 40s. may be paid by the guardians to a district medical officer. In 1859 the Local Government Board found that a practitioner with only the qualification of a physician was not competent to attend a pauper surgical case, and so ordered that each medical officer appointed must possess both a medical and surgical qualification. Is it not also indisputable that a person practising midwifery must also have a medical and surgical qualification? The Medical Act, 1866, says so. There are some Poor-law guardians who evidently think that a poor woman in her hour of labour deserves less attention than a sow, and that anything which will lighten the death-rate of pregnant women and of infants is worthy of their support.—I am, etc.,

Liverpool, Dec. 6th.

ROBERT R. RESTOUL.

CONTROL OVER MIDWIVES.

SIR,—Since the publication in the BRITISH MEDICAL JOURNAL of July 27th of my proposed definition of a midwife or midwifery nurse, namely, "a woman who attends a case of natural labour under medical control and personally undertakes the subsequent nursing of the mother and child," I have been frequently asked what control I suggest, and shall be glad if you will grant me space to explain it. I hold that every case attended by a woman of this class should be seen by a duly qualified medical practitioner within twelve hours of delivery. A complete check would by this stipulation be placed upon the midwife, knowing her work would be carefully scrutinised on arrival of the doctor; she would run no risk during the labour, nor would she be tempted to keep back information of any accident, such as ruptured perineum, the neglect of this mishap alone being the cause of subsequent and often permanent injury to the patient in an enormous number of women. Nor would she dare to trifle with the life of the child, a thing she is so generally accused

of. I name twelve hours because within this time of delivery the primary operation for a lacerated perineum could be performed with a perfect assurance of success.

It is objected, however, that as this would mean forcing medical attendance on every woman it would not be tolerated. That being so, by far the best control to adopt would be that in force in Austria, where, by decree of the Minister of the Interior, in the instructions to midwives on "summoning of doctors," rules are laid down with such definiteness as to entirely preclude a woman from doing mischief. Take an example, "(8) If placenta be not expelled in one hour, even if no bleeding has occurred; (9) In all cases of ruptured perineum as soon as they occur; (14) In the apparently dead newborn child," and so forth.

The Committee of the East Anglian Branch appointed to consider the registration of midwives reports that "no legislation can be permitted which tends in the least degree towards the licensing of a lower grade of practitioners." Substantial reasons are given for this opinion, and the report very properly points out the stern regulations of the State which forbid any district medical officer employing an unqualified person to attend a pauper.

I am, however, quite at a loss to understand how the East Anglian Branch Committee could recommend the Bill of the British Medical Association, seeing that Clause 2 actually allows a nurse to practise without any control at all. This Bill defines a midwifery nurse as a "woman who undertakes to attend cases of natural labour," and there is no penalty provided for malpractice. The mischief such a woman may do is incalculable.

Further this Bill by Clause 8 imposes all the expenses of the Midwives Board upon the General Medical Council, and the cost of prosecutions, which may presumably be frequent amongst an enormous number of ignorant women, are to be borne by this Council—in other words, out of the pockets of registered medical practitioners. Surely the profession will never submit to such barefaced robbery. It was bad enough when proposed by the Midwives' Institute, but when seriously suggested by our fellow practitioners it is most ill-advised.—I am, etc.,

Old Trafford, Oct. 16th.

JAS. BRASBY BRIBLEY.

DEATHS UNDER CHLOROFORM.

SIR,—Mr. E. C. Cripps asks why chloroform was administered and not ether to the case reported on October 12th. The following are my reasons: (1) The patient had, six weeks previously, taken chloroform well. (2) The surgeon who was about to perform the operation requested me to administer chloroform, as he much preferred it. (3) I saw no sufficient reason why chloroform should not be administered.—I am, etc.,

Newport Infirmary, Oct. 20th.

RICHARD COATES.

THE CASE OF DR. LIONEL SMITH.

SIR,—The case of Mr. H. Lionel Smith, whose unjust treatment by the Government of Western Australia was commented on in the BRITISH MEDICAL JOURNAL of June 1st and 8th has, we are glad to say, assumed a more hopeful aspect. After an eight years' struggle with what Traill designated as "bitter persecution" Mr. Smith found himself practically ruined and unable to obtain redress in Australia. Fortunately, however, we have in Mr. Chamberlain a Minister who acts promptly. On August 8th he sent a courteous reply to an official letter on Mr. Smith's case from the Royal College of Physicians of Ireland, and this week Mr. Smith has received the offer of the appointment of District Surgeon in Zululand from the Colonial Office. The salary is small, but it will enable Mr. Smith to start once again on his professional career. To do this, however, he is urgently in need of funds to meet expenses which have been incurred for the education of his children, now all but completed, and to provide for the passage and outfit of his wife and two youngest children. If prompt and substantial relief is not forthcoming, we are no alternative but the workhouse for Mr. Smith and his family; but, on the other hand, if he is enabled to accept the post which has been offered to him, he will have the opportunity of making a provision for them. In the eight years which have elapsed

since his dismissal, Mr. Smith has exhausted all his own resources, hence he is reluctantly compelled to allow this appeal to be made, and we cannot but think there must be those within and outside the profession both able and willing to help under circumstances so urgent and yet so temporary. The Editor of the BRITISH MEDICAL JOURNAL has kindly undertaken to receive and acknowledge subscriptions.—We are, etc.,

London, Dec. 15th.

JAMES F. GOODHART.
F. DE HAVILLAND HALL.

HOW TO AVOID THE TITLE OF "DR."

SIR,—I am a Member of the Royal College of Surgeons of England, and a Licentiate of the Royal College of Physicians of London, and have a trouble which causes me to seek your kind assistance and advice. I am perpetually called "Dr." instead of "Mr.;" my visiting cards are printed "Mr.;" my bills are headed "Mr.;" and my doorplates advise the world that I am "Mr.," not plain "Dr." Patients will call me "Dr.;" follow practitioners—themselves Doctors of Medicine, who should know better—write letters to me and address the envelopes "Dr.;" as public vaccinator, bills over which I have no control style me "Dr.;" cheques are made payable to me as "Dr.," and, ridiculous though it seems, I must endorse them "M.R.C.S.," not "L.R.C.P."—for does not the Royal College of Physicians make us promise we shall not call ourselves "Dr.," while the Royal College of Surgeons does not forbid it?

I went to a place many hundred miles away. I was asked whether I was "Dr.," and denied it, for I wished for a holiday, and if one is known as a medical man everyone wishes to address you as "Dr.," and to talk shop or ask advice—generally the latter occurs in hotels in the middle of the night. Unfortunately the next post brought me a letter with "Dr." on it, and I was at once regarded as a fraud.

When I first settled in practice I tried hard to stem the tide, but in vain, and now life is too short to try afresh; in fact I am branded "Dr.," and when I die "Dr." will be found as a cicatrix on my placard.

All this shows the ridiculous aspect of the case and how little the public cares for qualifications when one is a general practitioner in the country. I am glad to see how sensibly you sum up the subject in the BRITISH MEDICAL JOURNAL of December 14th. Of course anybody who is qualified in surgery, medicine, and midwifery, and practises them all, is a "Dr." to the world, and the ludicrous aspect of the case is for anybody to deny it.—I am, etc.,

December 14th.

STRYNHAM.

MILK FOR DIABETIC PATIENTS.

SIR,—With reference to Dr. Ringer's article in the BRITISH MEDICAL JOURNAL of December 7th, I would say that, under his advice and direction, I have been preparing milk for several weeks in the manner he suggests, and administering it with some amount of success to a child of 2 years suffering from diabetes.

I find, however, that a 10 per cent. solution of acetic acid is not sufficient to precipitate the caseinogen, and have been compelled to use one of twice that strength. Moreover, in the case of my patient, the addition of one tabloid of saccharin to the pint and a-half of milk makes a more palatable preparation than when the 2 per cent. of glycerine is used.

A very good preparation of milk may also be made by using a Pasteur Chamberland filter, but the process is tedious and expensive.—I am, etc.,

Newark, Dec. 15th.

F. H. APPELEY.

NAVAL AND MILITARY MEDICAL SERVICES.

ARMY MEDICAL STAFF EXCHANGE.

The change for inserting notices respecting Exchanges in the Army Medical Department is No. 61, which should be forwarded in stamps or post office order with the notice. The last post on Wednesday is the latest by which these announcements can be received.

A JUNIOR SURGEON-CAPTAIN A.M.B., at present stationed in Rangoon, wishes to exchange with an officer whose position on the roster would assure him three years at home. Advertiser arrived in India on December 2nd, 1895. State terms.—Apply, Surgeon-Captain Davis, c/o Messrs. A. Scott and Co., Rangoon.

CHANGES OF STATION.

THE following changes of Station amongst the officers of the Army Medical Staff have been officially notified to have taken place during the past month.

	From	To
Surg.-Maj. Gen. J. R. Hamilton, M.D.	C. of Good Hope	Devonport.
Surg.-Col. W. D. Wilson, M.B.	Secunderabad	York.
" W. Taylor, M.D.	Dover	Gold Coast.
" J. H. Hughes, M.D.	Leicester	London.
" J. Maturin	Colchester	Colchester.
Brig.-Surg.-Lt. Col. T. O'Farrell, M.D.	Colchester	London.

" C. F. Dear	Portsmouth	Colchester.

Surgeon-Captains G. Wilson, M.B., J. Maher, and J. FitzG. Burke, who have been serving on the West Coast of Africa, are to do duty on the Gold Coast, in connection with the Ashanti expedition.

THE NAVY.

FLEET-SURGEON J. W. H. HAWTON has been placed on the Retired List, at his own request, December 9th. He was appointed Surgeon, March 31st, 1874; Staff Surgeon, March 31st, 1886; and Fleet-Surgeon, November 20th, 1894.

Staff-Surgeon GEORGE F. WALES has been appointed to the *Pallas*, and Surgeon GEORGE F. DEAN to the *Widder*, additional, for the *Sans Pareil*, both dated January 1st.

INDIAN MEDICAL SERVICE.

THE following promotions, which have been already announced in the BRITISH MEDICAL JOURNAL, have received the approval of the Queen:—Bengal: Surgeon-Majors F. A. WHEAT, F. J. FREYER, M.D., P. DE H. HARRIS, JOHN LEWIS, M.D., and JOHN O'NEILL, M.D., to be Surgeon-Lieutenant-Colonels, September 30th; Surgeon-Captains J. J. PRATT and ROBERT SHORE, M.D., to be Surgeon-Majors, September 28th. Madras: Surgeon-Majors EDWARD FERRAND and F. H. PEDROZA to be Surgeon-Lieutenant-Colonels, September 30th; Surgeon-Captains W. B. BANNERMAN, M.D., and HENRY THOMSON to be Surgeon-Majors, September 28th. Bombay: Surgeon-Majors J. W. CLARKSON and JOSEPH PARKER, M.D., to be Surgeon-Lieutenant-Colonels, September 30th; Surgeon-Captain O. J. SARGENT to be Surgeon-Major, September 28th.

The retirement from the service of Brigade-Surgeon-Lieutenant-Colonel

H. B. PURVES, of the Bengal Establishment, which also has been already announced in the *BRITISH MEDICAL JOURNAL*, has likewise received the sanction of the Queen.

Surgeon-Lieutenant-Colonel W. M. COURTESY, Bengal Establishment, has retired from the service, December 1st. He was appointed a Lieutenant Surgeon, October 2nd, 1855, and Surgeon-Lieutenant Colonel twenty years thereafter. He served with the Indian expedition in 1873-74; with the Burmese expedition in 1885-87, in medical charge of No. 1 Field Hospital with the 4th Brigade Upper Burma; and with the Chin Lushai Expeditionary Force, under Brigadier-General Symonds in 1890-92 as Senior Medical Officer in charge of the General Hospital.

An examination for appointments in the Indian Medical Service will be held in London on February 2nd and following days.

Brigade Surgeon-Lieutenant Colonel RAJENDRA CHANDRA CHANDRA, late of the Bengal Establishment, and formerly Professor at the Medical College Calcutta, died in London on December 14th. He entered the service as Assistant-Surgeon January 31st, 1858, and became Brigade-Surgeon February 24th, 1890. During the Indian Mutiny in 1858 he was present at the action with Ferozshah on the banks of the Jumna. He was also with the expedition against the Kookies in 1861, and in the Coosyah and Jyntiah Hills campaign in 1862-63.

THE MILITIA.

SURGEON-MAJOR SAMUEL HASTERY, M.D., formerly of the 2nd West York Light Infantry Militia, died at Sidcup, Kent, on December 11th, after a long and painful illness.

THE VOLUNTEERS.

Surgeon-Lieutenant T. E. STUART, 1st Essex Artillery (Eastern Division Royal Artillery), is promoted to be Surgeon-Captain, December 15th.

Surgeon-Lieutenant A. JONES, 1st Lancashire Artillery, has resigned his commission, December 15th.

Mr. REVERLEY GEORGE ANDREW MONTGOMERY, M.B., is appointed Surgeon-Lieutenant in the 1st Volunteer Battalion the Prince of Wales's Own West Yorkshire Regiment, December 15th.

Surgeon-Lieutenant K. MITCHELL, M.D., 1st Volunteer Battalion the Lancashire Artillery, is promoted to be Surgeon-Captain, December 15th.

Surgeon-Captain G. H. MACKAY, M.B., and (West Yorkshire) Volunteer Battalion the North Riding Highlanders, has resigned his commission, December 15th.

Surgeon-Captain G. T. RAWNSLEY, Army Medical Staff, is appointed Adjutant of the Volunteer Medical Staff Corps, vice Surgeon-Captain D. M. O'Callaghan, who has resigned the appointment, December 15th.

The Volunteer Officers' Decoration has been bestowed upon Surgeon-Lieutenant Colonel T. E. FRANKSON, M.D., 1st North Riding of Yorkshire Volunteer Artillery (Western Division Royal Artillery); Surgeon-Major S. H. MORGAN, M.D., 4th Volunteer Battalion the Cheshire Regiment; and Surgeon-Major L. W. BRAMWELL, 2nd Westmorland Volunteer Battalion the Border Regiment.

PAY OF SURGEON-LIEUTENANTS ON SERVICE IN INDIA.

A question which is being agitated, says the *Pioneer*, is the question of how the pay of surgeon-lieutenants who are in temporary charge of regiments shall be calculated, when they are ordered to join a field hospital proceeding on service. For instance, a surgeon-lieutenant who has passed the lower standard division and is in an acting charge of a regiment draws Rs. 254 in place for the first, a total of Rs. 380. 10. For practical purposes, this may be taken as the lowest pay drawn by anyone who has passed the 1st division and is in an acting charge, since the instances where an officer remains unemployed are rare. As soon as they start on service, however, they are at once placed on unemployed pay on Rs. 207. 5, thus incurring a loss of Rs. 10 per mensem. The anomaly that an officer when he is hardest worked should receive unemployed pay seems to call for explanation. The present rules only act partially as against the junior ranks, since those who are in permanent charge of regiments remain entitled to their full staff pay; but there is no reason why juniors should suffer wrongly.

THE ASHANTI EXPEDITION.

News has been received from Cape Coast Castle to the effect that the preparations for the expedition are in an advanced state. A hospital for the troops is being erected at Connor's Hill. In it beds will be provided for 5 officers and 75 men. A battery company of 60 men has already been organised to carry the sick. A great breakdown has occurred in the transport service, owing to destruction of carriers at Mame. In consequence work on the position before which is being constructed over the Frah, has been brought to a standstill. Three companies, capable of holding 20 men each, have been constructed for the passage of the river. Four rest camps have now been laid out along the route, and, with one exception, water is obtainable at all. Twenty officers and 50 non-commissioned officers and men of the West India Regiment have left Freetown, Sierra Leone, for Cape Coast Castle. The special service corps and draft Medical Staff Corps have left Lae Palamas in the *Albatross*, as also the transport *Medusa* with the 2nd Battalion West Yorkshire Regiment, from Gibraltar for Ashanti; both these vessels sailed for Sierra Leone. Surgeon-Captain Eckersley has started to organise the hospital at Frah.

THE INDIAN MEDICAL SERVICES.

It has been settled that the Bengal, Bombay, and Madras Indian Medical Services will be entirely amalgamated in January, under the control of the Surgeon-General with the Government of India. The Military Assistant-Surgeon class of the three services was so amalgamated in October last, but this was only preliminary, the amalgamation of the rank into the service also. It is with a view to arranging the details of this scheme that Surgeon-Major-General Gough is now on tour in the Bombay and Madras Presidencies. A not unimportant detail is the change in the designation of that officer, who, it is understood, will be

called the Director-General of the Indian Medical Department, a change of title which has been in contemplation for two or three years.

THE CASE OF SURGEON-MAJOR CLARENCE K. SMITH.

THE *Manchester Times* has been doing its best to deal with the case of Surgeon-Major Clarence Smith in its columns, and the verdict was now awaited with much interest. A letter from the *Pioneer* thinks it possible that a report of the proceedings may eventually be published.

MEDICO-LEGAL AND MEDICO-ETHICAL.

UNQUALIFIED PRACTITIONERS AT MANCHESTER.

AN advertisement "useful and useful," named Bernard John Sherman of 28, King Street, Manchester, was announced to appear at the Manchester County Court Library for the recovery of £200, which it was alleged was obtained by him by fraud. Bernard was accused of negligence in treating the plaintiff, Sir John Howard, for rheumatism. The evidence, according to the report in the *Manchester Times*, showed that the plaintiff had seen the advertisement issued by Sherman in which a cure was guaranteed. He had visited the defendant, and had paid him one guinea for examination, and was absolutely assured of a cure. Upon this assurance he underwent the treatment, which consisted in a bottle of a curative compound and an apparatus to be worn, and paid 30 guineas for the same. The defendant gave him great pain, which finally became so intolerable that he sought medical surgical advice, consulting Mr. Whitehead, F.R.C.S., who told him that he had a small rupture on the right side, for which a proper truss was needed and that the apparatus he was wearing was of no use and was the cause of the severe pain. The plaintiff went back to Sherman and told him what Mr. Whitehead had said, and was reassured by him that the rupture was on the left side and that for a guinea more he would be cured. The plaintiff continued the treatment, but after a short time was obliged to abandon it owing to the pain.

Mr. Whitehead supported the evidence of the plaintiff, and stated that there was no hernia on the left side at all, and that the appliance was an improper one, was cumbersome and heavy, and was useless.

Sherman gave evidence in defence to the effect that he had not promised a cure and that the truss applied was a good one. In cross-examination he stated that it was true he was not qualified, and that previous to taking up the work of hernial specialist he was connected with horse-drawing in the United States.

The Judge gave judgment for the plaintiff, observing that the case was one of considerable importance to the public. He held that the plaintiff had parted with his money upon fraudulent representation, and ordered £200 and costs to be paid him.

One of the features of this case was that "Dr. John Tanner of London," who it was said "held a number of high qualifications," supported the evidence of Sherman in so far as the value of the appliance was concerned. It may be interesting to learn that a very qualified medical practitioner was struck off the *Manchester Times* last year for covering Sherman, at the instance of the Medical Defence Fund; and that a learned specialist in the same case—publishing a notice in which he said that some of the prescriptions at New York by the Medical Defence Fund, and convicted for falsely using the title of "Dr."

The successful prosecution at the Manchester County Court is most satisfactory; if the public can only realize that when advised by quacks to the use of pills and ointments in order to get their money back, a good deal of mischief will be done to the fraternity of charlatans.

A CANCER CURE AT MANCHESTER.

AN action for damages for negligence in treatment was brought by Bernard Sayles, a clerk of 10, St. Mary, against Robert Whitehead, a "cancer specialist," of 28, Brunswick Street, Chorlton-on-Medlock, Manchester, last week.

The plaintiff in her evidence, as reported in the *Manchester Courier*, stated that she had seen an advertisement of the defendant's, and being ill with and excruciating pain, and was informed that she was suffering from weakness. About two months later she noticed a growth on her chest, which the defendant pronounced to be a "cancer," adding that it would turn into a cancer. She gave her name, address, and residence, and painted the growth with something which gave her great pain. The pain increased to such an extent that she wrote to her husband, who sent her to Mr. Whitehead, F.R.C.S., senior Surgeon to the Manchester Royal Infirmary, who removed the growth by operation. Mr. Whitehead gave evidence, stating that the tumor was a cancer one, and was much inflamed owing to the irritation from some ointment application. The growth was not a cancer, and the treatment adopted was a bad and painful one. The defendant gave evidence in his own defence, but the Judge gave judgment for the plaintiff for £200 and costs, and stated: "In this case definite harm had been done, as long as people would pay for unqualified assistance, they must be allowed to do so."

This case illustrates the value of the county court in exposing the methods of unqualified practitioners.

A YOUTHFUL ASSISTANT.

Insurance writes as follows: Would I be acting unlawfully by employing as an assistant a practitioner who has passed all the examinations necessary for the degree M.D., &c. (from Quack), and who is known to be a graduate, and therefore eligible for recognition of his degree in years? He would certainly hold a title from our house, and would be under no supervision.

* We think our correspondent may employ such an assistant, provided that the latter will act only under the immediate supervision of his employer, and will not be allowed to conduct a branch practice or dispensary.

THE PROTECTION OF SURGICAL APPLIANCES.

We have received the following statement: A surgeon some years ago designed and made for himself a small apparatus for use in a certain class of operations. Several of his colleagues, recognising the utility of the apparatus, obtained permission to send the original apparatus to a firm of surgical instrument makers, who copied it and made altogether a considerable number of the apparatus. Recently these surgical instrument makers received a communication from another firm of surgical instrument makers, warning them that by continuing to make and sell this apparatus they were infringing a patent of the second class. It appears on inquiry that this second firm patented the invention some year or more after the surgeon had made and put into use in hospital the original apparatus. This is proved by the printed receipts of a firm of instrument makers for supplying the surgeon with an essential part of the appliance which he could not make himself. The matter has been brought to our notice by the surgeon in question, and we wish to know

(1) Whether he or the firm of instrument makers who made the apparatus from his pattern have any remedy. Supposing this firm to go on making the apparatus, to what penalties are they liable and how are these enforced?

And generally he asks (2) for advice as to what would be the proper course for members of the medical profession to follow in like case, with the view of preventing outsiders from seizing upon devices which the members desire should be placed at the disposal of the medical profession in the public interest, bearing in mind that the medical profession generally consider it undesirable that surgical appliances should be patented.

. We have submitted this statement to a legal correspondent, who writes:

(1) I am of opinion that the alleged patent is bad, and that the firm of instrument makers who have issued the warning referred to have probably no right in the matter at all, assuming, as I do from the facts stated, that the appliance they purported to patent is the same thing as that originally invented in the hospital, and "published" to all surgeons who chose to use it, a year or more before the patent was taken out. I am also of opinion that the surgeons who originally invented the appliance, or the firm of instrument makers who are authorized by him to manufacture it, may petition for the revocation of the patent, on the ground that the surgeon was the true inventor of the invention, and that it had been publicly used within the realm before the date of the patent. These proceedings would now be taken under the Patent Act (1883), and if the facts are correctly stated in the memorandum, I think they ought to be successful. In this view it is also clear that the original firm who manufacture under the authority of the real inventor are liable to no penalties whatever, and that if any action for damages for infringement should be commenced against them they can successfully resist it.

(2) As to the general question, it appears to me that there is much to be said in favour of the legal protection of new appliances by their original inventors, as being the best means of carrying out the desire of the medical profession that such improvements should be available for the use of all authorised persons. If a surgeon obtains legal protection for some novel appliance, he would, as I understand, be bound by the prescriptive rule of conduct to charge no royalties to anybody for the use of it, and not to restrict its use for professional or scientific purposes in every legitimate way. He would, however, be able, if it was thought right, to prevent unauthorised makers or sellers of instruments from producing some counterfeit which would be incorrect, and which might, of course, undersell in the market the proper and authorised appliances. Beyond this, however, there is a further danger of still greater importance. Although, as I have said above, any patent which may be taken out by somebody who is not the true inventor, for an appliance which has already been invented and made known, is in itself invalid, and can, if necessary, be struck out; nevertheless, it must be remembered that it is not at all impossible for an unscrupulous trader to obtain a patent for something which he may allege to be an improvement upon the original appliance. Such an "improvement" might be in itself, from the scientific point of view, a matter of small moment, and yet it might be sufficient to make the subsequent patent to a certain extent valid, so as to cause considerable trouble.

My view, therefore, upon the whole question is that it will be found in the end to be the safest course for the medical profession, if surgeons who invent appliances will have them protected either in their own name or in that of an authorised instrument maker, with a distinct covenant to the effect that no royalties shall be charged, and that all members of the profession shall be entitled to use them for professional purposes without hindrance.

"A CARD."

Dr. ALFRED WORTHING. On returning from abroad after an absence of ten years, I came in August last to settle here. Being a stranger in the place and finding that, owing to the local *quack* having but recently been punished, I had arrived too late to take advantage of the orthodox method of medical advertising followed in this town, which is done, it appears, by having the doctors' portraits, with their names and qualifications, printed in the *Illustrated Guide to*

Worthing, I had to be satisfied with inserting in a local newspaper my "card," simply notifying my address to visitors and any others it might concern. I have to thank you for giving prominence to the same in the columns of the *HARRIS MEDICAL JOURNAL* for December 7th, p. 1461, for by this I hope that those of my formerly intimate and many other highly esteemed professional brethren throughout England of whom, owing to long absence abroad, I have lost touch will be made aware of the present address of an old friend.

. In giving insertion to the above note with the view to afford the practitioners of Worthing an opportunity of repudiating the questionable allegations with regard to the local "orthodox" mode of self-announcement on commencing practice therein, we would simply remark that if it be based on fact a more glaringly unprofessional device could not well be.

CHANGING THE "DR."

A. G.—The excerpt transmitted by B. formed only part of the rule referred to, and especially related to the case therewith submitted. We now append the entire rule, which, if fulfilled by our correspondent, would justify the course he pursued. "When a practitioner is called in to or consulted by a patient who has recently been, or still may be, under the care of another for the same illness, he should on no account interfere in the case, except in an emergency, having provided for which he should request a consultation with the gentleman in previous attendance, and decline further direction of the case except in consultation with him. If, however, the latter refuse this, or if the patient insist on dispensing with his services, and a communication to that effect be made to him, the practitioner last consulted will be justified in taking charge of the case, or assuming which, however, he should satisfy himself that such intimation has been given by the patient or family. Under such circumstances no unjust or illiberal insinuations should be thrown out in reference to the conduct or practice previously pursued, which, as far as candour and regard for truth and probity will permit, should not only be justified, but, if right, honourably persisted in; for it often happens that when patients (capricious ones especially) do not experience immediate relief from the treatment they become dissatisfied, and under the impression that their case is not understood by the 'doctor,' unjustly impute the blame to him. Many diseases, moreover, *per se* or of so protracted a nature that the want of success in the early stage of treatment affords no evidence of a lack of skilled professional knowledge."

SPECIALIST DOORPLATES.

A. B. writes: Is it desirable, or if not desirable, can the medical men of a district, with justice, take exception to the prefix "Ophthalmic" on a doorplate (*viz.*, "Dr. Smith, Ophthalmic Surgeon," the plate being affixed to the door of a house in a town where there is no eye hospital, nor other possibility of acquainting the public with Dr. B.'s special acquirements, about which there is no doubt. If inadvisable, kindly state how the public should be made acquainted with the fact that their eyes can be attended to by a competent specialist at their doors instead of having to go twenty miles for special treatment.

. With reference to the proposed innovation, although no legitimate objection could well be taken thereto by the district practitioners, we hold it to be professionally undesirable, and it would moreover be attended by the serious disadvantage of being unintelligible to the majority of the public. The most unexceptionable mode of intimating our correspondent's speciality might be to effect a cure of some ophthalmic case, and let the fact speak for itself through the medium of the patient, who probably would not be slow to make it known.

FREE ATTENDANCE ON HOMŒOPATHIC PRACTITIONERS.

DOUBTER asks: Has a fully-qualified medical man, who has spent his whole life as a professed homœopathic physician, any claim on members of the medical profession for gratuitous advice?

. In response to our correspondent's query, we deem it best to refer him to the following authoritative view expressed in the *Code of Medical Ethics*, chap. II., sec. 3, rule 1, and leave him to form his own conclusion as to the legitimacy (so to phrase it), or otherwise, of the homœopathic practitioner in question: "1. All legitimate practitioners of medicine, their wives, and children while under the paternal care, are entitled (not as a matter of right, but) by professional courtesy, to the reasonable and gratuitous services—railway and like expenses excepted—of the faculty resident in their immediate or near neighbourhood, whose assistance may be desired," etc.

NOTE PAPER.

M. O.—In answer to our correspondent's question, we are distinctly of opinion that exception might justly be taken to the third line of the proposed heading, which we regard not only as ethnically injudicious, but, as printed, calculated to convey an erroneous impression as to the real source of the title. We would suggest, therefore, the substitution of "Medical Officer of Health," which would be ethnically unobjectionable, and, moreover, fulfil the expressed object in view.

CERTIFICATES TO TRADESMEN.

INQUIRER.—The proposed report, if it be directly or indirectly recommendatory of an article of daily consumption, and printed on the back of the vendor's business card as suggested, with the practitioner's name appended, would not only contravene a well understood ethical rule, but constitute a covert mode of unprofessional advertising, and therefore subject him to severe criticism.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF CAMBRIDGE.

FIRST M.B. EXAMINATION.

Part I. Chemistry and Physics.—Bates, King's, Bentley, Joh.; Brown, Emm.; Butler, B.A., Pemb.; Carey, Emm.; Cave-Moyle, Gony. and Cal.; Child, Pemb.; Clarke, A. J. Emm.; Claxton, King's; Dixon, G. B.A., Trin.; Euston, H. Ayo.; Fehsen, Gony. and Cal.; Fox, W. M., Trin.; Gabb, Down.; Goughan, Gony. and Cal.; Gould, Trin.; Hardey, Queens.; Hoop and Suss.; Hedley, J. F., King's; Hewer, Mid. Suss.; Hindle, Corp. Chr.; Holroyde, Trin.; Hudson, A. G., Trin.; Ingram, Trin.; Ingram, A. C., Joh.; Kempthorne, Joh.; Knight, B.A.; Laycock, Joh.; Lee, W. E., Trin.; Loveday, Gony. and Cal.; McDunnell, Joh.; Naisb, B.A., Emm.; Notthwanger, Joh.; Phipps, Christ's; Richmond, B.A., Cla.; Roberts, J. H., B.A., Joh.; Sedgwick, Mid. Suss.; Sephton, Gony. and Cal.; Shipman, Trin.; Smapear, Christ's; Simoy, B.A., King's; Smedley, Pemb.; Spearman, Gony. and Cal.; Stiff, Gony. and Cal.; Stockwell, King's; Taylor, E. J. D., Gony. and Cal.; Taylor, non-coll.; Whale, Jes.; Woods, Gony. and Cal.; Wilson, G. R., Trin.; Wisdom, Emm.; Woods, Mid. Suss.; Worthington, Trin.

Part II. Elementary Biology.—Ball, Emm.; Browne, H. S. D., Trin.; Burrows, Emm.; Carey, Emm.; Carroll, Trin.; Claxton, King's; Cooke, J. G., B.A., Mid. Suss.; Cooper, J. G., Trin.; Dencke, Gony. and Cal.; Dickinson, W. H., Trin.; Dixon, G. B.A., Trin.; Enthoven, B.A., Gony. and Cal.; Gabb, Down.; Hawkins, Gony. and Cal.; Hardey, Gony. and Cal.; Lawson, G. C., Trin.; Laycock, Joh.; Lundington, Jes.; McDunnell, Joh.; Manser, Pet.; Marcy, G., Trin.; Masterman, H. W., Christ's; Miller, G. H., Trin.; Newton, Pemb.; Pares, Emma; Perkins, H. Ayo.; Rees, Down.; Roberts, J. H., B.A., Joh.; Roberts, N. O., Christ's; Ross, K. A., Trin.; Sanders, B.A., Christ's; Sanger, P., Joh.; Scott, G. A. St. J., Trin.; Sedgwick, Mid. Suss.; Scrimshire, Jes.; Spearman, Gony. and Cal.; Stiebel, Trin. H.; Stiff, Gony. and Cal.; Stokes, W. H., Pemb.; Stutland, H. Selw.; Taylor, E. J. D., Gony. and Cal.; Wales, Down.; Ward, W. D., Joh.; Wilgress, H. Selw.; Wilkinson, B.A., Pemb.; Woods, Mid. Suss.

SECOND M.B. EXAMINATION.

Part I. Pharmaceutical Chemistry.—Ainsworth, B.A., Pemb.; Almond, Emm.; Ascherson, non-coll.; Atkinson, Gony. and Cal.; Attice, Joh.; Bainbridge, Trin.; Barnicoat, Pemb.; Bell, E. L. B.A., Pet.; Bemrose, Joh.; Bigg, Gony. and Cal.; Boulton, Trin.; Bousfield, Pemb.; Breddon, Trin. H.; Burnard, Jes.; Carey, Gony. and Cal.; Crimp, Gony. and Cal.; Ede, King's; George, Gony. and Cal.; Gibson, Jes.; Hadfield, Trin.; Hall, J. G., Emm.; Holmes, Gony. and Cal.; Howard, C. R., Pemb.; Hubert, H. L. F., B.A., Trin.; James, W. M., B.A., Christ's; Kimmel, Trin.; Langton, J. M. E., Trin.; Larner, M.A., Pemb.; Leach, Christ's; Levy, Joh.; Mallin, Christ's; Mellor, King's; Mercer, Cla.; Morgan, Joh.; Mummery, Gony. and Cal.; Orme, Gony. and Cal.; Percival, Joh.; Pitkin, H. Ayo.; Roper, B.A., non-coll.; Saunders, G. G., Trin.; Scott, Christ's; Smith, T. D., Jes.; Spanton, Trin.; Stirling-Hamilton, Jes.; Talbot, E. B.A., Trin.; Taylor, C. E., Joh.; Telford, Gony. and Cal.; Ticehurst, B.A., Cla.; Truman, Trin. H.; Upward, Christ's; Urwick, R. H., Trin.; Weatherhead, Joh.; Whitmore, Gony. and Cal.; Williams, R. F., Gony. and Cal.; Woods, W. H. G., H. Selw.; Wright, Christ's.

Part II. Human Anatomy and Physiology.—Bates, T. W. M.A., Queens'; Holland, B.A., Emm.; Brincker, B.A., Joh.; Clarke, H. N., B.A., Gony. and Cal.; Cox, B.A., Gony. and Cal.; Curme, B.A., Gony. and Cal.; Dwyer, B.A., Trin.; Ellis, B.A., Gony. and Cal.; Glasier, B.A., Emm.; Gwynn, B.A., Cla.; Graham, J. G. W., B.A., Trin.; Harman, Joh.; Harmer, B.A., King's; Hay, B.A., Gony. and Cal.; Hedley, E. W., B.A., King's; Horne, B.A., Trin.; Hunt, E. R., B.A., Trin.; Keating, B. Gony. and Cal.; Killick, Down.; Lea, J. B.A., Gony. and Cal.; Le Fleming, E. K., B.A., Cla.; Maxwell, Trin.; Mayo, Cla.; Nicholas, Joh.; Parker, Emm.; Percival, Joh.; Priddle, Gony. and Cal.; Reid, B.A., Joh.; Rose, B.A., Joh.; Rowland, B.A., H. Selw.; St. Leon, B.A., Gony. and Cal.; Seapling, B.A., Cla.; Sewell, B.A., Pemb.; Shade, B.A., Trin.; Taylor, J. G., King's; Walker, A. N., B.A., Queens'; Wilkin, B.A., Pemb.; Wilson, A. G., B.A., Gony. and Cal.; Wood, E. A., B.A., Gony. and Cal.

THIRD M.B. EXAMINATION. MICHAELMAS TERM, 1895.
Part I. Surgery and Medicine.—Allan, J. L., B.A., King's; Appleyard, B.A., Emm.; Ashes, B.A., Christ's; Barker, E. M., B.A., Emm.; Barton, B.A., Joh.; Black, B.A., Trin. H.; Blatchford, B.A., Mid. Suss.; Edwards, C. D., B.A., Joh.; Falkener, E. M.A., King's; Garner, W. L., B.A., Pemb.; Harrison, L. K., B.A., Gony. and Cal.; Haward, B.A., Mid. Suss.; Henson, H., B.A., Joh.; Hewitt, B.A., Gony. and Cal.; Hutchinson, M.A., Trin. H.; Jackson, T. L., B.A., Joh.; Mackenzie, B.A., Gony. and Cal.; Maturin, B.A., Gony. and Cal.; Maxwell, B.A., Corp. Chr.; Mims, H. B., B.A., Trin.; Moritz, B.A., Gony. and Cal.; Pennington, B.A., Pemb.; Penny, M.A., Pet.; Rawling, B.A., Gony. and Cal.; Richards, W. G., B.A., Christ's; Robinson, B.A., Gony. and Cal.; Roper, B.A., Christ's; St. B.A., Emm.; Selby, B.A., Down.; Somers, G. D., B.A., Pemb.; Stawell, B.A., Trin. H.; Stead, B.A., Gony. and Cal.; Tod, H. F., B.A., Trin.; Tyson, B.A., Gony. and Cal.; Wadsworth, M.A., Megd.; Ward, A. B., B.A., H. Selw.; Wood, B.A., Down.; Wills, B.A., Gony. and Cal.

UNIVERSITY OF LONDON.

M.D. EXAMINATION. PASS LIST.

Medicine.—A. J. Adams, St. Thomas's Hospital; L. W. Bathurst, St. Bartholomew's Hospital; L. M. Bennett, London School of Medicine and Royal Free Hospital; A. E. Berry, Owens College and Manchester Royal Infirmary; E. E. Blandford, B.A., London and Guy's Hospital; J. R. Bolton, B.A., B.Sc., University College; J. Le M. Bouch, B.A., B.Sc., University College; R. H. Castellan, University College; R. H. Cole, St. Mary's Hospital; R. Collier, St. Bartholomew's Hospital; R. H. Crowley, St. Bartholomew's Hos-

pital; F. H. Eves, B.A., University College; R. C. Gully, St. Bartholomew's Hospital; K. Hamilton, Owens College, Manchester Royal Infirmary, and Guy's Hospital; J. H. Mabel, Agnes Jones, London School of Medicine for Women; A. H. Joseph, University College and Royal Infirmary, Bristol, and King's College; C. A. Lane, St. Mary's Hospital; A. C. Lister, St. Thomas's Hospital; A. H. Lister, B.Sc., Guy's Hospital; V. W. Low, B.Sc., St. Mary's Hospital; G. E. Manning, Guy's Hospital; H. B. Meakin, St. Bartholomew's Hospital; Elizabeth Margaret Pares, London School of Medicine and Royal Free Hospital; C. T. Parsons, St. Mary's Hospital; E. A. Petram, St. Bartholomew's; W. J. Potts, Owens College and Manchester Royal Infirmary; C. H. Roberts (gold medal), St. Bartholomew's Hospital; C. M. Rogers, Yorkshire College; J. A. Shaw-Maclean, University College; E. Smith, St. Thomas's Hospital; W. R. Smith, B.Sc., King's College; R. M. Smyth, St. Mary's Hospital; W. N. Soden, St. Bartholomew's Hospital; A. Stanley, St. Mary's Hospital; T. B. Steadman, University College; Mary Percy Sturge, London School of Medicine and Royal Free Hospital; A. C. T. Bois, St. Bartholomew's Hospital; E. C. Taylor, B.A., Guy's Hospital; F. R. P. Taylor, B.A., Westminster Hospital; T. Warner, King's College; S. K. Wells, B.Sc., St. George's Hospital; Edith Mary Wilson, London School of Medicine and Royal Free Hospital; S. Williams, University College; C. J. Woodhead, Charing Cross Hospital; S. J. Wright, St. Thomas's Hospital; *K. A. Young, B.Sc., Middlesex Hospital.

First Division.—H. L. Balfour, London Hospital; Frances May D. Berry, M.D., London School of Medicine and Royal Free Hospital; D. A. Channing-Pearce, Guy's Hospital; Charlotte Elizabeth Hall, Royal Free Hospital; G. B. Hunt, University College; W. T. G. Pugh, Middlesex Hospital; A. E. Russell, St. Thomas's Hospital; H. B. Shaw, University College; J. S. Sloane, B.Sc., St. Bartholomew's Hospital; T. M. Thomas, Guy's Hospital; W. Turner, King's College.

Second Division.—Elizabeth Louise C. Appel, B.Sc., London School of Medicine and Royal Free Hospital; Frances Armitage, London School of Medicine for Women; V. J. Blake, University College; J. H. Bodman, University College, Bristol, and St. Bartholomew's Hospital; J. N. Brown, University College; F. K. Bryce, B.A., University College; Alice Mary Gorton, London School of Medicine and Royal Free Hospital; F. J. Coates, University College; C. S. De Segundo, St. Bartholomew's Hospital; A. Dimsey, University College; D. E. Evans, St. Mary's Hospital; L. E. V. Evert-Clayton, Guy's Hospital; J. W. Haines, St. Bartholomew's Hospital; W. S. Handley, Guy's Hospital; R. Hopton, Yorkshire College; J. Hova, Guy's Hospital; W. E. L. Horner, University College; A. Munnard, University College; W. H. Jewell, Guy's Hospital; H. D. Levick, St. Thomas's Hospital; A. A. Martin, St. Mary's Hospital; L. J. Meakin, St. Thomas's Hospital; A. Pafford, Middlesex Hospital; I. A. Parry, Guy's Hospital; B. A. Richmond, B.Sc., Guy's Hospital; A. J. Rodocanachi, B.Sc., University College; A. Suter, Guy's Hospital; F. A. Smith, St. Bartholomew's Hospital; G. H. Sutter, St. Bartholomew's Hospital; J. R. Stenhammer, Guy's Hospital.

M.S. EXAMINATION. PASS LIST.
Louisa B. Aldrich-Hake, M.D., London School of Medicine and Royal Free Hospital; E. T. K. Hamilton, M.D., B.Sc., Guy's Hospital; A. W. Sheen, M.D., Guy's Hospital.

UNIVERSITY OF EDINBURGH.

THE FACULTY OF MEDICINE.

The following table gives the number of students enrolled for the various years in the Faculty of Medicine in the University as at November 20th last, and at the corresponding date of 1894.

	First Year.	Second Year.	Third Year.	Fourth Year.	Fifth Year.	Total.
November 20th, 1894	203	245	223	246	210	1,327
November 20th, 1895	224	195	244	209	201	1,373
	Increase.	Decrease.	Increase.	Decrease.	Increase.	Decrease.
	21	51	21	37	9	56

Total number enrolled in all the Faculties for Dec 5 to 25th of November 1895, and that for 1894 is 2,173, showing a decrease of 132.

It will be remarked that the number of first year students shows an increase of 21 in place of "a large decrease," as has been stated in some quarters. Doubtless the error has arisen from inferences drawn from the numbers, recently reported, of candidates who had passed the preliminary examination. But, as has already been pointed out in the *British Medical Journal*, such inferences are quite invalid, since there are two ways of taking the preliminary. This will be best illustrated by taking these 2nd first-year students of medicine, and including the mode in which they variously qualified for registration. The figures are as follows:—(1) Passed University Preliminary Examination, 51; (2) passed Preliminary, partly with outside exempt work, 21; (3) passed Preliminary entirely with outside exemptions, 32; (4) exempted by M.A. qualification, 2; total who completed Preliminary in October, 1894, 106; formerly com-

* Obtained the number of marks qualifying for gold medal.

placed. Preliminary or otherwise accounted for, of total first-year students of medicine, etc. The college examinations will be held on pp. 100 to 101 of the University Calendar for 1896. Tests in England and the Oxford Examinations and Matriculations, the Cambridge Preliminary Examinations, the Oxford and Cambridge Schools Examinations, the Matriculation Examination of the University of London, the Victoria University Preliminary and Arts Entrance exampt. It is matter for much regret that comparatively less than 1 per cent. of these 200 students are graduates in Arts.

THE UNIVERSITY COURT.

The Court met on Monday, December 18th. A letter was read from Dr. Archibald Robertson intimating his resignation of the Lectureship on Lectures of the Eye, an office which he has held for thirteen years. Dr. Joseph Bell was appointed a member of the steering body of the Medical Lectureship in Agriculture.

It was intimated that the Senatus had re-elected Professor Crum Brown as an Assessor in the University Court for four years from November 25th.

Leave of absence from the Christmas recess until the end of the current session was granted to the Professor of Clinical Surgery (Mr. Anderson) on account of the state of his health. The Court further approved of the recommendation of the Senatus that the Professor's duties should during his absence be discharged by Dr. John Duncan.

On the recommendation of the Senatus, and in order to meet the changes effected in the curriculum by the new ordinances, it was agreed to schedule the following regulations for those at present in force regarding the Vans Dinslip Scholarships in Medicine: (1) For students of the first year, a scholarship shall be offered for competition in the subjects of chemistry, physics, and elementary anatomy (with definition of the last subject), and one in the subjects of botany and zoology, to be completed for in July. (2) For students of the second year, a scholarship in the subjects of physiology comprising the subject as required for the second professional examination and surgery, the examination to be held in March. (3) For students of the third year, a scholarship on the subjects of advanced anatomy and physiology to be completed for in October, and a scholarship in materia medica (including pharmacology), to be completed for in October. In the case of these two scholarships the examinations are to include practical tests in dissecting, in experimental physiology, and in experimental pharmacology. In the case of each of the above scholarships special papers will be set for the written examinations. The general conditions of tenure of these scholarships will remain as at present. It was also agreed that the Grierson bursary in pathology and materia medica, shall in future be divided into two bursaries, one of which shall be offered for competition to students of the third year on an examination in materia medica alone, and the other to students of the fourth year on an examination in pathology alone.

The Court approved of a recommendation of the Senatus that remitted candidates in the Faculty of Medicine who are required to reattend classes, and have taken any of these classes with extra-accidental teachers, shall not again be admitted to examination unless the fees paid for former attendance have been, in the case of extra-accidental classes in Edinburgh, the same as those charged for the corresponding classes within the University.

Applications by Mr. J. R. Whitaker, M.B., Lecturer on Anatomy, and Dr. F. W. N. Haughton, Lecturer on Midwifery, for continuance of recognition on charge of teaching premises were granted.

Two applications of Mr. H. Barclay Mess, M.A., M.B., Anderson's College Medical School, Glasgow, for recognition as a teacher of materia medica and practical materia medica was granted.

On the recommendation of the Senatus, the following request of the University of New Zealand was granted: That graduates in arts or science of that University be exempted from examination in botany, zoology, physics, and chemistry required from candidates for degrees in medicine, provided that they have passed in these subjects as part of their arts or science course.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

The following gentlemen (whose names are arranged in order of seniority as Members) having passed the necessary examinations and having conformed to the by-laws and regulations, have been admitted "Fellows" of the College:

E. Ferrand, Surgeon-Lieutenant-Colonel I.M.S., M.D.D.Rh., L.R.C.P. Edin.; A. G. R. Foulerton, L.R.C.P. Lond.; H. Tanner, L.R.C.P. Lond.; L. J. Pisan, Surgeon-Captain I.M.S., L.S.A. Lond., N.C. Water, M.B. Lond., L.R.C.P. Lond.; F. Lacey, L.R.C.P. Lond.; C. B. Lead, M.B. B.C. Camb., L.R.C.P. Lond.; H. J. Curtis, L.R.C.P. Lond.; C. Addison, L.R.C.P. Lond.; H. A. Ballance, M.D. Lond., L.R.C.P. Lond.; E. M. Hainworth, M.B. and B.S. Lond., L.R.C.P. Lond.; M. Hanford, M.D. and L.R.C.P. Lond.; W. G. Sutcliffe, L.R.C.P. Lond.; H. L. Barnard, L.R.C.P. Lond.; T. R. H. Smith, M.B. Camb., L.R.C.P. Lond.; W. Turner, M.B. Lond., L.R.C.P. Lond.; H. S. Elworthy, L.R.C.P. Lond.; G. J. Arnold, L.R.C.P. Lond.; H. A. D. Dickson, L.R.C.P. Lond.; F. E. A. Colby, M.B. Camb., L.R.C.P. Lond.; R. C. Brown, M.B. Ch.B. Melb., L.R.C.P. Lond.; W. H. Brodie, M.D. Edin.

Seventeen gentlemen were referred for six months and two for one year.

The following gentlemen, having passed the necessary examinations, have been admitted Licentiates in Dental Surgery:

W. H. Baker, E. O. D. Hascombe, F. C. Beaumont, J. J. Breakell, T. R. Chambers, S. W. R. Colyer, W. J. O. Dawson, N. Denham, E. C. Dimock, J. W. Goddard, F. E. Händel, S. J. Hanky, E. Harrison, W. J. Humber, B. E. James, H. E. Jepson, E. W. Jones, H. King, T. Lees, J. W. Lewis, S. P. Ludbrook, G. E. Macdonald, R. McKay, W. Marston, H. D. Mathews, J. L. Payne, W. H. Pidgion, H. J. Reiph, H. L. Robertson, S. F. Rose, A. B. Ryle, C. L. Seccombe, G. R. Spenser, A. W. Taitton, W. H. Venn, J. Wood.

Seventeen gentlemen were referred for six months.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

FELLOWSHIP EXAMINATION.—The following gentlemen, having passed the requisite examination, have been elected Fellows of the College:

L. W. J. V. L.R.C.P. Lond., M.R.C.S. Eng.; E. G. Fawcett, M.B., C.M. Edin.; A. W. Hall, L.R.C.P. & S. Edin., L.F.P. & S. Glas.; F. M. Graham, L.R.C.P. & S. Edin., L.F.P. & S. Glas.; J. I. Yell, M.B., Ch. Glas.; T. H. Morgan, M.B., Ch. Glas.; T. H. Kelly, L.R.C.P. & S. Edin.; W. J. C. Nourse, L.R.C.P. & S. Edin., L.S.A. Lond.; A. S. Ferguson, M.R.C.S. Eng., L.R.C.P. Lond., F. T. Anderson, L.R.C.P. & S. Edin.; A. N. Macleod, L.R.C.P. & S. Edin., M.D., C.M. Edin.; G. C. A. Moir, M.R.C.S. Eng., L.R.C.P. Lond.; W. A. Henderson, M.R.C.S. Eng., L.S.A. Lond., L.R.C.P. Edin., M.D. Glas.

Prizes and Fests.—Two highgate medals of prize, open to all students who have taken their course of materia medica at the School of Medicine of the Royal College, and who have passed in the second examination under the old regulations or the third examination under the new regulations of the triple qualification, has been presented to Mr. Patrick Pearse.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

PROFESSOR ALEXANDER FRANK, having passed the necessary examination, has been admitted a Fellow of the College. Mr. Richard Keatinge, L.R.C.P. and L.S.A. Lond., having passed the necessary examination, has been admitted a Licentiate of the College.

INDIA AND THE COLONIES.

INDIA.

SANITARY ARRANGEMENTS IN THE BOMBAY PRESIDENCY.—The sanitary staff in this presidency consists of one sanitary commissioner, five deputy sanitary commissioners allotted to as many registration districts into which the presidency is divided for administrative purposes, and twenty-three inspectors of sanitation and vaccination distributed to as many collectors. A correspondent draws our attention to the fact that these latter functionaries are not qualified medical men, and points out that, at a slightly enhanced cost, medical graduates of the Bombay University could be obtained. Sanitary inspectors should certainly be specially trained men, and medically trained by preference, on the basis of the scheme of sanitary organization proposed by Dr. Simpson and Mr. Ernest Hart. Probably under the orders recently issued by the Government of India, the present untrained staff of district inspectors will be replaced by properly educated men.

DISSECTION IN CALCUTTA.—The new dissecting rooms in the Calcutta Medical College, though not yet completed, have already been taken into use. Their size may be gauged by the fact that they comprise 2,000 square feet of space as compared with 500 feet in the Edinburgh Institution, where space is anything but cramped. They are fitted with marble slabs and all the latest appliances, and are an enormous improvement upon the miserable godowns in which the work had previously to be carried on.

DR. SIMPSON AND THE BENGAL GOVERNMENT.—A little learning is a dangerous thing, especially when used to delay necessary public reforms. None would be more ready than ourselves to acknowledge and to appreciate the remarkable ability and the large smattering of all-voluptuous knowledge which characterise the secretaries of the various Indian provinces, and on the whole, we have observed that their activity is generally used for excellent purposes and in the right direction. In dealing with sanitary questions, however, they are too often apt to press upon their inadequate smattering of knowledge and to show their smartness by criticising the reports of experts with dangerous results. We have before us a communication from one gentleman occupying this high position in an important presidency, addressed to the provincial medical officer, begging him not to make any new suggestions, and not to write long reports, for he frankly confesses his inability to understand the reports and his want of time even to read them, but expresses the unwillingness of his Government to act upon new suggestions which involve expense, and their desire not to be troubled with the reports which would involve expenditure. The Secretary of the Bengal Government has recently placed himself in an unenviable position by completely misunderstanding a report by Dr. Simpson, the able medical officer of Calcutta, and advertising upon the notoriously bad drainage of that city, and attributing to it a causal relation to the increasing prevalence there of febrile and malarial affections of a typhoid type. The Secretary of the Government interprets this as meaning an increase of typhoid fever, a vulgar error which is pernicious, perhaps, in no one else than a Government officer penning an official criticism. Unfortunately this ill-informed criticism may easily be interpreted as an argument against introducing a better system of drainage so much needed in Calcutta. Typhoid fever is essentially a waterborne disease, and so long as the water supply of Calcutta is undelivered typhoid fever is not and is never likely to be prevalent there. On the other hand, the waterlogged and polluted soil of Calcutta is in itself a threatening condition, tending to give a typhoid type to all forms of fever and debilitating disease. Dr. Simpson's reply is complete and overwhelming. It means, we fear, that the ill-judged action of the Government Secretary is likely to be prevented. Dr. Simpson has a sufficiently hard task in combating the obstructive tendencies of the native population, and it is unfortunate that these difficulties should be increased by the result of misapprehension on the part of a high European official. In the main we are sure that the sympathies of the Bengal Government under the enlightened rule of Sir A. Mackenzie will be in favour, as they have been under the distinguished rule of Sir Charles Elliott, of decisive sanitary reform, and we trust that this unpleasant episode will soon be forgotten. Meantime it is unnecessary to say that all the sympathies of intelligent Europeans must always be enlisted on the side of the admirably successful exertions of the eminent medical officer of Calcutta who has won for himself both here and in India the highest esteem and confidence of all well informed sanitarians, and who under great difficulties is carrying out a most important work for which he may fairly look for general encouragement and appreciation.

TYPHOID FEVER AT DUNBAR.

AN outbreak of typhoid fever has occurred at Dunbar, in the county of East Lothian, and Mr Henry D. Littlejohn has been called in to help the local authorities in determining the cause, and in taking measures to prevent its spread.

THE DRAINAGE OF LONDON.

THE drainage of London on the north side of the Thames is far from what it should be. The deficiency is due to the fact that in the original scheme the population allowed for was a million fewer than it now is. Some 1,000 houses are added annually to London. Additional intercepting sewers are now to be constructed with as little delay as possible at an estimated outlay of three-quarters of a million.

DUAL NOTIFICATION.

A MEDICAL OFFICER OF HEALTH asks whether the dual notification of infectious diseases can be enforced in a court of law, that is, whether the householder can be summoned for default of notification in a case where the medical attendant has notified.

"* The duty is obligatory upon the head of the family, under section 2 of the Notification Act, whether there be medical notification or not. It has not been customary to enforce this, where the medical notification has been duly received, and if such a case were taken into court, the magistrate would probably take a lenient view of the offence."

IS AN INFECTIOUS HOSPITAL AN "OFFENSIVE BUSINESS?"

A. K. L.—The question at issue appears to be whether a hospital for infectious diseases, including small pox, is an offensive trade or business. This point was settled in the negative by the Wiltlington (Manchester) case some three years ago (Wiltlington Local Board v. Corporation of Manchester, in the High Court of Justice, Chancery Division, before Mr. Justice Chitty; confirmed in the Court of Appeal by Lords Justices Lindley, Lopes, and Kay). In the absence of particulars it is impossible to say how far the question would be governed by this decision, but an account of the Wiltlington case was given in *Public Health* about March, 1893.

REMUNERATION OF MEDICAL OFFICER OF ISOLATION HOSPITAL.

HOSPITAL.—There are no standard conditions, and various arrangements are in force in different districts. Under the circumstances the practice of the neighbouring authority affords a convenient precedent, and the payment of a fixed sum per case is, on the whole, the most satisfactory arrangement.

AERIAL DISSEMINATION OF SMALL POX.

M. H. would refer "J. H. L." to the *Lancet*, February 9th, 1891, and August 15th, 1894, for a criticism by E. T. Wilson, M. H., of Mr. Power's paper; and also to a paper by the same author in the *Transactions of the Medical Officers of Health*, read January 16th, 1895.

NOTIFICATION DIFFICULTIES.

V. K. D.—The action of the Committee appears to have been singularly ill advised and calculated to create totally unnecessary difficulties in their relations with the medical profession. Whatever communication upon the subject was necessary might much more fittingly have come through another channel, and ought in any event to have been worded with more courtesy and consideration.

TENURE OF OFFICE OF M.O.H.

A. E. T. has no remedy if the local authority elect some other practitioner, duly qualified for the appointment, in his place. He should, however, make application for reappointment, and inform the Local Government Board of the circumstances. The short distance named cannot be regarded as a serious difficulty, although if the appointment were being newly made it would properly carry some little weight among other and much more important considerations. "A. E. T.'s" experience is a fresh illustration of the results of the perverse policy which the Local Government Board cherished until quite recently.

NOTIFICATION FEES.

J. A. A. inquires if a gentleman who holds a surgical qualification only can demand payment for notifying infectious diseases to the local authority.

"* We think that any duly registered practitioner is entitled to give the notice required by the Act, and to require payment of the fee."

ARCHÆOLOGICA MEDICA.

XVI.—THE JEWS AND THEIR INFLUENCE ON MEDICINE.

Jewish influences have never been of any importance in English medicine, though they have predominated in southern Europe. It is for this reason that no English book gives a clear account of the part played by the Jews in the history of medicine. Most people know that the Jews in the early Middle Ages numbered many great physicians among their race, and that the physicians of the great emperors and kings were usually of Hebrew extraction. Few, except the professed student of the history of medicine,

know to how great an extent the very existence of medicine has depended upon the Jews.

Dr. Richard Landau has just published a history of Jewish doctors which is full of interest, even to the general reader.¹ He traces the medical faculty amongst the Jews from Moses, their greatest law-giver, who was essentially a member of our profession in its highest and best form, for he was a sanitarian, through Solomon, Elisha, Isaiah, Ezekiel, and Jesus the son of Sirach, to the Essenes, whose Aramaic root-name shows that they at first professed medicine, though the sect soon became lost in mysticism. It was not until the first century of our present era, however, that the really great school of Jewish physicians began with Akiba and Ismael, followed by Hanina about the year 200. Hanina was contemporary with Samuel, the great oculist and even greater accoucheur, whose collyrium was long a formula throughout the then known world. Samuel practised first in Palestine and afterwards in Mesopotamia. His bosom friend was Raw, a man possessed of the truest scientific spirit, for the Talmud tells us that he would spend his all to obtain bodies for dissection to perfect himself in anatomy. Abba Oumna and Rabbi Gamaliel III in the fourth century ably maintained the prestige of the Jewish physicians, who in the fifth century became pre-eminent in Western Europe.

When a knowledge of Greek was lost they made themselves masters of Arabic and obtained a key to all that mass of literature which was locked away for many subsequent years. Soon after Spain had been conquered by the Caliphs in the eighth century great schools arose in Africa and in Europe, and in these the Jews were the leading teachers. The Jewish School at Cairo first migrated to Cordova, then to Sicily, and, afterwards moving to the Italian mainland, it established itself at Salerno, proceeding thence to Arles, Narbonne, and, still later, to Montpellier and Paris. Avicenna, a Latinized form of Ebn-Sina, Ebn Zohar, who is better known to us as Avenzoar, Ibn Roschd, or Averroes, and Moses ben Maimon, called Maimonides, were the most illustrious Jews in the tenth and eleventh centuries; their names are familiar to us from Chaucer's mention of them in his Prologue to the *Canterbury Tales*. The priests looked with a jealous eye upon the encroachments of the Jews in medicine, and they obtained a formal excommunication against all who committed themselves to the care of a Jewish physician, whilst the canon law enacted that no Jew might give physic to any Christian.

During the twelfth and thirteenth centuries the Jewish doctors spread from Spain over the whole of Europe, penetrating even to the far East, for Saad Eddula was both physician and Prime Minister to the Great Cham, Argun. This was the time of their highest repute. The Spanish decree of 1492 compelled 100,000 to 800,000 Jews to leave Spain within four months of its promulgation. About a tenth of these made their way into Portugal and established schools there; the rest were dispersed, but many thousands died by the way. The persecution of Spanish Jews was not an unmixed evil; it led to a still wider distribution of the Hebrew race throughout Europe and to a dissemination of the knowledge and of the culture possessed by its best members. France and Italy received especial benefit, and the Popes were wise enough to attach a Jewish physician to their service for several generations after the edict of banishment had been promulgated in Spain.

Dr. Landau is to be congratulated upon the readable form into which he has thrown the vast amount of information contained in his book.

¹ *Geschichte der Jüdischen Aerzte*. Berlin. 1895. 3s.

SANITARY REFORM IN CONSTANTINOPLE.—Redvan Pasha, the Prefect of Constantinople, some time ago commissioned Dr. Theodore Weyl, whose *Handbuch der Hygiene* is well known as a standard work, to carry out a complete inspection of the city. In this he is being assisted by three medical men and several police officials. He began with the filthiest quarters—Skutari, Hasköi, Balata, and Ouncapan, and has already sent in his report on these; but whether his recommendations will be accepted, or if accepted whether any serious attempt will ever be made to carry them into effect, is more than doubtful.

MEDICAL NEWS.

A GENEROUS gift of 3,000 guineas has been received by the Mid-dlesex Hospital from an anonymous donor as a perpetual endowment of one bed and two-cots, in memory of his wife.

INSANITY AND CIDER.—For some time past the claims of cider as a temperance drink have been loudly proclaimed; yet in the report of Burghill Asylum, the medical superintendent states that more people were in the asylum through cider drinking than through any other cause.

A LARGE CLAIM.—The mother of a boy, named Dunbar, has taken an action against the Ardee (Ireland) Board of Guardians for £10,000 for the loss of her son. He was in the fever hospital, and he escaped during the night. He was found in the fields almost naked eight hours afterwards, and he subsequently died. The question of the sufficiency of the nursing staff is involved.

AMONG the bequests left by the late Dr. Anthony, of Greenfield Crescent, Edgbaston, Birmingham, is a sum of £1,200 for the purpose of providing a new lifeboat and boathouse at Rhyl. The bequest is left in memory of a young lady to whom the late doctor was engaged, and who was drowned while bathing at Rhyl forty years ago. The deceased was an eye-witness of the occurrence, and used every possible effort to resuscitate life, but without avail.

STREET NOISES.—The Association for the Suppression of Street Noises is now at work. A Bill has been drafted which has the support of several members of Parliament. A subscription of not less than 2s. 6d. per annum is the qualification for membership; the vice-presidents comprising subscribers of not less than one guinea annually, and such ladies and gentlemen as, in the opinion of the Committee, can render valuable assistance. It is desired to bring electoral influence to bear upon parliamentary representation.

THE WEST END HOSPITAL FOR NERVOUS DISEASES, WELL-BECK STREET.—Sir W. H. Broadbent, Bart., has accepted the post of Consulting Physician on the staff of this hospital, rendered vacant by the death of Dr. Bristowe. Owing to the resignation of Dr. Hughes Bennett, on account of ill-health, Dr. T. Outerson Wood becomes the Senior Physician, Dr. W. Wallis Ord becomes second, and by arrangement with Dr. de Wailleville the beds allotted to the third physician have been taken over by Dr. Fletcher Beach. This rearrangement leaves a vacancy for a physician to out patients, which will be filled up in due course.

ANOTHER LUNG FOR LONDON.—London still suffers from want of breathing places, notably in the congested districts in the centre; and the deficiency in these places is difficult to make good owing to the value of land in such places. An excellent opportunity is just now afforded of acquiring an open space in a crowded district at Hoxton. The property belongs to the Haberdashers' Company, and is known as Aske's Schools. The schools are to be removed to another district, since they no longer answer the purpose for which they were intended. The London County Council intend to throw open the playground as an open space, and retain some of the premises for a municipal technical school. The space covers an area of about 1½ acre.

We are asked to state that as a wish has been expressed by some medical students who are to spend the Christmas vacation in London for facilities for making progress in the art of shorthand so as to be able to turn it to practical use at the beginning of the next term, steps are being taken to organise a class. Those interested in promoting the use of shorthand in medicine very wisely discourage any attempt by students to acquire it during the session. During the vacation, however, the study is a useful recreative occupation. Students willing to join such a class should communicate at once with Mr. J. F. Haynes, Westminster School of Shorthand, Palace Chambers, Bridge Street, Westminster.

The Committee of the After-Care Association for Poor Persons Discharged Recovered from Asylums for the Insane earnestly appeal for funds to enable them to carry on and extend their efforts. The objects of the Association are to assist cases (male and female) on their discharge from

asylums for the insane. Subscriptions and donations will be received by the Secretary, Mr. H. Thornhill Roxby, Church House, Dean's Yard, Westminster; or they may be paid into the account of the "After-Care Association," Union Bank of London (Regent Street Branch), Argyll Place, W.

THE TWELFTH INTERNATIONAL MEDICAL CONGRESS.—The date of the Twelfth International Medical Congress, to be held in Moscow, has now been definitively fixed for the week August 19th-28th, 1897—cholera and the state of the political atmosphere permitting. The Czar has signed the Imperial Rescript sanctioning the Congress, and His Majesty's uncle, the Grand Duke Sergi, Governor-General of Moscow, has consented to be its patron. The President will probably be Professor Klein, Dean of the Medical Faculty of Moscow University; Professor Erisman, Professor of Hygiene in the same University, will be General Secretary. The Russian Government has granted a subvention of 120,000 francs towards the expenses of the Congress. The official languages of the Congress will be French and German.

At the last meeting of the British Medical Temperance Association a paper was read by Dr. O. R. Drysdale on Therapeutics without Alcohol. He took the position that alcohol was of very little use, if any, in the treatment of disease. Sir B. W. Richardson, who presided, said that, in conjunction with the late Dr. Farr, he had found that alcohol caused more deaths in England and Wales than consumption. His experience at the Temperance Hospital had been most satisfactory. The discussion was continued by Dr. Norman Kerr, Dr. Havel, Dr. Paramore, and Dr. Ridge, and a vote of thanks was unanimously accorded to Dr. Drysdale.

On Tuesday evening, December 17th, the Romany Amateur Dramatic Club gave a performance for the benefit of University College Hospital at St. George's Hall. The well-known comedy in three Acts *The Overland Route*, by Tom Taylor, was excellently rendered. Mr. C. W. A. Trollope especially distinguished himself. Before Act III commenced, the pleasing announcement was made to the audience that the Club would have much pleasure, after paying all expenses, in handing over £80 to University College Hospital. During the twenty-five years that the Romany Amateur Dramatic Club has existed, it has handed over to various charities the sum of £3,300, for which its members deserve the warm and hearty thanks of the public.

OBSTETRICAL SOCIETY OF LONDON.—The following are the names on the preliminary balloting list recommended by the Council for election as the officers for 1896:—*President*: F. H. Champneys, M.A., M.D. *Vice-Presidents*: *W. Duncan, M.D.; J. H. Galton, M.D.; P. Horrocks, M.D.; T. O. Nesham, M.D. (Newcastle-on-Tyne). *Treasurer*: J. B. Potter, M.D. *Chairman of the Board for the Examination of Midwives*: C. J. Cullingworth, M.D. *Honorary Secretaries*: W. R. Dakin, M.D.; *J. Phillips, M.A., M.D. *Honorary Librarians*: *W. S. A. Griffith, M.D. *Other Members of Council*: T. R. Adams, M.D. (Croydon); *J. Walters, M.B. (Reigate); *J. Thompson (Nottingham); *A. Kisch, L. Drage, M.D. (Hullfield); W. Furner (Brighton); *P. Boulton, M.D.; *A. South, M.D.; *J. J. Tweed, jun., F.R.C.S.; O. Holman, M.D.; J. D. Malcolm, M.B., O.M.; *M. Handfield-Jones, M.D.; W. R. Pollock, M.B., B.O.; L. Ramfy, M.A., M.D.; J. H. Satter (Kelvedon); *H. A. Des Vaux, M.D.; *C. C. Claremont; W. W. H. Tate, M.B. Those gentlemen to whose name an asterisk is prefixed were not on the Council, or did not fill the same office last year. The election will take place at the annual meeting on February 6th, 1896.

MEDICAL VACANCIES.

The following vacancies are announced:

BRIDGEMOUTH AND SOUTH SHROPSHIRE INFIRMARY.—House-surgeon, doubly qualified. Salary, £20 per annum, with board and lodging in the infirmary. Appointment for one year, but eligible for re-election. Applications to the Honorary Secretary, Infirmary Rectory, Bridgworth, by December 24th.

BRIGHTON AND HOVE LYING-IN INSTITUTION AND HOSPITAL FOR WOMEN.—In West Street, Brighton. House-surgeon, unmarried, and under 35 years of age. Salary, £20 per annum, with furnished quarters and board, gas, coal, and attendance. Applications to the Honorary Secretary before December 24th.

BRISTOL INCORPORATION.—Medical Officer for the Workhouse at Stapleton; doubly qualified. Salary, £20 per annum, with residence

- and rates and taxes free, together with vaccination fees. Applications to J. J. Simpson, Clerk to the Guardians, St. Peter's Hospital, Bristol, by December 31st.
- CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL.** Great Portland Street, W.C.—Assistant Registrars. Applications to Richard A. Green, Secretary, by January 11th, 1899.
- CHILSEA HOSPITAL FOR WOMEN.**—Clinical Assistantships. Applications to the Secretary.
- CHORLTON LONDON DISPENSARY.** Manchester.—Resident House-Surgeon, doubly qualified, unmarried. Salary, £250 per annum, with furnished rooms and attendance. Applications to the Secretary before December 31st.
- CITY OF LONDON UNION INFIRMARY.** Bow Road, E.—Dispenser, must be between 25 and 45 years of age. Salary, £200 per annum, and dinner daily. Applications on forms provided to be sent to F. W. Crane, Clerk to the Guardians, St. Bartholomew Close, E.C., by December 31st.
- CITY ORTHOPEDIC HOSPITAL.** Hamlyn Garden.—Assistant Surgeon, who must be a Fellow or Member of the Royal College of Surgeons of England. Applications to the Committee.
- COUNTY BOROUGH OF CARDIFF.**—Resident Medical Officer of the Reception Hospital for Infectious Diseases, unmarried. Appointment for one year. Salary, £250 per annum, with board (except on alternate days) and residence in the hospital. Applications to Dr. Walford, Medical Officer of Health, Town Hall, Cardiff, by January 1st, 1899.
- DENTAL HOSPITAL FOR LONDON.** Leicester Square, W.C.—Assistant Dental Surgeon; must be L.D.S. Applications to J. Francis Pink, Secretary, by January 6th.
- DENTAL HOSPITAL FOR LONDON AND LONDON SCHOOL OF DENTAL SURGERY.** Leicester Square, W.C.—Demonstrator. Honorarium, £50 per annum. Applications to J. Francis Pink, Secretary, by January 6th.
- DEVON COUNTY ASYLUM.**—Assistant Medical Officer; single. Salary, £250 per annum, with board, lodging, and washing. Applications to Arthur E. Ward, Clerk to the Visitors, Bedford Circus, Exeter, by December 31st.
- HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.** Bromley.—Four Clinical Assistants in the Out-patient Department, and Clinical Clerks to the In-patient Physicians. Applications to the Secretary by December 31st.
- HULME DISPENSARY.** Manchester.—Honorary Physician. Applications to the Honorary Secretary by December 31st.
- KING'S COLLEGE, London.**—Demonstrator in Bacteriological Laboratory. Applications to Walter Smith, Secretary.
- LIVERPOOL DISPENSARIES.**—Assistant Surgeon; unmarried. Salary £200, to be increased to £250 per annum after the first year's service, with apartments, board, and attendance. Applications to R. B. Greene, Secretary, 64, Moorfields, Liverpool, by December 31st.
- OWENS COLLEGE, Manchester.**—Junior Demonstratorship in Physiology and Histology. Salary, £150 per annum. Applications to the Registrar by January 4th, 1899.
- PNMELAR AND STEPHEN BICK ASYLUM DISTRICT.**—Second Assistant Medical Officer for the Asylum at Bromley, Middlesex. Salary, £200 per annum, increasing £25 yearly to £225. Applications, on forms provided, to be sent to Robert Fawcett, Clerk to the Managers, Bromley, Middlesex, E., by January 2nd.
- SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN.** Marylebone Road, N.W.—Surgeon to the Out-Patient Department. Applications to the Secretary, George Scudamore, by January 7th, 1899.
- TAUNTON AND SOMERSET HOSPITAL.**—Assistant House-Surgeon. Appointment for six months, without salary, but board, washing, and lodging in the institution provided. Applications, endorsed "Assistant House-Surgeon," to J. R. Edmonds, Finchard, Secretary, 18, Hammet Street, Taunton, by December 31st.
- WESTMINSTER GENERAL DISPENSARY.** Gerrard Street, Soho, W.—Resident Medical Officer. Applications to the Secretary by December 31st.
- WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.** Wolverhampton.—Resident Assistant. Appointment for six months. Board, lodging, and washing provided. Applications, inscribed "Application for Resident Assistant," to the Chairman of the Medical Committee by December 30th.
- YORK COUNTY HOSPITAL.**—Assistant House-Surgeon, doubly qualified. Salary, £200 per annum, with board, rooms, washing, etc. Applications to Fred W. Howell, Secretary and Manager, by January 1st, 1899.

MEDICAL APPOINTMENTS.

- BACK, H. H., M.B.Lond., M.R.C.S.,** appointed Medical Officer of Health to the Aylesham District Council.
- BATR, J. Beabant, L.S.A.,** appointed Surgeon in the Royal Mail Steamship Company.
- BONN, R. St. G., M.B., C.M. Edin.,** appointed Second Assistant Medical Officer to the Metropolitan Asylum, Caterham, Surrey.
- BOWEN, W., M.R.C.S.Eng.,** appointed Medical Officer for the Sixth District of the East Ashford Union.
- CHERRY, A., M.R.C.S.Eng.,** reappointed Medical Officer for the Horsey District of the Smallburgh Union.
- DICKIN, E. P., M.B., C.M. Edin.,** appointed House-Surgeon to the Northampton Infirmary.
- EDWARDS, Alfred, M.D. Edin.,** appointed Physician on the staff of the St. George's and St. James Dispensary, King Street, Regent Street, W.

- FARRAR, Charles, M.D., L.F.P.S. Glasg.,** reappointed Medical Officer of Health to the Chatteris District Council.
- FOSTER, A. Graham Poljanbo, M.B., C.M. Edin.,** appointed Assistant House-Surgeon to the Northampton Infirmary.
- HARTER, Joseph, L.R.C.P. Lond., M.R.C.S.,** reappointed Medical Officer of Health to the Barnstable Rural District Council.
- HARVEY, Frank, M.R.C.S.Eng., L.S.A.,** appointed Medical Officer of Health to the Padstow Urban Council.
- HODG, J. A., M.R.C.S.Eng., L.R.C.P. Lond.,** appointed Medical Officer for the Stowood District of the Sturminster Union, vice C. Harwood, M.D., L.R.C.S. Edin., resigned.
- JENNINGS, W. M., M.B.,** appointed Medical Officer for the Kenchurch District and the Workhouse of Abbeystead Union.
- LAUGHTON, Gerald R., M.B., C.M., L.R.C.P. and S. Eng., L.F.P.S.G.,** appointed Medical Officer to the Skonfrith District of the Marnmouth Union.
- LEWIS, Frederick W., M.R.C.S., L.R.C.P. Lond.,** appointed Senior House-Surgeon to the General Infirmary at Gloucester and the Gloucestershire Eye Institution.
- LISTER, THOS. D., M.D., B.S. Lond., F.R.C.S. Eng.,** appointed Honorary Surgeon to the Westminster General Dispensary.
- MACLENNAN, D. V., M.D. Edin.,** reappointed Medical Officer of Health to the Widnes Town Council.
- MANN, E. P., M.B., M.R.C.S.Eng.,** appointed Assistant Medical Officer of Health for Liverpool.
- MOORE, T., M.R.C.S.Eng., L.M.,** appointed Medical Officer of Health for the Stockport Rural District.
- MORTON, A. G., M.R.C.S.Eng., L.S.A.,** reappointed Medical Officer of Health to the Smallburgh Urban District Council.
- NEWBY, Thomas, M.B. Lond., M.R.C.S.Eng.,** reappointed Medical Officer of Health for the Borough of Grimsby.
- O'CONNELL, J., L.R.C.P., L.R.C.S.,** appointed Senior Assistant Medical Officer at the Torketh Park Workhouse, vice—Walker, resigned.
- PATRICK, J., M.B.,** appointed Assistant Medical Officer to the Belfast Lunatic Asylum.
- PERROTT, G. J., L.R.C.P., L.R.C.S.I.,** appointed Medical Officer of Health to the Kingswood Urban Council, vice Henry Grace, L.R.C.P. Lond., M.R.C.S.Eng., deceased.
- RICHARDS, John E., L.R.C.P., L.R.C.S. Edin.,** reappointed Medical Officer and Public Vaccinator for the Woodhouse District of the Huddersfield Union.
- RICHARDSON, T. W., M.R.C.S.Eng.,** appointed District Medical Officer of the Beckham Union.
- RODERICK, S. J., M.B., C.M. Edin.,** reappointed Medical Officer of Health to the Ilanely Urban Council.
- STANLEY, H., M.B.,** appointed Medical Officer for the Fifth District of the East Ashford Union.
- STEPHENSON, Sydney, M.B., F.R.C.S.E.,** appointed Ophthalmic Surgeon to the North-Eastern Hospital for Children, Hackney Road, Shoreditch.
- THOMPSON, H. E., M.R.C.S., L.R.C.P. Lond.,** appointed Assistant House-Surgeon to the General Infirmary at Gloucester and the Gloucestershire Eye Infirmary.
- THIBBETTS, T. M., M.B. Lond., M.R.C.S.Eng.,** appointed Medical Officer of Health for the Quarry Bank Urban District, vice W. H. Thompson, M.D. Durh.
- WAGSTAFF, J. P., L.R.C.P. Lond., M.R.C.S.,** appointed Medical Officer for the Felham District of the Bishop Stortford Union, vice P. G. Griffith, M.B. Durh., resigned.
- WALKER, Dr.,** reappointed Medical Officer of Health to the Stoke Urban District Council.
- WALKER, Dr. E. W.,** appointed Medical Officer of Health for the Shoburness Urban District.
- WALSH, Leslie H., L.R.C.P. Lond., M.R.C.S.,** appointed Resident Medical Officer to the Royal Mineral Water Hospital, Bath.

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths to 2s. 6d., which sum should be forwarded in post office order or stamps with the notice not later than Wednesday morning, in order to ensure insertion in the current issue.

BIRTHS.

- BLATCHLEY.**—On December 10th, at 97, Evelyn Street, Deptford, S.E., the wife of J. B. Challands Blatchley, L.R.C.P., L.R.C.S., and L.M. Edin., of a daughter.
- BONAR.**—At his residence, 114, Via del Balduino, Piazza di Spagna, Rome, on December 8th, the wife of Dr. Thomson Bonar, of a son.
- RENDER.**—On December 4th, at 2, Buckland Terrace, Plymouth, the wife of C. E. Russel Rendle, M.R.C.S., L.R.C.P., of a son.

MARRIAGE.

- PATERSON—MUTLOW-WILLIAMS.**—On November 4th, at the Cathedral, Barbados, West Indies, by the Right Reverend the Lord Bishop of Barbados, assisted by his chaplain, the Rev. W. G. Murray, George William Paterson, M.R.C.S., L.R.C.P. Lond., of Grenada, W.I., to Olivia Hannah, second daughter of Thomas Mutlow-Williams, Esq., of Malda Vale, London.

DEATH.

- MIDDLETON.**—On November 23rd, at the residence of his father, Athgoe Park, Shanklin, co. Dublin, Abraham Hargreave Middleton, M.B., B.A., aged 25. Deeply mourned.

LETTERS, NOTES, AND ANSWERS TO CORRESPONDENTS.

COMMUNICATIONS FOR THE CURRENT WEEK'S JOURNAL SHOULD REACH THE OFFICE NOT LATER THAN MIDDAY POST ON WEDNESDAY. TELEGRAMS CAN BE RECEIVED ON THURSDAY MORNING.

COMMUNICATIONS RESPECTING EDITORIAL MATTERS SHOULD BE ADDRESSED TO THE EDITOR, 420, Strand, W.C., London; those concerning business matters, non-delivery of the JOURNAL, etc., should be addressed to the Manager, at the Office, 420, Strand, W.C., London.

ATTORNEYS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate beforehand with the Manager, 420, Strand, W.C.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look to the Notices to Correspondents of the following week.

MANUSCRIPTS FURNISHED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

IN ORDER TO AVOID DELAY, IT IS PARTICULARLY REQUESTED THAT ALL LETTERS ON THE EDITORIAL BUSINESS OF THE JOURNAL BE ADDRESSED TO THE EDITOR AT THE OFFICE OF THE JOURNAL, AND NOT TO HIS PRIVATE HOUSE.

PUBLIC HEALTH DEPARTMENT.—We shall be much obliged to Medical Officers of Health if they will, on forwarding their Annual and other Reports, favour us with duplicate copies.

Queries, answers, and communications relating to subjects to which special departments of the BRITISH MEDICAL JOURNAL are devoted will be found under their respective headings.

QUESTIONS.

M.D. asks to be referred to the best book of instructions for preparing and mounting specimens, pathological and physiological, for the microscope.

AN INQUIRER desires to know if there is any book written by a medical man which gives information to mothers and schoolmistresses on the treatment of girls on arriving at the age of puberty?

PRACTICE IN QUEENSLAND.

QUEENSLAND writes: Can any member kindly say from personal or reliable knowledge if a competence could be made in one of the Queensland Government village settlements by a fully qualified and experienced middle-aged man of robust health, and with £200 capital and some knowledge of agriculture and fruit growing?

COLONIAL MEDICAL SERVICES.

WHY INQUIRER asks: Is it necessary that candidates for medical appointments in the Colonies should be resident in the United Kingdom? In the answer on this subject in the Educational Number of the BRITISH MEDICAL JOURNAL this is implied, although not distinctly stated to be the case.

"Medical candidates resident in the Colonies are equally eligible for appointments in the Colonial Medical Services with those resident in the United Kingdom. The only difference of procedure is that candidates resident in the Colonies should, in accordance with the Colonial Office regulations relating to correspondence with the Secretary of State, send their applications through the Governor."

REMOVAL FROM THE "REGISTER."

X. Y. Z. writes: When the name of a person is taken off the *Medical Register* for the offence of "covering," but he still retains his qualifications, is he required to give up practice entirely? and, if not, what professional work can he undertake without detriment to the restoration of his name at some future time? What is the usual length of time before he may be restored?

"When the name of a medical man is erased from the *Medical Register* for the offence of "covering," or for an offence declared by the General Medical Council to be "infamous conduct in a professional respect," he should, although he may retain his degree or diploma, absolutely cease to practise his profession. It is only by ceasing to practise that he can recognise the penalty which has been inflicted, and which deprives him of the right to act as a registered medical practitioner. If such a person employed a registered medical practitioner to carry on his practice, while he remained in the locality taking part in the work, he would place the registered medical man in the untenable position of being liable to a charge of "covering" for enabling him to evade the consequences of the judgment of the General Medical Council. If he went to another locality and acted as a medical assistant he might compromise his employer in the same sense. There is, therefore, only one course to pursue—namely, to cease absolutely to practise, and, if possible, devote himself to the study of his profession by attending hospital practice or doing some similar work. Giving evidence of such action he might apply for restoration at the end of twelve months, but, unless under very exceptional circumstances, two years would probably elapse before his restoration to the *Register*.

ANSWERS.

LEX does not enclose his name. He should address the Public Branch of the British Medical Association on the subject.

M.H.—We have referred our correspondent's letter in a direction which is likely to lead to investigation.

A. would probably find what he desires in the catalogue of the National Temperance Publication Dept., 2, Finsbury Row, E.C.

F. T. M. writes, in reply to "Member," in the BRITISH MEDICAL JOURNAL of December 7th, p. 1470, 19 suggest phrenology (autography).

M.D.—The document in question is confidential. It should be brought to the notice of the Assistant Commissioner of the Metropolitan Police, New Scotland Yard, S.W.

A. A.—We entirely agree with our correspondent's view that co-operation is necessary, but we think that the best machinery for bringing about this co-operation is the formation of the Association of special local committees appointed by them.

CONVICTION OF SUPPOSITIOUS PRACTICE.

W. D. S.—In law a person may have all the qualifications required for registration, but unless he be registered under the Medical Act he cannot be recognised as a "duly qualified medical practitioner" according to the Act. The non-registered are therefore not entitled to assume any "name, style, title, or addition" implying that they are duly registered.

REVUE TUBERCULOLOGIQUE.

F. W. M.—The recent work by Professor Nocard, of Alfort, entitled *Les Tuberculoses Animales: leur Rapport avec la Tuberculose Humaine* (Paris: G. Masson. 2 fr. 80 c.) contains an excellent summary of the subject, and deals at length with the question of tuberculous disease, as to which our correspondent specially inquires. The book has been translated into English by Dr. H. Seufferd, and is published by Messrs. Baillière, Tindall, and Cox under the title *The Animal Tuberculous and their Relation to Human Tuberculosis* (2s.).

INSURANCE OF CHILDREN.

O. F.—We are not aware of any Act passed during the last five years which deals with the insurance of children. We know of no Act which gives a friendly society the power to enrol members down to the age of one year. The Friendly Societies Act of 1875 states that "a person under the age of 21 but above the age of 16" may become a member. Sec. 18, par. 8—and a special clause follows stating that "societies and branches consisting wholly of members of any age under 21 years, but exceeding 3 years" may register under the Act. Three years is, we believe, the minimum age of membership in any case, but in friendly societies small sums may be assured on the lives of children of any age, and large numbers of such assurances are effected on the lives of infants. This, however, does not make the infants members, the membership belongs to the parents who effect the assurances.

GAS AND ETHER APPARATUS.

DR. STANLEY B. DE BUTTS (Kelson Terrace, S.W.) writes: In reply to "X. Y. Z.'s" query concerning a gas and ether apparatus, I think he will find the pattern in which the same India-rubber bag is used for both the anesthetic vapours to be the best, as it is the least costly. It consists of an ordinary cover's rubber, to which a tap is inserted at the neck joint of the bag to admit nitrous oxide at the commencement of the administration. The apparatus costs complete 1s. 6s. (Messrs. Cox and Co., Bond Street, E.C.4.), but the necessary addition of the tap and tube to join the gas bottles could be fixed to any chamber or inhaler for about 1s. or 1s. 6s. Other patterns, such as Hewitt's and Harris's, though excellent, are considerably more expensive and less portable, as they require a separate gas bag, and include more or less complicated valve stopcocks. I should advise "X. Y. Z." to keep his gas in two 2-gallon bottles, which cost about 2s. 6s. empty, or 4s. 6s. if charged. I think he will also find the struggling during ether inhalation he refers to greatly obviated by strictly observing the method laid down in Dr. Hewitt's *Instructions*, the principal point being the absolute cessation of air till the patient is unconscious. I should be happy to answer more fully if "X. Y. Z." will communicate with me.

MEDICAL FEES FOR LIFE ASSURANCE EXAMINATIONS.

EXAMINER writes: Permit me to call attention to a mistake in Dr. Lockhart Telford's letter in the BRITISH MEDICAL JOURNAL of December 14th. He gives the Prudential Assurance Company amongst the list of those who pay 2s. 6d. for a proposal of 2000 and upwards. I examine a large number of cases for the Prudential Assurance Company, and would point out that for a proposal of 2000 they only pay a fee of 10s. 6d., but that for any sum over 2000 they pay 2s. 6d. For a proposal of 2000 the fee is 10s. 6d. They do not ask the medical referee or examiner to make a careful analysis of the urine for sugar, urea, etc., but they expect him to say if there is any reason to suspect disease of the kidneys or generative organs. I quite agree with the *Instructions* which state that the fee is too low, and I think one examines quite well enough for any examination the proposal for which amounts to 2000. I may also say that the highest fee paid by the Prudential in one instance, so that if the proposal is 2000 or 2500 the fee paid to the medical examiner is the same—namely, one guinea.

MEDICAL AID SOCIETIES.

H. writes: Our correspondent has a good very proper, and it is satisfactory to hear that this course has been decided on to support his own practice. Had his action been either to aid practitioners his own practice would have suffered in the long run, and he might not unnecessarily have been regarded by his professional brethren in the neighbourhood as the prime cause of any harm brought on their practice by the operations of the society. It is therefore highly probable that by the dignified action of a leading practitioner of a whole district may be protected from the ravages of these societies, which have done so much to bring discredit on the profession.

NOTES, LETTERS, ETC.

PASTEUR FILTERS AND THE MADAGASCAR EXPEDITION.

MAIDMARRY WRITES: As regards the form of fever prevalent among the troops of this expedition, as I know something of that island, I am disposed to think that at least 50 per cent. of it was malarial, fully under the control of quinine. This fever would not be so much affected by the use of the Pasteur filters, the microbe being generally airborne.

THE "INDEX MEDICUS"

MR. ROGER WILLIAMS, F.R.C.S. (Ireland) writes: Although the *Index Medicus* is an admirable bibliographical work, I am not at all surprised that it has failed to attract adequate support. The truth is that English speaking students require something more than a bare bibliographical record; they need as well brief abstracts in their own language of the chief publications. Germany and France are well provided for in this respect; but not a single work of the kind is issued in English. The progress of medical science in English-speaking countries is much impeded by this deficiency. It is a pity that the editors of the *Index Medicus* cannot be induced to modify their publication in the direction I have indicated, for I am convinced that it would then attract a large number of subscribers.

ENTERIC FEVER IN INDIA.

HINDU WRITES: The importance of water in propagating this fever in India cannot be overestimated, but there are two other factors (excluding age) in operation that are not much in evidence in this country (England). One, the dry earth system of conservancy in general use. The contents of the pails are soon dried up by the fierce heat, and as the latrines are never far from the sleeping rooms, the dust from them is often blown into these places, and over the soldiers' food stored in them. The other factor is the flies that act as carriers between the pails in the latrines and the food in the barrack rooms.

ALCOHOL IN MENTAL SHOCK.

MR. T. L. CHAISTER (District Surgeon of Natal, Cala, Cape Colony) writes: In your article on Alcohol and its Effects, you say, p. 992, "that alcohol acts first as a narcotic—that there is first no stimulation," etc. Perhaps it may be worth while for me to report the following case:

A lady who had not to my positive knowledge taken any form of alcohol for any number of years not less than seven, may be ten, was suddenly confronted with "information," which (to use her own words) "told her I feel overpowered, I am oppressed;" and she seemed to me to be suffering from mental shock. She was not a strong woman, but subject to weak heart and uterine complication. I at once administered to her half a tumbler of Perrier's Sans Sucre Champagne, and in five or less minutes she was apparently sleeping. I asked her "How she felt now?" "I feel quite comfortable, all thought is gone, just as if you had given me a little chloroform; I want to sleep." The effect I wanted was produced; the shock passed over.

I ought to add that this occurred at night—10 P.M.—long after any food had been taken, and after a quiet evening.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

Eight lines and under	20	4	0
Each additional line	0	0	6
A whole column	1	17	6
A page	5	5	0

An average line contains six words.

Advertisements should be delivered, addressed to the Manager, at the Office, not later than noon on the Wednesday preceding publication; and if not paid for at the time, should be accompanied by a reference.

Post-Office Orders should be made payable to the British Medical Association at the General Post-Office, London. Small amounts may be paid in postage-stamps.

N.B.—It is against the rules of the Post Office to receive letters at *Postes Restantes* addressed either in initials or numbers.

AN ADDRESS

DELIVERED AT THE OPENING OF

THE SECTION OF PATHOLOGY,

At the Annual Meeting of the British Medical Association at
London, July, 1886.By SAMUEL WILKS, M.D., F.R.C.P., F.R.S.,
Consulting Physician to Guy's Hospital.

ON REPARATION.

As President of the Section of Pathology I trust you will not consider it out of place if I give a short address embracing a few remarks on a subject in which I have all my life taken an especial interest. When looking back upon my own past medical career I have always found my mind dwelling with the greatest satisfaction upon opinions which I very early derived from my introduction to, and experienced in, the *post-mortem* room. I there soon perceived that diseases supposed to be recent were very often but the termination of chronic changes, and that the generally accepted idea that diseases arise suddenly in healthy persons was not in accord with fact. I am not alluding to specific diseases arising from the introduction of germs from without, for they appear to have a general preference for healthy persons, but to pathological changes originating from within, and mostly induced by the ordinary conditions of life. The opinions which I then formed with regard to these processes were probably strengthened, or, at all events, held with greater tenacity by myself when I subsequently found they were in accord with the doctrines which were coming into vogue with respect to every other branch of science both in the organic and inorganic world. They seemed to be in perfect agreement with the lessons taught in the *Origin of Species* by Darwin, and in the *Principles of Geology* by Lyell. The latter had shown in a most masterly manner how the changes we observe on the surface of the earth came about by slow degrees and not by violent catastrophic action, as had previously been taught. It was therefore satisfactory to think that pathology might take its place in perfect harmony with other branches of biology and natural history.

The most evident and most momentous fact in Nature is the incessant change ever going on in the world; in fact throughout the universe as far as the power of the telescope and spectroscope can reach motion and action never cease. This endless activity in the organic world implies continual growth and decay, or, in other words, life and death. As the earth in its revolutions produces the seasons, so we witness living objects growing up under the influence of the sun's rays, and again decaying as the warmth departs. The higher animals take a few revolutions round the centre of heat, during which time they first grow and then decay; and one of these is man. The variable time in which he endures is determined in great measure by his surroundings, for many of those which are detrimental to him and shorten his days are quite obvious to us, and to study still further his environments and discover their influences for good or evil is one of the most important provinces of the physician.

Now just as the body grows and decays as a whole during a term of years, so we may see the two processes of production and destruction going on in its several parts when subjected to any special stimulus, such as an injury or other morbid influence. It is to this subject I wish to draw your attention, for although my own mind has often been directed to it, I think in all that I have written and taught I have failed to lay sufficient weight on the distinction between them. When speaking of any unnatural condition or any adventitious substance found in the body, I have, like many others, employed the term "morbid," and been content with the expression, whereas a little further consideration would have shown that only a portion of what is found would rightly answer to the term, a part only being strictly pathological, whilst the other is a result of a true physiological process; in fact the simple words "disease" or "morbid" imply too much of destruction without a recognition of a corresponding reparation.

With regard to injuries, the reparative and conservative conditions are generally clear, witnessed in scars, or where

a spine of bone is made to support the fractured shaft of a limb which is united at an angle. In many forms of internal disease also we all recognise the reparative process, and have no difficulty in distinguishing the physiological from the truly pathological: for example, in valvular disease of the heart, where we at once perceive how the hypertrophied cavities are the manifestation of physiological and conservative processes, and in the same manner hypertrophy of the muscular fibre of the uterus, of the intestine, or of the bladder, indicate obstruction in the passages of these organs. There are, however, more complex states where the pathological and physiological changes have gone on side by side and thus make it more difficult to assign to each their due proportion. It may be that the constructive and destructive forces are more intimately associated than we have hitherto conceived, and that a mutual relation may exist between them of an electrical or chemical nature. This was suggested in the remarkable observations and experiments of the Golding-Birds, father and son, who showed that if one electrode be placed on an ulcer the latter will rapidly heal whilst a sore is being produced at the other positive pole. In an ordinary ulcer the two processes are seen going on before the eye, for although the old definition implied a simple destructive process merely, yet we can clearly perceive during the process of granulation, and in the secretion, that new material is being formed.

Mr. Golding-Bird has well said that in an ulcer we see a constructive inflammation, and that there is not merely a loss of tissue, but there is embryonic life going on again—a recommencement of evolution, a redevelopment of growth from elementary cells, the embryonic elements being always present and roused to action by the inflammatory process, so that the two conditions of growth and decay are mutually dependent. This local process is the same which is going on throughout the whole body, where the nourishment is obtained from outside materials, or, as Herbert Spencer puts it, "we grow by reconstructing the elements previously dispersed in animals and plants." It is the same process indeed which is going on throughout the world. Naturalists tell us, for example, of the formation and decay of coral reefs; whilst these are constantly growing and being renewed on the surface, they are wasting beneath, so that the lower parts consist of nothing but the detritus of the older reefs which have broken up. Growth and decay are thus constantly proceeding, and Nature, with her myriad voices, proclaims the great truth that life is ever ceasing and ever being renewed.

In the human being the same processes are perpetually going on, not only in health but in states so called diseases, as in the above-mentioned example of ulcer. Yet this double process is continually overlooked, no doubt from the difficulty we have in being able to separate the reparative from the true morbid action. In most instances this is owing to the fact of the reparative material not being equal in organisation and similar in structure to the original tissue. The complex parenchymatous structures are not renewed after injury like the simpler ones of bone or areolar tissue, although occasionally we meet with a true growth of nerve fibre or adenoid structure. What we generally mean, therefore, by repair is not reparation by a growth resembling the original structure, but by a growth of lower organisable material. Still the attempt at repair, in whatever way it may be accomplished, is continually visible, and the object of these remarks is to point out, not only where we have been remiss in failing sufficiently to recognise the true interpretation to be put upon many of the new changes we meet with in the tissues, but have been content to style them all in a very cursory manner "morbid." This distinction has an important clinical side as regards prognosis and treatment besides being one of pathological interest.

I will endeavour to illustrate my meaning by one or two examples, and will take first the case of phthisis. During a long experience in practice I have seen nothing so common as an error in the prognosis of this disease. And why? Because the constructive changes have been confounded with the destructive ones; in fact, the very signs which the beginner regards as the strongest proofs of disease are those which indicate the probability of cure. He learns the signs of a cavity in the lung, and then recognising its existence in a particular case he immediately condemns his patient,

feeling instinctively that nothing could be more terrible than the existence of a large hole in a vital organ. And yet a moment's consideration would show him that the dull resonant note, the absence of vibration in the chest walls, the sinking in, the pectoriloquy, etc., all point to a well-walled cavity due to a reconstructive action following the destructive process. The formation of this fibrous tissue has shut off the part destroyed from that of the healthy lung; a reparation and cure have been going on, and produced those marked physical signs which he has regarded as indicative of disease. No wonder, therefore, that a mistake in prognosis has been made, and that after condemning a patient who has manifested such physical signs the medical man has been surprised to find him still living years afterwards. I have, indeed, not only seen the mistake made by young and inexperienced men, but by older members of the profession; they have often confessed their surprise on seeing phthisical patients still alive whom they had condemned years before. This case of phthisis is perhaps the commonest example, where the constructive and destructive processes have not been sufficiently distinguished, but we will now take another case where the changes are more complex and where a greater difficulty exists in distinguishing those which may be regarded as destructive and those which are reparative. I refer to cirrhosis of the liver. This organ may be observed during life to be first enlarged and then become nodulated and shrunken; amongst other signs of the disease which the textbooks describe is an enlargement of the veins on the surface of the abdomen. These were thought at one time to be due to some pressure on the vena cava, but this is really not the case, and the appearance is now shown to be due to an enlargement of the epigastric vein in connection with the opening up of the old umbilical vein, which often becomes as large as a goose quill. Through this the portal blood flows and finds a free passage into the vena cava and systemic circulation. Injections may be easily made to pass from one system into the other. The patient in this way is relieved from an engorgement of the portal system and from the consequent dropsy. This enlargement of the veins, therefore, which is simply described as a sign of cirrhosis, should also be spoken of as a sign of a reparative character. And probably this is not all, for when the cirrhotic organ is examined carefully and microscopically, we find that, although the nodules are composed mainly of atrophied hepatic tissue, there has also been an attempt to replace it by a new formation of cells and vessels. New blood vessels may be seen and apparently new ducts, as well as cell growth. Now although these new elements are not perfect enough to take on the function of the liver, there can be little doubt that they do relieve the circulation in a disabled organ. That new hepatic structure may grow under the strain of necessity is seen in those cases where portions of the liver have been destroyed by injury or disease in the same way that one kidney will double its size when its fellow from any cause has become atrophied; illustrating the doctrine of Aristotle that function precedes organisation.

Many other illustrations might be mentioned where a truly morbid process occurs intermingled with the reparative. A common example of this may frequently be found in cancerous pylorus, where a hard lump is felt in the right hypochondrium. This is composed not only of cancer but of hypertrophied muscular and areolar tissue, and sometimes, if the primary affection has been the cicatrization of a chronic ulcer, the whole tumour is composed of a conservative or reparative material.

In diseases of the spinal cord it is very difficult to place the truly morbid and conservative processes in their right category. I have little doubt that in a case, for example, where a man for 20 years has had symptoms of locomotor ataxia, the sclerosis from which he is said to suffer is the result of a more active pathological change which occurred at the commencement of his malady. At that time the new tissue took the place of the old, and the cord has remained quiescent ever since. As such a patient is able to follow his sedentary occupation and has a fair enjoyment of health, he can scarcely be regarded as the subject of disease, or no more so than a person who has a cicatrix on the skin arising from an old injury, although the tissue may differ from the original healthy one.

If time had allowed me to carry the subject into clinical medicine I could have shown the importance of endeavouring to distinguish physiological processes from the purely pathological ones, such as the splutary hæmorrhage from the lungs in heart disease or the serviceable hæmatemesis and melæna in cirrhosis of the liver; we might also see how diarrhoea is a real safeguard in nephritis, or a profuse sweating in bronchitis. The mode in which organs and functions accommodate themselves to one another or supplement one another requires our most careful study. That vigorous action must go on to a greater extent than we imagine is even in the fact that when we die ever after death the kidneys to be scarcely a quarter of their normal size, we express our surprise at the absence of symptoms indicative of so great a destruction; and the same when we find a marked cirrhosis of the liver where the disease has never been suspected. A study of these relations of organs ought to lead us to more rational modes of treatment, and prevent us from merely making an attack upon symptoms whilst in ignorance of their true significance.

I have now, I trust, said sufficient to make my opening statement clear, that, as a teacher of pathological anatomy, I have not paid sufficient regard to the distinction between constructive and destructive processes; that whilst there have been decay and degeneration there have been also growth and regeneration. To study these for the sake of discovering the several influences exerted in the production of each is a matter of great practical import; they also show, as I have already affirmed, that pathology is governed by the same laws as those which exist in every other department of Nature, and therefore may safely take its place among the other sciences.

SOME CASES IN WHICH ARTHRITIS AND ENDOCARDITIS WERE PRODUCED BY DRUGS WHICH DIMINISH THE SOLVENT POWERS OF THE BLOOD FOR URIC ACID.

By ALEXANDER HAIG, M.D. Oxon., F.R.C.P.,

Physician to the Metropolitan Hospital, and the Royal Hospital for Children and Women.

For how many years was the evidence which now seems so obvious of the earth's motion or the blood's circulation overlooked because the facts were regarded through the mist of preconceived ideas and partial ignorance? May not our failure to find the cause of acute rheumatism be due to similar difficulties, our preconceived ideas and our ignorance of the chemistry of uric acid combining to prevent our seeing the real relation between cause and effect?

For years we have been observing that people get their first attack of rheumatism or a relapse later on, under several fairly definite conditions, such as exposure to cold after heat and fatigue, the sudden onset of a febrile disease, or some change in diet, or the administration of some acid or acid-forming food.

But what we did not know was that one and all of these causes affected in a most important manner the solubility of uric acid in the blood, preventing the blood from continuing to hold it in solution, and so bringing about its precipitation or concentration upon the fibrous tissues of the joints, the fascia, or the heart; with the result that it set up more or less marked irritation in these structures, and produced the phenomena of acute rheumatism.

We did not know further that a very large number of drugs, metals, salts, acids, and other things which directly or indirectly interfere with the solubility of uric acid in the blood, produce precisely the same results as the above-mentioned causes, and precipitate more or less irritation of fibrous tissues by uric acid.

Further, we did not know that every drug which we had empirically used in the treatment of acute rheumatism, alkalies, colchicum, hot baths and blankets, or salicylates, had this one effect common to them all—that they increased the solubility of uric acid in the blood, and so led to its being taken up from the fibrous tissues and excreted in the urine,

with the result that the irritation in the fibrous tissues quickly begins to subside.

So long as we persist in believing that rheumatism is due to some unknown cause, miasm or microbe, we shall continue to say that the patient had an attack or a relapse with endocarditis, which resulted in serious heart lesion and a crippled life, and shall regard these things as inevitable, much as do the jury who bring in a verdict of "Death by the visitation of God."

But once we realize that these diseases depend solely upon the quantity and solubility of uric acid in the blood, and that, as I have further pointed out, the quantity of uric acid in the blood and its solubility in that fluid are absolutely and completely within our control, we shall pass at one bound from the unknown to the well known, shall see that these deadly diseases are not the result of unpreventable causes, but of our own dietetic follies; and that our children need not be crippled or decimated by them, if we allow them to live according to their own inclinations on milk and garden produce, and abstain from forcing down unwilling throats the stimulating but deadly products of animal metabolism.

For some years past I have been in the habit of asking all rheumatic children I have seen this question: If I offered you a plate of fruit and a plate of meat, which would you take? I have never seen a child that would have taken the meat.

Before giving you my own cases I will just refer to the well known cases of Sir W. Foster, who, with the object of diminishing the amount of sugar, administered lactic acid to two patients suffering from diabetes, with the result of producing severe arthritis resembling acute rheumatism, and in one of the cases six attacks were produced by repeated administration of the acid.

I have every reason to believe that any acid that is absorbed and affects the alkalinity of the blood will produce similar effects if it is given at a time when there is an excess of uric acid in the blood,¹ and the only point about diabetic cases is that they very frequently have an excess of uric acid in their blood as I have elsewhere pointed out.² Not only acid but any drug (and there are many of them) that interferes with the solubility of uric acid in the blood will do the same thing.

Dr. Lauder Brunton speaks³ of cases in which both rheumatism and endocarditis have been produced by injecting acids into the blood, and he also mentions an instance in which drinking the red wine of Southern Europe appeared to keep up a lumbago from which a man was suffering, and that it had often acted similarly in other cases. With regard to endocarditis, he refers to a thesis for the degree of M.D. in the University of Edinburgh presented by Dr. J. A. MacDougall in 1865, and says that he was able, by injecting phosphoric acid into the blood "to produce undoubted evidence of endocarditis."

Coming a few years after these remarks of Dr. Brunton's were made, the following case startled me very greatly and made me fear that I had inadvertently caused both rheumatism and endocarditis, and I shall leave my readers to judge for themselves whether this was so.

CASE I.—M. J., aged 17, was suffering from phthisis of the left apex, with some tubercular trouble also at the left base. In March, 1894, he had some fever, and on March 10th the temperature at the left base, with a thermometer of 100°. After a few days it had the temperature began to come down, and on March 15th, as his appetite was bad and he was a good deal pulled down by night sweats, I gave a mixture containing some nitro-glycerine, and a few days later, on March 20th, he came to me with the complaint of pain and tenderness about the left shoulder joint, increased by movement of the limb; the temperature had risen very decidedly, and on touching over the apex of the heart I was horrified to find a distinct systolic murmur which I had not noticed before. I at once stopped the mixture and gave a mixture of colic and opium, and it was found that the temperature was down and the pain in the shoulder had gone; but the systolic murmur remained, and, though I saw him from time to time for six weeks, it never completely disappeared. I have no doubt whatever that I have caused some arthritis, and I fear also some endocarditis as well.

CASE II.—J. B., aged 17, suffering from chorea, was admitted under my care at the Royal Hospital for Children and Women on October 25th, 1894. The temperature on admission was 100°, the pulse 120. I examined the heart, and, finding no murmur, but having a mixture containing nux. at the apex, and to be taken three times a day. On the 28th the temperature was nearly normal, on October 31st it rose to

100° in the evening, on November 1st to 100°, and November 2nd to 100° in the evening. It then kept between 99° and 100°, but on November 5th the pulse had risen to 140 and above, and it remained at the same time after this; the arthritis was left off. On November 10th the highest temperature was 100°, and higher (101° and 102°) was given three times a day. On November 15th the temperature remained just about 100° until November 20th, when the arthritis was left off. On November 21st a well-marked systolic murmur was observed at the apex. From this onward the temperature kept about 99° rising to 100° on November 25th, and on December 1st. By this time the chorea, which had improved on the large dose of arsenic given at first, and more slowly afterwards, was quite gone. She was allowed to get up, and on December 27th she went home, the murmur at the apex of the heart remaining well marked to the last.

With regard to the onset of this murmur, I should say that Dr. Huntley, our very able resident medical officer, believed that there was a very slight systolic murmur at the apex from the first, but that it became more marked while under observation. It is quite certain, however, that I heard no murmur on admission, for my rule is not to give arsenic, and certainly not the large dose I gave in this case, if there is any sign of endocarditis.

The fairly marked rise of temperature under the arsenic, and its fall later on when it was reduced and left off, point, I think, to some inflammatory trouble in the body, and there was no evidence of any except in the heart; and then the very marked rise in the pulse rate about November 5th may, I think, be taken as pointing to some fresh heart trouble. I may say that my researches show that arsenic, so long as it does not upset digestion, causes a diminished excretion of uric acid in the urine.

CASE III.—A. S., aged 7, was admitted under my care at the Metropolitan Hospital on February 12th, 1895, suffering from bronchopneumonia, coming on pretty suddenly with headache and shivering. The temperature on admission was 100°, but it at once began to drop, becoming in the evening normal on the evening of February 13th. On February 14th it rose slightly above 100° in the afternoon, and on February 15th it kept between normal and 100°. On February 16th was the most obvious sign, and pneumonia was at its most serious point; at the left lung but a few days later there were more obvious signs of consolidation at both bases. There was no murmur over the heart and no increase of dulness. On February 17th, after the temperature had been at 100° or below it for four days, a systolic murmur was noticed at the apex of the heart, and the cardiac dulness was slightly increased to the left. The temperature rose and fell for some time between 99° and 100°, on February 22nd it became subnormal, making, however, daily excursions from 98° to 100°. On March 6th it became more steady and kept nearer the normal, but occasionally ran up to 100°. On March 9th the systolic murmur was still heard at the apex, and reduplication of the second sound at the left base. On March 10th I gave three times a day, a mixture containing 10 grains of digitalis, 10 grains of sulphuric acid, and some opium. I gave this mixture, and was very certain whether the raised temperature and the systolic murmur meant endocarditis or not; and, on the other hand, if the murmur was merely due to distention, the digitalis ought to have some effect. As there was none, however, I had the mixture changed to stop the digitalis at once if the temperature rose. On March 10th and 11th it rose to 100° and 100°, on March 12th it rose to 100°, and on March 13th to 100°. Accordingly, on March 14th the mixture was left off, and the temperature, though it touched 100° that day, at once began to fall, and did not reach 100° on either the two following days. On March 15th, as the temperature, though lower, was still unusually high, I gave some more of opium, and the temperature then became more steady, and with two exceptions, was always below 100° till the end of the month. The systolic murmur remained, and if anything it now became distinct over the base, and can be heard forwards in the axilla. The rest of the history is uneventful, the temperature during April and up to his discharge on May 23rd kept between 98° and 100°. The systolic murmur continued, and on April 13th the whole of the first sound was replaced by a murmur.

I have very little doubt that we had here to deal with an endocarditis possibly originating, as I have elsewhere suggested,⁴ in the great strain which falling temperature and its consequent rising blood pressure put upon the valves of the left side of the heart; that this went smouldering on for some time, and accounted for the irregular temperature which followed convalescence, and then blazed up again at once on the acid and digitalis mixture, for the digitalis not only put extra pressure and strain on the valves of the left side, but the sulphuric acid very probably precipitated some fresh urate upon them.

The temperature fell at once when these drugs were left off, but the local irritation went on smouldering as before, though before the patient went out it had been practically normal on several occasions for a few days.

CASE IV.—L. G., aged 6, was admitted into the Metropolitan Hospital on January 22nd, 1895, suffering from pneumonia of the right lung. He had just died in the local and hospital, and came that in the hospital, his mother at home. The pain and swelling in the fingers, which were swollen, tense, and shivering, began two days before. Temperature of admission 100°, pulse of night 120°. He was given a mixture containing

¹ *British Medical Journal*, 1895, vol. 1, p. 406.

² *Ibid.*, 2nd edition, ch. xiv.

³ *Proceedings of Royal Medical and Chirurgical Society*, April, 1890.

⁴ *Practitioner*, 1893, p. 176.

c. xx of salicylate of sodium four times a day. On January 24th the pain in the fingers had ceased. The temperature fell in the evening to 98.6° . After this he went on well, and the salicylate was left off on February 1st. On February 23d and 24th he suffered pain due to an alveolar abscess. On February 13th the temperature rose at night, and there was some return of the pain in the fingers and in the burden of the ocreanous process on the left side. On the morning of February 12th the temperature was 100.4° ; the clumps were extracted and some salicylate given again, and the temperature soon fell to normal and the pain went.

I have elsewhere¹ narrated the case of a boy where similar teeth trouble brought about a relapse of acute rheumatism; and I have also seen a case where the fever of an attack of pneumonia produced a relapse of gout in a patient who had had previous attacks.

CASE V.—E. S., aged 34, admitted into the Metropolitan Hospital on December 21st, 1894, suffering from acute rheumatism; had been confined nine weeks before.² The pains began three weeks before admission, first in the head and then in the limbs, shoulders, knees, wrists, and elbows in that order. The joints were all very tender. The temperature was 100° . She was given a mixture containing salicylate of sodium gr. xv and bicarbonate of potassium gr. i. to be taken every two hours. On January 1st the temperature was 100° , but the joints were still tender. The bicarbonate of potassium was omitted from the mixture. The temperature ran up that night to 102.8° (the highest it had been since admission), and there was a sharp return of all the pains. It fell to 100° the following morning, soon went down to normal, and never rose again.

Now what was the meaning of this sharp and sudden relapse when the drugs were altered? Was it due to the untamable microbe? I believe it is in my power to show that it was simply and solely a matter of the solubility of uric acid, for I have observed the same thing before under similar conditions.

Some years ago I had under my care a patient suffering from subacute Bright's disease whom I had put on admission on a mixture containing citrate of potassium. After she had been on this for several days she got some pain and swelling in several joints, so I stopped the potash salt and put her on salicylate of sodium, and in a few days her pains were very much better, and the salicylate was therefore left off and the potash mixture resumed; here again, just as in the case of E. S., there was a sharp but temporary return of all the joint pains as the result of the change of drugs.

It seems then quite clear that when arthritic pains are being relieved by a salicylate it will make them worse to add potash, and, conversely, when arthritic pains are being relieved by potash, it will do harm to add a salicylate. My own personal experience quite bears this out, for when some years ago I had my uric acid under less perfect and complete control than at present, I used occasionally, after severe exercise in hot weather, to get some pain and stiffness in the fascia either of the neck or the lumbar region; and I often found that these troubles were completely removed by a few doses of salicylate of soda, so long as I kept quiet and cool in the house in the morning; but if in the afternoon I went out and got overheated, still continuing the salicylate, my pains returned, and were worse—perhaps much worse—than if I had taken nothing.

Now what is the effect of going out and getting hot? It has been shown by Sir A. Garrod and myself that it produces a fall in the acidity of the urine, or, to put it more correctly, a fall in the hourly excretion of acid in the urine—say the hourly excretion of acid in any individual is equal to 3 grains of oxalic acid, then going out and getting very hot will, other things being equal, reduce it to $\frac{1}{3}$ or 2 grains in the following hours; that is to say, getting hot is equivalent to a dose of alkali.

But we have already seen that alkalies and salicylates do not pull well together, and we know that uric acid may be excreted in excess under alkali or under salicylate, and it must be extremely annoying to preconceived opinions that giving the two together does not produce the best effect of all; but unfortunately it does not, as can be proved by experiment.

And further there is, as I have for years been trying to point out,³ a chemical explanation of the fact, for it appears that salicylic acid differs from all other compounds of uric acid in being soluble in more or less acid fluids.

Now it is well known that salicylic acid compounds act best in acute arthritis, and better the more acute the case

and the higher the temperature; and it is a matter of the most simple observation that the higher the temperature the higher the acidity of the urine, the greater the hourly excretion of acid, and the less the alkalinity of the blood; therefore salicylates act well when the alkalinity of the blood is low.

It is further known that in subacute cases with but little rise of temperature salicylates may act far less satisfactorily, and I have pointed out that in such cases their activity may be increased by giving them along with substances which raise the acidity or in alternate doses with an acid; therefore salicylates act badly when the alkalinity of the blood is high or undiminished.

It appears, then, that uric acid in the blood may be in solution either with a salicylate or with (potash or soda) alkali, but it cannot be in solution with both at one and the same time; and that if it is in solution with alkali and a salicylate is added this will diminish the alkalinity, and hinder the solubility of uric acid under alkali; but until the alkalinity has been very greatly reduced the uric acid will not pass into solution as salicylic acid, that is to say, between the two drugs there is a dead point at which the uric acid is not in combination with either, in fact, it is rendered insoluble, and is driven out of the blood into the fibrous tissues of the joints or fascia, producing a relapse of the gout or rheumatism, and a rise of temperature. If the salicylate is continued the acidity rises still further, and then salicylic acid is formed and got into solution, the uric acid passes freely in this form from the joints into the blood, the temperature falls, and the pains subside once more.

Now, what occurred in the case of E. S. was that she was being given a considerable amount of potash along with some salicylate and her urates were got into solution with potash and little or at all with salicylate; but when the potash was left off the alkalinity fell, the potash lost its hold over the urates before the salicylate gained it, and the urates were for a time driven out of solution into the joints and fibrous tissues, producing a sudden relapse of all her pains, and a temperature of 102.8° ; later on, the salicylates had it all their own way, and there was no further joint irritation or rise of temperature. This shows, I think, that salicylates control the pain and temperature of arthritis simply by eliminating uric acid; if anything prevents their eliminating uric acid the pains promptly return, and the temperature rises in spite of them.

On the other hand, I have seen salicylates given in various local and traumatic inflammations and in pyæmia, and their effect on the pain and temperature was just nothing, because these were not due to uric acid. Further, I have pointed out⁴ that the compounds of salicin and salicylic acid are powerful in the relief of acute rheumatism exactly in proportion to their power over the solubility and excretion of uric acid; and that those that have least power of elimination (salicin) must be given in much larger doses than those (salicylic acid) that have most. I make bold to say that every drug that has ever been used with benefit in acute rheumatism in the past, and every drug still to be discovered that may be used with benefit in the future will be found to do good in direct proportion to its power of dissolving and eliminating uric acid. But I believe most strongly that, once these simple facts about the causation of rheumatism are generally recognised, prevention will be so simple and so certain that it will soon become quite a rare disease.

I shall now, in conclusion, shortly mention one or two cases in which a relapse of chronic rheumatism was produced by drugs given for other purposes.

CASE VI.—T. P., aged 71, was admitted into the Metropolitan Hospital on January 14th, 1895, suffering from chronic rheumatism (gout). He had had an attack of sciatica ten years earlier, and, two years later, arthritis in both hands. This he had had off and on ever since, chiefly in the legs, but the hands were a good deal distorted and crippled. He was ordered salicylate of sodium and given some cod liver oil. He improved steadily, and was soon able to walk much better, and had little or no pain. The temperature varied from 97° to 99° . On February 8th he had some little bronchitis, the salicylate was stopped, and he was given a mixture containing ammonia and senega. As the pain returned the ammonia mixture was stopped and the salicylate resumed on February 9th. On February 12th the pains were distinctly better, but the salicylate was kept on, and, as the previous dose was small, it was increased to gr. xv, and the improvement was steady and continuous. We have here only

¹ Uric Acid, second edition, p. 334; and Wood's Medical and Surgical Hematology, 1894, p. 305.

² Parturition generally brings an excess of uric acid through the blood, and some of this was eventually driven into the joints.

⁴ Medical-Chirurgical Transactions, vol. lxxiii, p. 297.

the patient's word for it, as the temperature showed nothing, but there was no reason why he should have complained of more pain just at the time the drugs were altered.

CASE VII.—H. K., aged 58. This case very similar to the above, was suffering from chronic rheumatism and sciatica. He was admitted into the Metropolitan Hospital on January 12th, 1895. There was a history of having suffered for nine years. Pains were now chiefly in left knee and hip. He also was put on salicylate, and improved considerably, but he also later on got bronchitis, and on March 2nd was given the same ammoniac mixture as in the other case. On February 23rd the note says: "Can get about better and pain is comparatively speaking gone." On March 2nd he got some bronchitis. The salicylate was stopped, and next evening *cina ammoniæ* ordered. On March 23rd the pains were decidedly worse again, especially in the knee. He was ordered to have the salicylate mixture as well as the ammonia, and the pains soon got better.

I may explain that urate of ammonium is one of the more insoluble urates, and that ammonium raises the acidity of the urine and increases the hourly excretion of acid. It would therefore increase gouty or rheumatic pains when given alone, but would not interfere with the action of salicylates; on the contrary would aid it.

I could easily give a number of similar cases; indeed, a week never passes without my seeing one or more of them. Almost every time a uric acid headache is cured some joint pains are produced, and in gouty and rheumatic cases the well-known effects of changes of weather can almost always be translated into changes in the alkalinity of the blood, secondary to the effects of the weather on the excretion of the skin.

Thus a patient recently seen gives me the following history of an attack of gout. He lives in India, but occasionally comes home to England, and after a previous visit to England, where he had been "feeding up," he felt the heat very much in the Red Sea on the way out, and then in Bombay was exposed to comparatively cold March winds, and had a violent attack of gout. Can anything be more simply and easily explained than this history? We have (1) the ingestion of a lot of uric acid, (2) its solution in the blood (uricæmia) as the result of heat, and (3) its precipitation on the joints by the rising acidity produced by cold winds.

Similarly in patients who suffer from mental depression, pains in the joints are often looked upon as the harbingers of better things; and in women, when menstruation with its depressing influences causes a rise in the alkalinity of the blood and an excess of uric acid in that and the urine, mental depression or headache are generally worse, while rheumatic pains are to some extent relieved.

It is not my object in this paper to lay any great stress upon the cases quoted above, which I have been able to collect in a few months, but I hope, by bringing them to the notice of clinical observers, to induce them to regard their cases of arthritis and endocarditis in the light of what is now known about the solubility of uric acid; and if I am successful in doing so, I feel sure that they will very soon see hundreds and hundreds of similar cases, which only the mist of an erroneous pathology has prevented their seeing before, and they will not only see, but will be able to prevent and control, these disease processes to an extent which was previously impossible.

Disease by the visitation of God, or the work of that Jupiter Tonans of modern pathology, the nervous system, will give place to disease the result of folly in diet; the straightforward and easily verified chemistry of uric acid will replace the hypothetical microbe, and gout and rheumatism will be regarded as mere modifications of one and the same disease—arthritis due to uric acid.

[See BRITISH MEDICAL JOURNAL, 1895, previous reference.]

THE MEDICAL PROFESSION IN HUNGARY.—According to a statistical report recently issued by the Hungarian Minister of the Interior, the total number of medical practitioners and lower grade Surgeons (*Wundärzte*) in Hungary in 1894 was 4,280, being an increase of 108 as compared with the previous year. The distribution of practitioners throughout the country is very unequal; thus there are counties where 20 per cent. of the population are without a doctor. The average proportion of medical practitioners to population in the towns in 1894 was about 11.1 in 10,000. In Buda-Pesth there was 1 doctor to every 345 inhabitants, the lowest proportion in any town being at Hód-Ménz-Vasárhely, where it was 1 in 3,400. In rural districts there was on an average 1 medical man to every 4,992 inhabitants.

OBSERVATIONS ON THE PATHOLOGY OF ENLARGED OR HYPERTROPHIED PROSTATE.

By REGINALD HARRISON, F.R.C.S.,

Surgeon, St. Peter's Hospital.

In advocating what I would speak of as the muscular theory in explanation of hypertrophy of the prostate I am not aware I ever denied that the prostate was dissociated from the genital function. I have referred to it as "a muscle containing a tolerably large proportion of glandular or secretory tissue embedded in it," and though failing to see evidence showing that it is engaged in elaborating the secretion of the testicles I adopt the view of Dr. Handfield Jones' expressed in the following words: Its function relative to the sexual act is "in supplying a vehicle which enables the fecundating fluid to act with greater certainty over a larger area, whilst at the same time it supplies a muscular buttress against which the ejaculatory muscles of the urethra may advantageously act in the emission of the semen." It is therefore, I believe, to this extent a compound organ, and I am not aware that anyone has brought forward arguments contravening this limitation of duality.

I regard senile enlargement of the prostate as an example of a muscular hypertrophy analogous to other similar kinds of overgrowth, and arising out of the muscular functions in which the part is unconsciously engaged. It is of the first importance that its muscular action should be clearly established, for unless this can be done the whole of my argument necessarily falls to the ground. The difficulty that has hitherto arisen in fully recognising this explanation is in some measure due to the isolated manner in which the prostate has been studied.

It has been urged that though the prostate is in some measure involved in the process of micturition, the fact that it is used for this purpose half a dozen times or so in the twenty-four hours is insufficient to account for its overgrowth. This, I would emphasise, is merely the casual part the organ plays in what we generally regard as a voluntary act. Such a limited view as this implies is in a large measure due to the habit we have acquired of taking our ideas of the living organ from the condition it presents after death when removed from the body in a more or less contracted state, somewhat resembling a Spanish chestnut in shape. This is no more like the living prostate than the dead heart resembles the organ in full vigour and activity. The prostate assumes, I believe, no such appearance during life except on the rare occasions when the bladder is absolutely empty, but, on the contrary, the muscular fibres of which it is so largely composed are spread out like a funnel so as to furnish a contractile support for the bladder and its varying contents. This disposition is probably best appreciated by examination by the rectum when the patient is in the erect and semi-erect positions with the bladder empty as well as in various degrees of repletion. Though the existence of a prostate is not limited to man, I am not aware that in any animal it undergoes a change analogous to the senile enlargement observed in the human species. Hence, though enlargement of the prostate and the habit of maintaining the erect position may be mere coincidences, this fact cannot be allowed to pass unnoticed.

As the normal prostate is in this funnel-shaped manner spread out, so is it when it is enlarged. We are often surprised to find after death, or by a suprapubic incision, how much smaller the prostate turns out to be as compared with what it was when examined during its functional activity by the finger in the rectum. Under an anæsthetic an enlarged prostate usually ceases to oppose the introduction of an instrument into the bladder. Unless this continuous muscular action of the prostate in supporting the contents of the bladder in accordance with the degree required, as well as in minimising the effects of shock applied to this part of the body are fully appreciated, it is impossible to understand how the functions of the viscera can be discharged without some other provision than that afforded by a mere fibrous floor.

It was not until I recognised the funnel-shaped manner in

which during life the prostate was disposed in contradistinction to the contracted mass presented after death that I could find an explanation for certain results following different lesions of the part, as for instance in the various perineal incisions made for the removal of stone by lithotomy. Why an incision into the prostate, radiating from the urethra passing through it, and not as a rule dividing more than one-third of the solid mass presented by the dead prostate, should be followed by absolute incontinence of urine for some days seemed difficult to understand when so much of the circumference remained intact. Such a result, however, at once became intelligible when we recognized that the incision, though limited, absolutely destroyed, until repair took place, the capability of a cone-shaped muscle to hold fluid.

The male bladder, in its mechanical arrangements, has little in common with that of the opposite sex. In the latter the process of micturition and the axis of urine pressure relative to the pelvic outlet are different, whilst there is an absence of provision for ejaculation of semen or even any direct connection with the genital function. In the female the manner in which the bladder is supported when distended has a resemblance to what is found in some quadrupeds.

Further, the surgery of the part furnishes evidence in various ways of the muscular power of the prostate. Thus openings may be made into the urethra in any part of its course as high up as what we term the apex of the prostate without incontinence of urine following. After lithotomy by the median operation patients often retain full control over the bladder during the whole period of their convalescence, in spite of the dilatation to which the prostate has been subjected by the introduction of the finger and the extraction of the stone. Directly, however, the knife impinges to any appreciable extent on the prostate, as in the lateral operation for stone, incontinence from that moment takes place; the patient has no command over his urine, he can neither collect nor expel it; and in this condition he remains until the healing process has made considerable advance. Some instances I have examined in which permanent incontinence of urine followed the operation of lateral lithotomy appeared to have been connected with the complete division of the prostatic circumference by too free an incision. I can hardly see how such a consequence as this could follow if the prostate during life presented the appearance of the contracted mass [we are accustomed to look at after death].

In cases of extroversion of the bladder, in which there is no receptacle for the urine, the prostate is only met with in a rudimentary form. In advanced life, so far as I have been able to ascertain, hypertrophy never occurs in these malformations, though sexual desires are often vigorous. I have recorded the case of a boy³ in which incontinence of urine appeared to be associated with an arrest in the development of the prostate. This, however, may merely be a coincidence, as at this period of life this part only exists in a very rudimentary form. In an instance⁴ of removal of the prostate I performed for malignant disease, although the patient recovered completely from the operation, and lived over fourteen months afterwards, during the greater portion of which time he followed an active and laborious occupation, control over the bladder was lost. To provide against the incontinence the patient was fitted with a sort of truss, which, by exercising pressure on the urethra below the arch of the pubes, enabled him to prevent the involuntary escape of urine and go about his work. Before proceeding to point out the steps by which prostatic enlargement seems to me to be brought about, I would mention one or two points which are generally admitted in connection with the natural history of its growth. In the first place there can be no doubt that though a considerable proportion of elderly males develop it, only a minority suffer from any ill-effects on the urinary apparatus it may produce. If such a growth serves no useful purpose, it is difficult to understand how this can be, and why we should draw our conclusions as to the process being a morbid one from the lesser number of instances of it than the greater. It is a matter of common observation to find persons with largely hypertrophied prostates, and

yet showing no other structural defect either in the capacity of the bladder to contain or to expel fully the urine for which it acts as a reservoir. Nor with proper safeguards is it necessary that persons so situated should develop any prostatic trouble calculated to shorten their lives. Another point is also worthy of notice. The process of hypertrophy involves no structural substitution or the importation of tissue foreign to the part other than those degenerations, such as the fibrous, to which the human body is liable. Hence we are narrowed down to offering an explanation as to the purpose for which this excess of normal structure is called into existence.

In studying pathological lesions, more particularly in relation to function, instances can be found in the human body where defects may call into existence such compensatory changes as eventually themselves constitute disease. A very small lesion, for instance in the mechanism of the heart, if it happens at the right spot, is capable of producing a hypertrophy which, though first compensatory, by-and-by proves to be a source of disorder. Thus the prostate in the course of its growth, so as to form a buttress or support for the most dependent portion of the bladder, tends to project in directions in which the resistance is least, and to form, by the fibrous degeneration these portions undergo, those obstructing masses with which we are familiar. Nor, though the whole gland is eventually more or less involved in the hypertrophy, can we fail to observe that in these changes the posterior segment, where it exists, is usually primarily and principally involved.

I have already laid stress on the importance of not regarding the normal prostate merely in the light of an individual organ, but as forming a part of the genito-urinary system. This holds good with its pathology. In the study of instances of enlarged prostate in the *post-mortem* room it is impossible not to be struck by the coincident changes that are taking place in the adjacent parts. For some reason or other there is a concentration of hypertrophied tissue in the form of buttresses or supports about the perpendicular axis of urine pressure at the base of the viscus. This is seen in the development of the inter-ureteral bar, the growth of the prostate, the gradual approximation and consolidation of these two structures, and the restriction of the natural trigonal area.

The trigone or floor of the bladder, in addition to being a highly sensitive part, is peculiar in that it contains the minimum amount of muscular fibre as compared with the rest of the viscus; muscle in abundance may be found as low as a transverse line drawn between the openings of the ureters marking the superior boundary of the trigone, and below in the prostate, but between these two points the power of muscular contraction can hardly be said to exist. Assuming, as I have stated, that from any cause, such as the long retention of urine, habit, position of the body, or the debility connected with advancing years, the floor of the bladder sinks lower within the pelvis relatively to the prostate, so as to offer some difficulty in expelling the last portion of urine, the effect will be frequently repeated efforts in all the muscles immediately adjacent to a part of the bladder which by reason of its connections and structure has but little power of contracting. It is suggested that in this way quantity is substituted for quality, and that as age advances structural deterioration and incapacity are in a measure provided against by superabundant tissue.

I have said that although hypertrophy usually includes the entire gland, the posterior segment or that in relation with the rectum is principally involved. When the part which was originally described by Sir Everard Home⁵ as the third lobe, but subsequently shown by Sir Henry Thompson⁶ to have no independent or isolated existence, is imperfectly or not at all developed, as is sometimes the case, it is interesting to notice that hypertrophy of the inter-ureteral bar may be observed taking place independently, and thus provision is made by a buttress of this kind for the support of the posterior wall of the bladder.

An inability to empty the bladder and the discomfort, or rather the consciousness of an incompleteness, of the act of micturition, is a common symptom in connection with the

changes are mainly compensatory, whilst in others they are excessive and hurtful; (4) that in the latter respects it resembles other provisional hypertrophies.

GIDDINESS AND STAGGERING IN EAR DISEASE.

By THOMAS BARR, M.D. GLAS.,

Lecturer on Diseases of the Ear, Glasgow University; Aural Surgeon, Glasgow Western Infirmary; Surgeon, Glasgow Ear Hospital; Honorary Auralist, Glasgow Sick Children's Hospital.

Ménière's classical paper on aural giddiness in the *Gazette Médicale de Paris* for February 9th, 1861, marked an epoch in the history of medicine. Founding his conclusions partly on the experiments of Flourens in 1825-42, but chiefly upon very carefully observed cases, he demonstrated that a sudden attack of giddiness, with nausea and vomiting, with noises in the ear and deafness, has frequently its pathological basis in the interior of the ear. The view previously held that such an attack meant a lesion in the brain involved serious mistakes in prognosis and treatment. Paralysis, imbecility, and death itself were the gloomy prospects held out to such a patient; while blood-letting, mercurials, and vesicants were the usual remedies employed. All this is now changed. In the light of Ménière's discovery and of subsequent investigations the patient who is the subject of such a seizure may now, in the majority of cases, be assured that the ear and not the brain is the seat and source of the mischief; that the danger to life is very slight; that the dread of mental disease may be dismissed, and that, by simple and rational treatment, the symptoms will partially, if not entirely, disappear. It must be admitted, therefore, that the knowledge of the connection of these symptoms with the organ of hearing has been a great gain to medical science and fraught with valuable practical results. How desirable it is that every medical practitioner should be fully alive to the far-reaching influences of Ménière's discovery.

FREQUENCY OF GIDDINESS IN EAR DISEASE.

Since Ménière's discovery the profession has become gradually impressed with the importance of giddiness as a symptom of ear disease, and most practitioners now think of the ear when a case of giddiness presents itself. As a sign of ear disease it is by no means a rare phenomenon, occurring in all degrees of intensity from that of a slight and temporary lightness in the head to so violent a disturbance of the equilibrium as necessitates the lying posture. From my own experience, gained both in private and hospital practice, I am prepared to say that in a marked form it is far from being rare, while in a comparatively mild degree it is a very common concomitant of ear disease. At the Glasgow Ear Hospital a scheme is in use in which the existence of giddiness is included among the questions put to every patient of sufficient age, and the answer recorded. Examination of the scheme shows that in 1,275 consecutive cases, occurring in hospital practice, there were 73 cases, or 5½ per cent., of marked giddiness; while in 287, or 18 per cent., there was slighter or occasional giddiness. In 1,025 consecutive cases, occurring in private practice, there were 63 cases, or 6 per cent., in which giddiness was a distinct and indubitable feature. In the case of hospital patients we cannot, of course, vouch for the accuracy of all the replies. Excluding slight and occasional giddiness observed in hospital practice from our calculation, these being possibly in many instances connected purely with gastric or hepatic disturbance, the proportion in the severer forms is pretty much the same in hospital as in private practice.

Considering the importance and frequency of giddiness as a symptom of ear disease, it is remarkable that it seems to have eluded such able observers as Wilde and Toynbee. Neither in Wilde's volume on *Aural Surgery*, published in 1863, nor in Toynbee's treatise on *Diseases of the Ear*, published in 1860, do we find any definite reference to giddiness as a symptom of ear disease. In the supplement to the 1868 edition of Toynbee's work, however, written by James Hinton, there is reference to the symptoms of Ménière.

VARIOUS FORMS OF GIDDINESS DUE TO EAR DISEASE.

Ménière's discovery naturally stimulated much investigation, with the result, not only of still more widely connecting the symptom of giddiness with disease in the ear, but also at the same time of modifying some of his views. While he believed that these symptoms had always as their basis a lesion, usually hæmorrhagic, in the labyrinth or semicircular canals, further investigation and experience have modified and enlarged this view, and it is now well known that giddiness may be associated with almost any form of ear disease. In the light of the fuller experience of recent years aural giddiness may now be conveniently described as manifesting itself in four distinct forms.

I. The typical form, or true Ménière's disease (sometimes termed apoplectic form deafness), due to the presence of exudation in the labyrinth. In a person with either previously normal hearing, or who may have suffered from a chronic affection of the middle ear, the four great symptoms—namely, sickness and vomiting, giddiness and staggering, subjective sounds in the ear and deafness—occur as a sudden seizure. In this class entire disappearance of all the symptoms is rare.

II. This form of aural giddiness is due to pressure upon the walls of the middle ear of air, liquid, or inflammatory products. Here the symptoms are somewhat less severe in character, the sickness and vomiting being occasionally absent. The vertigo is usually preceded by other symptoms of auditory disturbance. Disappearance of the symptoms, however, is usually effected by suitable treatment.

III. The giddiness is in this class due to pressure upon the walls of the external auditory canal or outer surface of the tympanic membrane, especially by ceruminous masses. Here, also, the giddiness is usually preceded by disturbance of the hearing, and here also entire recovery is often brought about by treatment.

IV. In the fourth class of cases, the giddiness is due to irritation of the auditory nerve, chiefly through chronic processes in the middle ear leading to pressure upon the labyrinth at the fenestral openings, or to vasomotor disturbance in the labyrinth. The vertigo of this class is that usually termed by writers *vertigo ab aure laesa*, and may occur in almost any affection of the ear, but usually in the course of a chronic inflammatory affection of the middle ear. The giddiness is generally preceded, accompanied, and followed by subjective sounds and deafness, but it is frequently without nausea or vomiting. Recurrences of the giddiness are common from time to time. In most cases the giddiness eventually disappears, but the deafness and noises in the ear remain permanent.

I.—LABYRINTHINE GIDDINESS.

This is true Ménière's disease or apoplectic form deafness, and is a form of aural giddiness, which is most apt to be confounded with cerebral or cerebellar disease. It is perhaps best illustrated by the description of an actual case, such as the following:

CASE 1. *Typical Ménière's Disease*.—A married lady, aged 32, was never, up till the time of seizure, conscious of any impairment of hearing or affection of the ear. On a spring forenoon, while walking in the garden, she became suddenly conscious of a loud sound in the left ear and left side of head, like steam blowing off, accompanied by deafness in the same ear. Almost immediately afterwards she became extremely giddy, staggering with difficulty into the house, where she became very sick and vomited freely. After resting in the dining room for two or three hours she was helped up stairs to bed, still extremely giddy. Next morning, however, the vertigo had, to a great extent, disappeared, and, with the exception of slight transient attacks, has never returned. The nausea and vomiting did not return after the first day, but the noises in the ear and deafness continued. A few days after the attack I examined both ears. In the left, or affected, side there was no sign of disease in the external or middle ear. The hearing by air conduction was practically gone, while bone conduction, as tested by Rinne's and Weber's tests was very defective. Inflation of the middle ear by Politzer's method and the catheter had no appreciable effect upon the deafness or on the subjective sounds. The right ear was perfectly healthy, with normal hearing. Seven years after the seizure the condition of the left ear was unchanged. Neither tick of watch nor speech was heard, and the bone conduction was defective. No abnormal change in external or middle ear. The subjective sounds still continued pretty much the same, but there had been no return of the vertigo. This patient had given birth to a child prematurely a few months previous to the attack, and a year afterwards a child—born at full time—had to be treated with anti-specific remedies. The husband, some years prior to his marriage, had a specific affection, for which he was treated for a long time. In the case of the lady a course of pilocarpin, employed subcutaneously, as well as long continued mercurial treatment, made no impression upon the ear affection.

ANALYSIS OF THE LEADING SYMPTOMS IN TRUE MÈNIÈRE'S DISEASE.

Let us now consider the leading individual symptoms which go to make up a typical case of true Mènière's disease. The giddiness is very sudden and intense, and is usually the first symptom of the seizure. The objects around may seem to rotate, or the ground in front may seem to rise or fall, or there may be a sense of movement only in the patient's body, either that of rotation or of moving backwards or forwards. There may simply be a staggering or want of control in the legs, especially in the dusk or dark, when the movements may resemble those of a drunken man. The patient is generally apt to turn or fall in the direction of the affected ear. If attacked while walking in the street, he staggers and tries to hold on by the wall or lamp-post. If he be in bed he feels as if in a ship in a storm. After a short time, from a few minutes to several days, the giddiness passes off or markedly diminishes, but it may return again, even repeatedly, although generally more slightly. A certain degree of staggering or giddiness is especially apt to return when the patient at first resumes the upright posture. It is apt, also, to be excited by sudden movement of the head, and it is often much worse in the dark. A gentleman recently informed me that in the dark his legs collapse as if paralysed, while in the light he has no difficulty in walking. Another young gentleman says that in the dark "his legs go all ways," and he takes the whole breadth of the road, so that he avoids going out at night. He walks quite well during the day. The giddiness seems sometimes to be excited by superficial irritations, or by particular postures. A patient said that when, in combing his hair, the comb touched a particular spot on the side of his head, he dropped on the floor and felt like a "spinning top." The following is the case of a lady in whom giddiness was excited when she lay on the affected ear, and who, if she turned on that side while sleeping, immediately awoke quite sick and giddy.

CASE II. Mènière's Disease, Giddiness Excited by Lying on the Affected Ear.—A lady, nervous and liable to headaches, 41 years of age, was seized at the end of January, 1893, just before breakfast, with giddiness, dulness, and noises like machinery in the left ear, followed in an hour by nausea and vomiting. Before the attack she had perfect hearing. I saw her first on March 31st, 1893, when the hearing on the right side was *no*, and on the left *+*, where the bone conduction was defective. She was examined by me again on April 5th, 1893, when she reported that since the last visit, a month before, she had had only one attack of giddiness, accompanied by nausea or vomiting, when coming out of church. In a letter to me in April, 1893, she writes: "I dare say you would not be astonished to hear that I was still quite deaf in my left ear. I do not ever so much mind from giddiness as I did at first, if my stomach is out of order. I suffer sometimes from it when I go to bed; not everything moving round and round, but the feeling as if I were sailing in a storm, everything moving up and down—a most unpleasant feeling. I cannot sleep on my left side (affected side); if, when asleep, I unconsciously turn to that side, I immediately awake quite sick and giddy, perhaps I should persevere and try to overcome that feeling, but I think I would get sick if I persevered. I cannot do with any public speaker speaking loudly or rather howling. It makes me all in a quiver, ready to jump, and the effect does not pass off for some hours. I know I am rather nervous, so far as temperament is concerned, and that may probably intensify all these feelings. I have always more or less noise, sometimes a humming sound, but, strange to say, this week the noise has been like the trickling of water accompanied by the hum. Indeed, I could not describe it better than by saying it is the sound of water in the distance running gently but accompanied by the hum of water, or, rather, more water at a great distance."

In the great majority of cases the giddiness sooner or later passes permanently away.

The sickness and vomiting usually begin soon after the disturbance of equilibrium, and are probably due to reflex action through the vagus nerve. This symptom naturally suggests the possibility of brain mischief. On the other hand, owing to this symptom, both patients and practitioners frequently regard such attacks as purely bilious in their nature. The sickness and vomiting soon pass off, and rarely extend beyond a day or two.

The subjective sounds in the ear are always well-marked, and in many cases they are most distressing features of the disease. They generally come on simultaneously with the vertigo, but sometimes they are not experienced for a few hours after, or in rare cases for a day or two. The characters of these sounds are variously described by the patients; the following taken from my notebook are some examples—Sound of a shell, waves, railway whistle, bell, rushing, buzzing, loose shutters in wind, singing, humming, ticking,

roaring, rushing water and waving of trees, whistling, sound of factory, twittering and whistling of birds and crickets, blowing off steam, howling, hissing, flaring of gas, piano playing, electric bell. The behaviour of these sounds is sometimes peculiar. For example, in the case of the electric bell, a sound precisely like an electric bell was heard followed by half a minute or so of silence, then there again came the sound of the electric bell followed by silence, this alternation going on continuously. In nearly all my cases the sounds in the ear, while varying in intensity at different times, remain permanent. I have always found them present years afterwards when I had the opportunity of examining the patient.

The loss of hearing is usually very marked, often practically total. It is sometimes found to precede for a few hours the other symptoms, but in general it comes on almost simultaneously with the giddiness. As a rule a loudly-ticking watch is not heard close to the ear, neither are words whispered into the ear perceived. Bone conduction is also defective, as tested both by Weber's and Rinne's test. Objective examination usually shows nothing abnormal in either the external or the middle ear. Fortunately in the large majority of cases only one ear is affected; the disease sometimes, however, affects both ears, and then, if occurring in young children, deaf-mutism is generally the result. The deafness, like the noises in the ear, is in the great majority of cases permanent.

Pallor of the face and cold sweats, with, in some cases fainting, are often observed. Unconsciousness is rare, and, if present, is very short in duration. Headache is in some cases complained of. Depression, slowness of thought, and weakness of memory may follow for a time.

THE CAUSES OF TRUE MÈNIÈRE'S DISEASE.

In regard to the causation of this class of cases, there is no doubt that many occur in persons who, on careful inquiry, are found to have nasal obstruction or other forms of nasal disease, and who have had, at some past time of their lives, a catarrhal affection of the ear. I have been struck by the frequency of the association of *ozæna* with Mènière's disease.¹ It might be expected that a tendency to vascular disturbance of the middle ear is likely to be associated with a similar tendency in the internal ear. As exciting causes, abnormal states of the constitution or blood are the most frequent sources of the attack, and my own experience would place specific disease, either in the hereditary form or during the tertiary stage of the acquired form, among the most important of all the causes. (See Case I.) In such constitutional states the proximate cause is no doubt effusion of blood into the cavities of the labyrinth from rupture of a vessel specifically diseased. Such effusions constitute irritative lesions which act upon the auditory nerve terminals in the membranous ampullæ or utricle. The degenerative lesions of the vasa, connected with Bright's disease, are no doubt in some instances the explanation of the hemorrhage. The following case is probably an instance of this.

CASE III. Mènière's Disease associated with Bright's Disease.—An unmarried lady, aged 20, of a nervous temperament and dyspepsia, was the subject of chronic albuminuria, and, owing to external attacks in the middle ear, awoke one morning (April 10th, 1893) with a severe headache and the sense of being quite deaf in the left ear. An hour or two afterwards she was seized with great giddiness, great "beating" in the ear and sickness. For three days she vomited everything and had some slight diarrhoea, and had to go to bed for a week. The giddiness during that time being such as to forbid the erect posture, it was regarded as an "attack of the liver." I saw her about a fortnight afterwards, when disturbance of equilibrium had to a considerable extent passed off, although it still threatened to return when eating fatigued. There was practically total deafness in left ear to tone and air conduction. The noise and distress have continued permanent, and on June 25th, 1893, the hearing was: in right, *+* and in left *+*. The second attack was a continuation of hearing and the third was the last, and consisted of a brief, was distressing, and almost unendurable, but not of extreme nature. Some circumstances have a pecuniary effect upon the head and sounds in the ear. She has had two attacks of acute conjunctivitis, with partial suppuration, and once during those attacks has been much troubled with a feeling as if the head were surrounded with a tight band.

Atheromatous disease of the vasa is, in elderly people, an important cause of the disease. When we consider the intimate relation between the blood supply of the labyrinth and that of the interior of the cranium, the internal auditory

¹ *Ozæna* deafness is a relatively more frequent in aural pathology. J. M. P. *Arch. Otolaryngol.*, 1894, 1895.

artery being a branch of the basilar, it is easy to understand that affection of the cerebral arteries is likely to be associated with a like degeneration of the labyrinthine vessels. The following case is a notable instance of this.

Case 1. *Mr. J. H. G., a Glasgow gentleman, aged 74, having normal ears and hearing, while seated in his office one forenoon, became suddenly conscious of a sound "humming" or "singing" in one of his ears, with deafness in the same ear. He almost immediately afterwards became extremely giddy and sick. When I saw him a day or two afterwards the vertigo and sickness had greatly subsided, leaving behind, however, profound deafness and most distracting noises in the ear. No mischief whatever was found in the external or middle ear, and I believed it to be due to sudden haemorrhage into the labyrinth. The deafness and sound continued, and a few months afterwards he was attacked with cerebral apoplexy, and died some time afterwards. Professor Cairdner, who saw him, wrote in answer to an inquiry from me, that "the death was from some accident of the ordinary kind, my doubt from haemorrhage into the corpus striatum or other medial part of the brain."*

In young children the condition may be associated with "mumps," acute labyrinthitis of Voltolini, cerebro-spinal meningitis, or leucocythæmia. The haemorrhage may, on the other hand, be traumatic in origin, and due to a blow or a fall on the head. Many instances of this kind have come under my own observation. The giddiness continued in such cases for many weeks, and was especially severe when the patient assumed the upright posture. There was also total loss of hearing, with great subjective sounds, which were permanent. Examination of the external or middle ear usually yielded in such cases a negative result. Excessive exertion, especially of the respiratory organs, occasionally excites effusion into the labyrinth. I have had, for example, under my care, a young gentleman, an enthusiastic football player, who, during a keenly-contested game of football, was seized with great giddiness and excessive noise in one of the ears, which also became deaf, the latter symptoms—the noise in the ear and the deafness—remaining ever after. In another of my cases, excessive blowing with the mouth in the use of a blow-pipe for several hours seemed to be the exciting cause of the disease. The disease, on the other hand, may come on while in bed, the sensation of the bed heaving, as if in a ship in a storm, being the first indication of the seizure.

DIAGNOSIS OF TRUE MÉNIÈRE'S DISEASE.

We assume the affection to be labyrinthine, if, immediately after the sudden occurrence of the typical symptoms, an examination fails to discover any affection of the middle or external ear, while, at the same time, the deafness is extreme, with defective bone conduction. With such symptoms as those described, and, in the absence of disturbance of innervation or paralysis in the areas supplied by the other cerebral and spinal nerves, we may safely exclude the possibility of an intracranial affection, because, if the nuclei of the auditory nerve centre in the brain were affected, some of the other nerves whose centres are in juxtaposition would certainly also be involved.

TETANUS FROM A CHILBLAIN.

The following case may be of interest on account of such a trivial ailment as a chilblain terminating fatally: On March 18th, 1895, I was called to see J. K., aged 12 years. His mother believed that for five days he had been suffering from "influenza," and she did not think it necessary to seek medical aid, as her other children had all recovered from that disease a fortnight previously. I found the patient semi-conscious, with well-marked trismus, slight dysphagia, and both tonic and clonic spasms all over the body. There was also opisthotonos, and so rigid were the muscles that it was impossible to put him sitting in the upright position. The temperature was 100°, the pulse about 120, respirations very irregular, perspiration profuse. During examination I noticed, on attempting to move

him in 1895, do we had any other of total loss of hearing in both ears a symptom of ear disease. Her observations, in the Glasgow 1895 edition of Toybee's work, how Hinton, there is reference to the symptom.

the left leg, that the spasms were greatly increased, and the patient cried out, apparently in much suffering. The leg was not swollen, nor was there any enlargement of the inguinal glands. On the upper and posterior surface of the heel there was an ulcer about as large as a threepenny piece, with a purple areola about half an inch in diameter. The mother then informed me that he had complained of a chillblain a few days before. I could only obtain a very vague account of the early part of his illness, nor do I believe he had had influenza. The patient was able with difficulty to swallow a little milk and beef tea, and I administered chloral, 10 grains, every fourth hour. When I saw him on the following morning he was moribund, and died shortly afterwards.

DEATH OF A CHILD FROM THE PRESENCE OF VOMITED MATTER IN THE LARYNX.

On August 6th, 1895, at about 4 p.m. I was summoned in haste to see a child who, it was feared, had died suddenly. I found the child, a little girl about 5 years of age, dead, and, to all appearance, from asphyxia. The presence of a little vomited matter on the bedclothes sufficed to confirm the suspicion, and to suggest the cause.

The history was as follows: The child's dinner consisted of ham and eggs with tea. In the interval between breakfast and dinner she had an orange and some melon, and after dinner she was provided with a second orange.

About 45 minutes before I was called, the child, feeling sick, was put to bed by her mother. Shortly afterwards she seemed to be asleep, and the mother went on with her scrubbing, etc., in the same apartment.

When next she looked at the child it was apparently dead. Neither noise from vomiting nor from expulsive efforts had occurred sufficient to arrest the attention of the mother, who had not in the meantime been out of the apartment. The vomited matter consisted of a bit of ham measuring roughly half an inch square, and a little orange pulp.

The authorities appearing satisfied with the opinion I had expressed, that death was due to suffocation from the presence of some vomited matter in the trachea; no formal post-mortem examination was ordered. Permission, however, was granted me by the parents to make an incision in the windpipe, which I did 24 hours after death, and found, as I suspected, firmly engaged in the rima glottidis a piece of orange pulp rolled up upon itself lengthwise, and measuring 1 inch in length, and when opened out, $\frac{1}{2}$ inch in breadth at its widest part.

Death from such a cause is very uncommon. Occasionally such cases occur in association with drunkenness, and a case is referred to in Taylor's *Medical Jurisprudence*, p. 418, in which an infant of one year old was suffocated from the presence of curdled milk in the trachea and bronchi. What happens in such a case is that when vomiting occurs in the horizontal position a portion of the vomited matter is readily drawn by aspiration into the trachea with resulting suffocation unless sufficiently vigorous expulsive efforts are set up. What is singular in the present case is that a child of 5 years of age should have been thus suffocated without any struggle occurring or noise being produced, sufficient to arrest the attention of the mother.

Rothsary.

D. MITCHELL, M.D.

A NOTE ON THE METHOD OF SKIN BRIDGING IN INGUINAL COLOTOMY.

In the *BRITISH MEDICAL JOURNAL* for April 6th, 1895, Mr. Bidwell, of the West London Hospital, describes a method of insuring free exit of faeces from the upper opening in the bowel after inguinal colotomy, and at the same time of preventing recession of the gut into the abdomen. The method consists in bringing the upper lip of the skin wound through an opening made in the meso sigmoid, and attaching it to the lower lip of the wound, by which manœuvre the bowel comes to be placed across a bridge of skin, in lieu of one of glass or rubber, as employed by some surgeons.

I can fully endorse all that Mr. Bidwell has said in praise of this proceeding. The operation is rapid, and the bowel need have no sutures inserted into it, and, if the length of the skin incision is properly calculated, nothing more than the

one suture to fasten the bridge of skin is necessary. I have tried it in two cases—one a case of inguinal colotomy, the other of Littré's operation. The former, a broken-down man aged 57, recovered and left the hospital in a short time without any mishap. The skin bridge united at once, and the bowel opening (made on the fourth day) remained patent and well up on the surface. The latter was a woman, aged 59, in whom, as a purely palliative measure, to alleviate suffering, I did Littré's operation. The bridge of skin united at once, in spite of the fact that the bowel had to be opened at the time to relieve distension. In this case some interrupted sutures to attach the bowel to the skin were employed to prevent the chance of the intestinal contents getting into the peritoneal cavity. She also, as far as the operation was concerned, made a rapid recovery.

C. H. GOLDING-FIRD,
Surgeon to Guy's Hospital.

A CASE OF ISORIASIS OF TWENTY-SIX YEARS' STANDING: RECOVERY.

ON November 25th, 1894, I first saw G. N., a farmer, aged 59. He appeared of a full alcoholic habit, and said he had had skin disease for over twenty-six years, and been under treatment nearly all that time, but for the last few months had ceased. He was covered (except the face, hands, and feet) with an eruption, raw and reddish-purple, varying to scab, fissured and exuding serum in most places, and having a large amount of scaling.

He had taken many drugs, including arsenic, in small doses at various times. I thought the only thing to do was to persevere with the arsenic. This I did, commencing with 3 minims of the liquor arsenicalis, and increasing the dose every fourth day. Improvement commenced about the eighth day, and continued till his skin was smooth and pink and almost normal. About the seventeenth day he (though only taking about 24 minims of the liq. arsen. daily) showed marked symptoms of arsenic poisoning, and I had to delay the treatment a few days, but resumed it later in smaller doses. In about five weeks his skin was, except for a little deep pigmentation, quite normal, and while he continued taking small doses of arsenic kept quite clear. Now and again he leaves it off for a few weeks, and the spots and patches begin to manifest themselves, but on taking a few doses they rapidly disappear. In order to prevent all the facts fairly I may say I combined potassium iodide with the liquor arsenicalis, and gave him an ointment containing white precipitate, but as he had taken large doses of the iodide, and had a mercurial externally in several of his former prescriptions, I think we are justified in putting their effect down as supplementary only.

The patient appeared to be rather susceptible to arsenic, and never took more than 8 minims of the liquor arsenicalis three times daily.

ADVANCEMENT OF THE RECTI MUSCLES.

The fixation of the muscle to the conjunctiva has made the advancement of the recti muscles a satisfactory operation. Sometimes, however, cases are met with in which the conjunctiva tears so easily that the surgeon would desire to have something more reliable to depend upon. Such an experience about eight years ago led me to adopt for these cases a method which I have employed on several occasions. Instead of severing the muscle close to the eyeball I leave a small portion, sufficient for the placing of a suture, attached to the sclerotic; a single suture is passed (from within outwards) through this and the overlying muscle (drawn into position) and tied; the end of the muscle is then fixed to the conjunctiva in the neighbourhood of the cornea by two sutures parallel to the extremity. The incision is vertical and near the insertion of the muscle. The suture through the tendon and the muscle, if it does not absolutely prevent tension upon the conjunctiva, reduces it to a minimum. Where there is no ground for misgivings about the conjunctiva I only use the two conjunctival sutures mentioned above.

W. H. BAKER.

DAVID McKEOWN, M.D.

MASTOID DISEASE IN AN INFANT AGED 7 MONTHS: OPERATION: RECOVERY.

At the end of September, 1895, I was called to see a child aged 7 weeks on account of a "lump behind the ear." I had attended the mother in the confinement, and the labour had been quite straightforward, and no instruments were used. I found a small fluctuating tumour situated behind the left ear over the mastoid process. The skin was slightly red. The temperature was 103.6°. There had been no vomiting. A purulent discharge was issuing from the external meatus, but had not previously been noticed, so small was it in amount. On clearing this away with a probe and wool, and pressing over the tumour, pus was seen to exude from the external meatus. There was no wound visible which could have caused glandular infection.

Chloroform was administered by Dr. G. Lacy Barritt, of Spalding, and an incision was made over the swelling, and a fair amount of pus escaped. The bone was found bare, and a minute opening through which communication with the ear had been established. I enlarged this opening, and inserted a small drainage tube, plugging the rest of the wound with gauze.

The ear was then syringed daily with antiseptic lotions, and the discharge, at first profuse, gradually subsided. The tube was removed on the eighth day. Now, five weeks after operation, the wound is quite healed, and there is no discharge from the ear.

The age of the patient and the favourable termination of the case seemed to make it worth reporting.

COURTNEY C. WEEKS, M.R.C.S. Eng., L.R.C.P. Lond.
Pinchbeck, Lincs.

THE TREATMENT OF DISLOCATION OF THE PERONEUS LONGUS TENDON.

As Mr. Walsham, in his instructive paper, has brought up this rather rare accident, the following case, treated successfully without operation, may be of interest:

John Goodall, the well-known International football player, during a match in December of last year suddenly displaced, for the first time, the peroneus longus tendon of his left foot. I saw him about two hours after the accident, the appearance of the injury being very typical, the tendon lying about 1 inch in front of the external malleolus. He could himself replace it with his fingers, and then by muscular action displace it again.

I determined to try first complete rest, so as to give the torn fibrous sheath the opportunity of running. With that object, after firmly bandaging a semicircular pad over the displaced tendon, I fixed the foot and leg in plaster of Paris. This was taken off at the end of three weeks, and the pad held in position with strapping; finally, at the end of six weeks, he was allowed to go into training again, wearing an elastic anklet, having being cautioned to avoid, as he well knew how, the particular action that caused the accident.

Three months after the accident he played for England against Scotland, and is still playing, his skill in the football field being in no way diminished. The tendon has never since left its proper place.

Derby.

C. H. TAYLOR, M.D. (Lon.).

THE ABSORBING AND DISINFECTING PROPERTIES OF SAWDUST.

Nor only is sawdust of great value in deodorising urine which has been absorbed by it, as shown in the interesting demonstrations of Professor G. V. Poore recorded in the BRITISH MEDICAL JOURNAL of August 31st, but it forms one of the best absorbents for serum, pus, and other putrescible fluids. For many years we have employed cedar and pine wood sawdust enclosed in muslin bags of fine texture and various shapes. We have found that these dressings answer all the chief requirements of an ideal surgical dressing, being cheap, easily procurable, soft, firm, convenient to handle, and capable of being rendered reliably antiseptic. Dr. Poore's experiments remind me of a series conducted by my teacher Mr. Arthur Newe with aseptic serum and pus. Muslin bags full of sawdust were saturated with these fluids and kept various lengths of time. The results were most interesting, being similar in kind to those recorded by Dr. Poore. Further

investigations were carried on by us as to the enhanced value of sawdust when saturated with solutions of corrosive sublimate, and then dried and filled into muslin bags treated with zincocyanide of mercury according to Lister's method.

We have been so satisfied with the result that these sawdust bags constitute now our chief surgical dressing. While thoroughly reliable for simple surgical wounds, such as those of laparotomy or the excision of tumours, it is, however, especially in cases in which there is excessive discharge that the sawdust dressing proves to be of conspicuous value.

I feel sure that if this form of dressing, modified to taste, were introduced in our large hospitals and infirmaries, and carefully tried, it would be found that much saving could be effected in the at present expensive item of surgical dressings. —I am, etc.

CANCER HOSPITAL, BROMPTON.

TWO CASES OF EPITHELIOMA PENIS TREATED BY DIFFERENT OPERATIVE METHODS.

(Under the care of Dr. HERBERT SNOW.)

1. WALTER P., aged 39, married, painter, was admitted on August 3rd, 1893. The duration of the disease was 18 months, of which 8 had been occupied by the notorious Mallett treatment. The cause of the disease was a long prepuce, under which the secretion had been allowed to accumulate. There was no family history.

The whole glans penis was converted into a large fetid mass of fungous granulations, and the infiltration extended along the body of the organ nearly to the scrotum. The inguinal glands were normal. After the temporary introduction of a bougie, the penile structures were exposed by a median perineal incision, dissected out until the finger could be hooked around it and transfixed. The crura were divided as near the rami as possible, the urethra about $\frac{1}{2}$ inch in front. The penis was dragged forwards and liberated by a circular incision through the skin and fascia of the scrotum, without division of the raphe, and without interference with the testes. The perineal and scrotal wounds were separately closed, the urethra being sutured to a buttonhole aperture in the skin, and a self-retaining catheter left in. The man was discharged well on September 4th.

He reappeared in March, 1895, with a superficial cicatricial contraction of the perineal orifice, duly relieved. There was no trace of disease; and although the man was in excellent general health, wiry and fairly youthful in appearance, no sexual desire whatever had been experienced since the operation.

2. J. L., aged 60, a carpenter, was sent, in October, 1893, by Dr. Howells, of Talgarth, Brecon. The cause of his disease was chronic balanitis, the result of neglect; its duration four years; there was no family history of cancer. The greater part of the glans was occupied by a hard mass of epithelioma, the body of the penis remaining, however, free. As a sufficient margin of healthy tissue was thus obtained, it was considered sufficient to excise in front of the raphe, the urethra being slit and sutured to the skin in the usual way. A good recovery ensued, the patient being discharged on November 21st. Dr. Howells has just (September, 1895), kindly written to say that he remains in "excellent health, with no sign of recurrence."

REMARKS BY DR. SNOW.—The course of both these cases illustrates an exception to what is or should be the golden rule in average instances of malignant disease dealt with by operation. In most situations carcinoma or epithelioma infects the adjacent lymph glands within a very few weeks or months of inception, and enlargement is a relatively late symptom of that infection. Hence as a general rule, whether evidently larger or not, these should be carefully removed simultaneously with the primary lesion. Penile epithelioma

may not however be transferred to the inguinal glands for a much longer period, and this "anticipatory" extirpation is uncalled for; though a vigilant watch should be maintained for the subsequent twelvemonth. The operation in Case 1 substitutes two small wounds for one much larger, avoids division of the raphe and removal of the testes, steps which involve a huge raw surface in a spot specially prone to subsequent cellulitis. After radical removal of the penile structures, there need be no fear of trouble from subsequent sexual instincts, thus practically annulled.

REPORTS OF SOCIETIES

EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

Wednesday, December 18th, 1895.

W. CRAIG, M.D., Vice-President, in the Chair.

CLINICAL MEETING.

CASES.

DR. W. ALLAN JAMIESON showed a case of Xeroderma Pigmentosa in a boy aged 3½ years. This he believed to be the second seen in Scotland, the first having been a case of Dr. McCall Anderson's. In the present case the disease only occurred on the face, on which also there were several warty growths. There was a history of cancer and of tuberculosis in the family.

MR. MCGILLIVRAY showed a girl in whom he had excised the Condyles of the Humerus for dislocation and fracture, and the resulting condition was extremely satisfactory. He also showed a boy on whom, after a preliminary tracheotomy, he had performed Thyrotomy for Papillomata on the Vocal Cords. This was the fourth case in which he had done this operation. The operation seemed safe enough, but the voice did not appear to be restored to its normal.

MR. COTTERILL showed a young girl on whom he had operated for the Drainage of a Pancreatic Cyst. She had been ill twelve weeks, and was very ill when she came under his care. There was a large swelling in the spaces known as epigastric, umbilical, left hypochondriac, and left lumbar. There was also some dulness in the direction of the right hypochondriac region. Aspiration was first done, then later incision immediately below the left twelfth rib, and continued drainage for three months. She was fed on Benger's liquor pancreaticus, etc., and had made an excellent recovery. He also showed a rare form of Spina Bifida in a boy who seemed to be a pathological curiosity. The spina bifida was large, to the right of the middle line and over the sacrum. The bowel could be invaginated through the opening in the sacrum, and one's fingers nearly met. The boy's ears were feebly developed, he had a right congenital inguinal hernia, he was able to perform an extraordinary series of movements of the right forearm and hand, in consequence of great freedom and relaxation at the shoulder-joint, and finally he had club foot. He also showed a case of Actinomycosis on the Right Cheek in a young woman, with two illustrative microscopic preparations. The important feature was the difficulty of diagnosis.

MR. F. M. CAIRD showed (1) a young man who had suffered from Osteomyelitis, and had been treated by passive congestion, etc.; (2) a young man who had his Mastoid opened for suppurative disease of the ear; this was followed by a meningitic attack, probably tuberculosis: trephining was resorted to, and some fluid escaped after the dura mater had been punctured; he was unconscious for several days, but recovered; (3) a young man after Operation for Dilatation of the Stomach.

DR. JOHN THOMSON showed a boy suffering from Peripheral Neuritis following Measles, and a case of Elephantiasis of the Face and Neck in a girl of 14, which appeared to have come on after whooping-cough.

MR. DAVID WALLACE showed a young man, aged 19, who had recovered after Operation of Cerebral Abscess following or coincident with Otorrhoea.

MR. STILES showed (1) a baby with Arrest of Development of Both Ears, which seemed consequent on arrest of development of the petrous part of the temporal bone. There was no auditory meatus on either side, and evidently no hearing sense. There was defective development of the left lower

jaw, and paralysis of the occipito-frontalis on that side; (2) a baby with Cervical Ribs; and (3) a child with Symmetrical Tuberculous Lesions, Osseous Tubercles of the Orbit.

Mr. ALEXIS THOMSON showed two cases, both elderly men, after Neurectomy for Trigeminal Neuralgia of long-standing anaesthesia of the lower jaw seemed to be the condition mainly complained of now.

Dr. NORMAN WALKER showed four cases of Lichen Planus, and a case of Leucoderma on the Abdominal Wall of a child.

SPECIMENS.

Dr. BURN MURDOCH showed (1) a Foreign Body (a piece of rhubarb) which caused intestinal obstruction; (2) Caries of the Atlo-axoid Articulation.—Dr. W. ALLAN JAMIESON showed a series of Microscopic Preparations, stained and unstained, illustrating the Parasites of Ringworm.—Mr. MCGILLIVRAY showed the Condyles excised from a Humerus. Warts removed from the Larynx, and a Calculus (oxalates) removed from the Ureter.—Dr. GRAHAM BROWN (for Dr. R. MACKENZIE JOHNSTON) showed Foreign Bodies removed from the Nose, Throat, and Ear.—Mr. D. WALLACE showed Epithelioma of Larynx (complete laryngectomy) and second malignant Double Structure of the Oesophagus.—Dr. LEITH showed specimens illustrating a case of coincident simple Perforating Ulcer of the Stomach, and primary Colloid Cancer of Cecum, with great secondary Infiltration of the Omentum and Mesentery, etc.; also two specimens illustrating Malignant Disease of the Terminations of the Common Bile Duct.

EXHIBITS.

Mr. F. M. CAIRD: A Portable Steriliser for Instruments.
Mr. D. J. STILES: An improved Tensiotome (Matthieu).

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF PATHOLOGY.

CONOLLY NORMAN, M.D., President, in the Chair.

Friday, November 29th, 1895.

TUMOURS OF THE KIDNEY COMPOSED OF SUPRARENAL TISSUE.
Dr. McWEENEY described two new cases of this condition. The paper will be published.

Dr. O'SULLIVAN, when in Vienna last summer, had seen two of these growths.

The PRESIDENT said there was a case published in the *Journal of Pathology* about three years ago by Kanthack and Holliston, resembling in many ways that of Dr. McWeeney. Another case of adenomata of the kidney, not mentioned by Dr. McWeeney, was published in France in 1882. It was argued that adenomata of the kidney were almost invariably associated with a cirrhotic condition of the kidney. He had himself brought before this section a somewhat similar case. It occurred in an elderly man who was dying of cirrhosis of the kidney.

Dr. McWEENEY, replying, said that in the class of cases he was referring to, the tumour originated in the kidney, altogether apart from the suprarenal. In both his cases the tumour originated in the lower end of the kidney. Because adenomata occurred in a cirrhotic kidney it did not follow that they were caused by it. The fully formed tissue of these tumours is not like urinary tubules. In the cortex of the human suprarenal, but more especially in that of the higher mammals, pseudo-tubular structures of the same kind were found by Creighton, Marchand, Flaudier, and others.

JOINT MEETING OF SECTIONS OF MEDICINE AND STATE MEDICINE.

THOS. W. GRIMSHAW, M.D., F.R.C.P.I., President of the Section of Medicine, in the Chair.

Friday, November 15th, 1895.

Dr. GRIMSHAW made some opening remarks, and thanked the Academy for his present position as President of the Section.

THE INFECTIOUS HOSPITALS (DUBLIN) SCHEME.

Dr. J. W. MOORE read a paper in which he severely criticised the draft scheme prepared by the Superintendent Medical Officer of Health of the City of Dublin "for the formation of a Board for establishing hospitals for infectious diseases in

the County Dublin" as unnecessary, inexpedient, calculated to damage the Medical School of Dublin, and likely to prove a costly failure. He freely admitted, however, that the accommodation for small-pox patients in the late epidemic was neither adequate nor safe. Again, for twenty years he had been advocating the provision of refuge, or temporary habitations, for the reception of the inmates of houses in which infectious disease had broken out, and of convalescent homes for those recovering from infectious disease. So far he was heartily in accord with Sir Charles Cameron. Let, then, the urban and rural sanitary authorities of the Dublin metropolitan district combine under Sections 12, 149, and 153 of the Public Health (Ireland) Act, 1878 (41 and 42 Vict., cap. 32) to carry out these needed sanitary reforms.

ISOLATION OF FEVER CASES.

Sir CHARLES A. CAMERON prefaced the essential part of his paper by some statistics showing the much greater decline in the mortality from zymotic disease than in that from all other causes. These statistics showed the possibility of the extinction of zymotic disease. The reduction of the fever death-rate was largely due to the sanitary measures passed by Parliament, and the enormous sums expended in the sanitary improvement of towns. Medical men had also contributed to it by the suggestions and by the action of medical officers of health—the latter had successfully resisted two threatened invasions of cholera. The isolation of fever cases and the adoption of a perfect system in the management of hospitals for infectious cases were telling favourably in England, but in Dublin they were open to the reproach of not only having two fever hospitals in somewhat crowded parts of the city, but of having no fewer than seven fever departments in general hospitals. There was no proper provision for an epidemic of small-pox, and in the recent epidemic of that disease both fever hospitals were crowded with patients, and 153 cases of small-pox had to be accommodated in huts erected in the workhouse grounds. Sir C. Cameron advocated provision for a future epidemic of small-pox, the establishment of one or two hospitals outside the city for typhus and scarlet fever cases, and that a hospital for convalescents from infectious cases should be provided, and the restriction of enteric fever, pneumonia, and diarrhoea to the present city hospitals.

Dr. JAMES LITTLE said that for the last thirty years he had been connected with the Adelaide Hospital, where they had always taken infectious diseases of all kinds except small-pox. During that time he had known only two patients who contracted an infectious disease in the hospital. One was a patient with enteric fever, who caught typhus. The other was also suffering from enteric and he caught scarlatina. In each case the patient that gave the disease was lying in the next bed. There had never been a spreading of scarlatina from the fever hospital to the main hospital, which was a few yards from it. He thought students would learn a great deal more about fever by carefully watching one or two cases than by going into a large fever hospital. According to Sir Charles Cameron, there was a great decrease of fever cases under the existing circumstances, and so he did not know why they should be changed.

Mr. TOLIN said there was a great necessity that students should be thoroughly instructed in each variety of fever.

Dr. WALTER SMITH said it was perfectly absurd to talk of theory as against the enormous mass of practical facts. Besides the finances of Dublin must be considered. It would inflict an irreparable loss on the education of students. How was the proposed new hospital to be always kept a mile outside the town? How were people to be prevented from building around and up to it?

After remarks from Dr. C. F. MOORE, Dr. S. M. THOMPSON, Surgeon-Major DALY, and Dr. J. JOYNT, Dr. CHAMBERLAIN said he did not think they should consider the cost of the hospital if it was good for the public health. With regard to the interference with medical teaching he would not discuss that, as it would not carry much weight either with the public or with the corporation. All who had any experience knew that the friends of those suffering from infectious diseases had a great objection to sending them into a fever hospital. If not able to send them into the fever wing of a general hospital they would keep them at home, and a great deal of concealment

would go on. The people must be taught that small-pox was preventable by proper vaccination and revaccination, and sufficient force was not laid on this point. The spread of typhus could also be prevented by better sanitation. Refuges for the temporary accommodation of the inmates of houses in which small-pox had broken out were also needed.

Sir THOMAS STOKER was entirely in accordance with the previous speaker, that the proper course with regard to small-pox was its prevention, and not its cure. He agreed with Sir Charles Cameron on the necessity for a convalescent home for patients getting well from infectious diseases. He was not aware that fever found its way into the Richmond Hospital, nor did they even find any inconvenience from the small-pox when it was treated in the Hardwicke Hospital. He thought that one fever, to a certain extent, prevented an attack from another fever.

Mr. CHOLY thought that if they had in Dublin a good arrangement for treating small-pox and cholera, and a good place for convalescent patients, the present hospitals should be left as they were.

Dr. BRAWLEY said that if Sir Charles Cameron had no evidence to show that the various general hospitals were the centres of infection, his argument fell to the ground. He would like small-pox excluded from the town, as there was good evidence that it was transmissible through the air to a considerable extent. But with regard to the other fevers, unless it could be shown that there was a greatly increased prevalence of them around the hospitals, they were very well contented with the present condition.

Mr. W. THOMSON said that, according to Sir Charles Cameron, there were nine centres of infection from hospitals in Dublin. If any members of the families of those present were taken ill with an infectious disease, Sir Charles Cameron would not require the individuals to be removed from their homes. Suppose there were 20 such cases through the city, and the present fever hospitals were abolished, and one outside the city were erected in their place, how would simply extinguishing the nine centres and leaving 200 centres scattered in individual houses through the city get rid of the difficulty? In a hospital the physicians, students and nurses look care, as far as possible, that they did not bring infection outside. In private cases these rules were not obeyed.

Dr. PARRONS said that, if statistics proved anything, then Sir Charles Cameron had furnished very strong evidence in favour of the present system of treating infectious diseases. They were better here than in other cities where they had isolated hospitals. If the scheme was carried out, they would require half a dozen isolation hospitals for the different diseases.

Dr. DAY did not agree that people were unwilling to let their friends go to a fever hospital. As regards the spread of infectious diseases, artisan dwellings had been put up within 300 yards of Cork Street Hospital. They had had only one case of typhoid and one case of scarlatina from these dwellings.

Dr. FALKINER endorsed Dr. Day's opinion that patients now wished to go to a fever hospital. The poor people would go to any institution where they were properly treated.

Sir CHARLES CAMERON, replying, said he wished to make an explanation with regard to the scheme, and under which the scheme was brought before the Committee of the Sanitary Authorities held in the Public Health Office. The original Conference was held simply for making arrangements for future epidemics of small-pox, and also for providing one or more homes for patients convalescing from fever. There was considerable discussion at the first meeting. He was asked to meet Dr. Stafford and prepare a scheme. He was distinctly asked to include in the scheme the consideration of hospitals for other infectious diseases. Dr. Stafford fully approved of the scheme which was drawn up, and was quite willing to share the responsibility. It seemed they all were agreed that two out of the three objects set forth in the scheme should be carried out. He had subordinated the third all along if the first two were accomplished. He would be glad to have the third also, because he was still convinced that what they did in other countries was right, and that it would be better to treat in-

fectious diseases in special hospitals. The Public Health authorities had the power of compelling all infectious cases in tenement houses to go to hospital. When he had a case of scarlatina in his own family he sent it to hospital. When his child was at the Adelaide Hospital the Resident informed him that he had got scarlatina from his child. When small-pox was received in the Adelaide Hospital there was not a house in one street at the back of the hospital which had not a small-pox case. He thought that if the Corporation of Dublin contributed £5,500 to the Dublin hospitals they might also contribute to the expense of having a hospital for small-pox. He said there were 250 square miles in London, and as the fever hospitals could not be established outside London, but they were in the best position that they could be. If they admitted that small-pox and typhus and scarlatina could be transmitted through the air, their position fell through altogether. He did not say that typhus and scarlatina were as contagious as small-pox. Everything done to prevent contagion must be of some use. The chances that persons in the neighbourhood of patients suffering from small-pox or scarlatina would get it were more than if they were at a distance from them. The cause of the decrease in the death-rate from infectious diseases was the general improvement in sanitation. He had no intention of interfering with existing Dublin hospitals. He resisted the proposal that the grants to them should be considered, but he was defeated. The scheme was proposed with the very best intentions. Having regard to the weighty opinions expressed by the leading medical men, he had decided to abandon the third part of the scheme. His paper contained his honest conviction as a sanitarian. The two primary objects, namely: (1) The making proper provision for a future epidemic of small-pox; and (2) the establishment of a home for convalescent infectious cases, he was determined to keep to, and to use all his influence to carry them out.

Dr. J. W. MOORE, replying, said that he had heard with great gratification the statement made by Sir Charles Cameron, that he would limit his scheme to providing accommodation for small-pox patients, and of having a convalescent home for persons recovering from all infectious diseases.

Dr. DUFFY proposed, and Dr. FALKINER seconded, the following resolution, which was passed:

Resolved: That the General Council be requested to convene a special general meeting of the Academy to consider and express an opinion upon the proposed scheme for a hospital for infectious diseases in Dublin.

LIVERPOOL MEDICAL INSTITUTION.

CHAUNCEY PERRY, F.R.C.S., President, in the Chair.

Thursday, December 12th, 1895.

REMOVAL OF SINGER'S NODULE.

Mr. BARK showed a man, a "star comique," who at one time had completely lost his singing voice. In July, 1893, a growth was completely removed by Grant's guarded laryngeal forceps; two weeks later he was able to fulfil a professional engagement, and said that his voice had never been better; there had been no recurrence since. A second patient, a choir-master, had suffered from hoarseness and loss of singing voice for over two years. In June, 1894, a nodule was removed from the larynx in the same manner, and the voice had been good ever since.

A RESPONSIBILITY TO THE LYING-IN PATIENT FROM A SANITARY POINT OF VIEW.

Dr. STEVENS thought that a variety of puerperal fever existed that was caused by defective sanitation, and he gave instances in which he believed puerperal septicæmia had resulted from atmospheric infection by sewer gas. In the city of Liverpool one-third of the reported cases of puerperal fever were from houses described as insanitary. The prevalence of the disease was no necessary index of the amount of zymotic disease existing, for, in 1894, though there were nearly 1,000 more cases of zymotic diseases than in 1893, the number of puerperal fever cases was considerably less. When a medical man is engaged to attend a confinement he rarely inquires into the sanitary condition of the house, but

Dr. Steeves thought that this should always be done, and if the medical man did not consider himself fully competent he should obtain an expert opinion. A protracted period of ill-health frequently followed a confinement, and Dr. Steeves thought this not seldom due to chronic sewer gas poisoning. Dr. Steeves then moved the following resolution, which was seconded by Dr. IMELACH:

That in the opinion of the members of the Liverpool Medical Institution it is the duty of every medical practitioner, when engaged to attend a confinement, to forthwith inspect, or cause to be inspected, the premises of the patient, with a view to having any sanitary defects which may exist corrected, and so further the stamping out of puerperal septicæmia by the methods of preventive medicine.

Several members spoke on the resolution, some stating that, in their opinion, insanitary conditions had nothing whatever to do with puerperal septicæmia. Others thought that the resolution, to be effectual, should apply to illness of every kind, and not especially to the puerperal woman. It seemed to be generally agreed that it would be very unwise that any such resolution should go forth to the public from the Medical Institution, and, on being put to the vote, it was rejected by an overwhelming majority.

SPINAL LOCALISATION.

Professor SHERRINGTON referred in his paper to the distribution to the skin of the sensory spinal nerve pairs arising from the cord. He pointed out that experiments show the field of skin supplied by each sensory spinal nerve root to be a large area of somewhat simple configuration. Where simplest, as in the trunk and neck, the segmental skin field is band-like, wrapping transversely round one lateral half of the body. In the region of the limbs the mid-dorsal line of the body may be said to extend laterally in a side branch, forming a secondary axis almost at right angles to the main axis; upon this secondary axis, which may be called the limb axis, the spinal skin fields are arranged as though upon folded portions of the axial lines of the trunk itself. Each spinal skin field spreads out to a marked extent into neighbouring spinal skin fields, and in this way has an overlap into the field in front and behind it. There is, therefore, no area of skin which is supplied by one spinal nerve alone; the supply is from two roots in some places and three in others. Although in a plexus each sensory spinal root gives separate contributions to many nerve trunks, the cutaneous distribution of the root composes a field, not of discrete or disjointed patches, but of patches so joined that the distribution of the entire root forms one continuous field.

Professor PATERSON, by means of a large parti-coloured model of the "Fighting Gladiator," demonstrated the distribution of spinal nerves to the skin and muscles of the trunk and limbs in man. This showed how closely the skin fields in man corresponded with those found experimentally in the monkey by Professor Sherrington. Professor Paterson pointed out that, while superficially segmental in origin, the spinal nerves are truly segmental in distribution only to the muscles of the thoracic wall. With regard to cutaneous innervation, it was certain that overlapping took place in the distribution of the simplest type of nerve, so that it was possible to affirm that no spot of skin and no muscles (except the intercostals) were supplied by a single spinal nerve. With this qualification, the cutaneous innervation of the trunk, between the limbs, was zonular; continuous belts of skin were supplied from back to front. The growth of the head and limbs caused the adjacent nerves to be drawn out of their primitive position. In the limbs, lines—dorsal and ventral axial lines of Sherrington—could be drawn from the middle line of the body down the limbs, and indicated the meeting place of widely-separated nerves; it was only at the ends of these lines that a continuity of distribution again appeared.

ostosis in a boy, aged 12. The condition was a'm'et entirely confined to the cranium, the bones of the face being very slightly affected. The principal bosses were two—one at the vertex and a second on the left side of the skull, involving chiefly the parietal region. In addition there was irregular thickening of the occiput, and an invasion of the orbit producing marked proptosis, absolute loss of one eyeball and complete blindness in the other. The upper jaw was much compressed laterally, the two halves forming a very acute angle in front, and the teeth growing very irregularly [Plaster casts by Mr. MARCHISON were shown.] The lower jaw was normal. There was no evidence of intracranial disease, of hydrocephalus, or congenital syphilis, and no deformity of the limbs or joints. The patient's mental development was quite up to the average; he had a good ear for music, and was being educated on the Braille system. The case seemed nearest akin to leontiasis ossea.

Dr. GAIRNTH mentioned that the Museum of the Medical School contained a skull closely resembling that in the case shown, and he himself had shown a somewhat similar case at a previous meeting.

The PRESIDENT had seen a somewhat similar case improved by iodide of potassium.

Dr. EDDISON asked whether there was any evidence of syphilis in the parents. He thought the appearance of the boy suggested it. It was unlike any case of osteitis deformans he had seen, nor was it ordinary hydrocephalus.

FRACTURE OF THE ETHMOID BONE WITH BASAL MENINGITIS.

Mr. W. H. BROWN read notes of this case, a boy of 16, who was struck over the occipital region of the skull by a falling stone. He fell forward, his forehead coming violently into contact with the ground. He was unconscious for a short time. No special symptoms were noticed but he was kept in bed. On the third day when sitting up a copious watery discharge ran from both nostrils and continued for six days, when it ceased. Temperature rose to 104.5° F., and was accompanied by intense frontal pain, photophobia, tinnitus, and a transient strabismus. Three weeks after the accident he was admitted to the Leeds Infirmary under Mr. Brown's care. There were then no external signs of injury beyond some discoloration of the skin at the root of the nose. He complained of severe temporal pain; the movements and sensations of all limbs were normal. Temperature 100°; convergent strabismus affecting both eyes, pupils dilated, reacted slightly to a bright light, don't oped pupils present. Later on vomiting occurred at irregular intervals, the boy was irritable and at times delirious, but gradually his symptoms disappeared and he was now quite well. Mr. Brown believed that only a few cases of basal fracture with nasal discharge of transparent fluid recorded, and said that a discharge from the Schneiderian membrane might be taken for cerebro-spinal fluid. He thought the fluid in this case was cerebro-spinal on account of the quantity and absence of any effusion of sense of smell.

Mr. SECKER WALKER had lately examined the eyes again, and all the ocular symptoms had disappeared except some slight swelling of the optic disc: vision in each eye was good. He mentioned that at least 4 cases of double optic neuritis associated with constant discharge of cerebro-spinal (?) fluid from the nose had been reported, but in these cases there was no traumatism.

Mr. WARD and Mr. LITTLEWOOD both thought that the JCB bag was of little value in the treatment of head injuries.

Dr. TRAVELMAN thought it a typical example of traumatic cerebro-spinal meningitis both in its symptoms and temperature chart. He observed that the prognosis of these cases of non-tuberculous meningitis was a matter of exceptional interest. The longer the disease had lasted after a certain point the better the patient's chance of recovery. Spinal puncture might in the future throw light on the particular micro-organism settling up the disease, and show how far the pathological processes might extend in the direction of pus production and yet be consistent with recovery.

SHORTENING AT THE NECK OF THE FEMUR.

The PRESIDENT demonstrated a method of measuring the shortening at the neck of the femur which he had employed

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.

A. W. MAYO ROBINSON, F.R.C.S., President, in the Chair.

Friday, November 24th, 1906.

AN UNUSUAL CASE OF CRANIAL HYPERTROPHY.

Mr. HARTLEY showed a case of congenital cranial hyper-

for several years, and which, he believed, had not been hitherto described. The method consisted in drawing a transverse line from the tip of the great trochanter forward to the front of the thigh on each side and dropping a vertical line to meet this from the tip of each anterior superior iliac spine; the latter lines constituted the ones in question. The advantages presented by these measurements were: (1) The ease with which they can be made with the patient in the dorsal decubitus; (2) the degree of exactitude which the method renders possible; (3) the manifest advantages for demonstration purposes of seeing at once the limbs which have to be compared.

AN EPIDEMIC OF HYSTERIA.

Dr. J. CROSSLEY WRIGHT gave an account of an epidemic of hysteria, which took place on the girls' side at the Crossley and Porter School. It consisted of 14 cases, the ages of the patients varying between 11 and 14 years. They occurred between November 11th and November 24th, and in the majority one type was distinguishable—namely, clonic rhythmical spasm of the upper limbs, varying in intensity between a fine tremor and coarse violent movements involving the whole of the trunk. In some of the cases the elbow-joint was rigidly extended, the fingers being flexed firmly into the palm, while the chief motion was at the shoulder-joint, giving rise to forcible alternate adduction and abduction as well as internal rotation of the whole limb. In two cases there was a distinct hammering action of the clenched fist against the side, table, or against any surface with which it was placed in contact. In a single instance there was spasm of the eyelids, with an occasional quick opening and shutting. No definite cause for the commencement could be ascertained. Some one or two of the girls were in for an examination. The treatment was the same in all the cases, namely, isolation, rest in bed, milk diet, faradism, a succession of blisters in order to cause pain to the moving part, and, as for drugs, valerian and bromide of potash. That which seemed to have the greatest effect was the blistering, and a marked improvement was at once recognisable after the first one or two blisters had been applied.

Dr. BARRIS considered that tremor was a common symptom in hysteria.

Dr. EDDISON advocated a more vigorous line of treatment, and asked if it was certain, as Dr. Wright had stated, that the movements continued during sleep.

CARD SPECIMENS AND CASES.

Card specimens and cases were shown by the PRESIDENT, Mr. LITTLEWOOD, Mr. BROWN, Mr. SECKER WALKER, and Dr. T. WARDROP GRIFFITH.

PATHOLOGICAL SOCIETY OF MANCHESTER.

H. R. HUTTON, M.B., President, in the Chair.

Wednesday, December 11th, 1895.

DILATATION OF RECTUM WITHOUT OBSTRUCTION.

Mr. FRICKE showed the rectum and sigmoid flexure of a man, aged 35, who had suffered from general paralysis of the insane. He had been employed at outdoor work up to the morning of his death, when he began to vomit at breakfast, dying at 2 P.M. the same day. During the last year his abdomen had been noticed to become very big. *Post-mortem* examination showed that the peritoneal cavity was full of faeces mixed with exudation; the rectum was enormously distended, at least 5½ inches in diameter, and ascended close to the middle line from the pelvis as far as the left wing of the diaphragm, displacing the heart upwards. At the lower part of the sigmoid flexure there was a perforation the size of a shilling with much-thinned edges and without any sign of inflammation, through which the faeces escaped into the peritoneal cavity. The contents of the intestines consisted of softish faeces of slightly greater consistency than cow-dung; there were no hard masses anywhere. There had never been any constipation, the patient being very dirty, and passing faeces at all times in his bed and clothes. There was no trace of organic obstruction, the whole hand being easily passed through the anus into the rectum.

FRACTURED SKULL.

Mr. FRICKE showed the fractured vault and base of a female

epileptic aged 36. She was 16 stone in weight and 5 ft. 4 ins. in height; she fell in a fit down three steps, each 6 ins. high, on the back of her head, and died immediately afterwards. A fracture was found starting from the upper part of the right lambdoid suture, going downwards and then forwards into the foramen magnum, leaving the latter at the right side of the basilar process and then extending forwards on the same side as far as the pituitary fossa; at this level the fracture went across to the left side through the pituitary fossa, and ended in a slight crack extending slightly backwards on the left side. The body of the sphenoid bone was completely broken through. Although the skullcap was much thickened the lower occipital fossa was very thin.

ANGIOSARCOMA OF KIDNEY.

Mr. FRICKE showed the microscopic preparations of an encapsuled renal tumour from a patient aged 72, who died from heart disease. The tumour was considered to be angiosarcoma.

SECONDARY CANCER OF THE HEART.

Dr. WILD showed a heart of which the myocardium presented numerous nodules of cancer; the left ventricle was chiefly involved and one papillary muscle was deeply infiltrated, the pericardium was only affected where a nodule in the heart muscle reached the surface. Microscopic preparations showed that the nodules had the structure of a squamous epithelioma, typical cell nests were numerous and the new growth infiltrated the cardiac muscle. There were no cardiac symptoms during life. The specimen was obtained from a man, aged 43, whose tongue had been removed for epithelioma nearly four months before death; rapid recurrence took place in the cervical glands, which ulcerated deeply, and involved the surrounding tissues. Death occurred from exhaustion, consequent on septic absorption and inability to take food. As far as could be ascertained, less than five months elapsed from the first appearance of disease in the tongue to death. The lungs also presented secondary growths of a similar character to those found in the heart.

COLLOID CANCER OF OESOPHAGUS.

Mr. RAY showed for (Dr. DIXON MANN) a specimen, with microscopic sections, of colloid cancer of the lower end of the oesophagus. Secondary growths were found on the left third rib, and in a submaxillary gland on the left side. There was also a fibroid stricture of the pylorus.

CARD SPECIMENS.

Dr. KELYNACK: Chronic Ulcer of Stomach from an elderly female.—Dr. STOCKS: Large Sarcomatous Growth below the Lower Mandible of a Fowl.

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY.—At a meeting on December 12th, Mr. CHARLES KING, President, in the chair, Dr. BREVOR gave an account of a case of Abdominal Aneurysm showing peculiar symptoms. The patient was admitted into the Great Northern Hospital under his care suffering from symptoms of pressure on the roots of the upper lumbar nerves on the left side. Thus on carefully comparing the sensation of each thigh it was noted that there were areas of comparative anaesthesia on the left; the left knee-jerk was also diminished on comparison. A certain amount of reflected pain was complained of over the left great trochanter, and on percussion over the spines of the first and second lumbar vertebrae, tenderness was found. It was then observed that there was a small abdominal tumour on the left side of the spine, but from the other symptoms it was thought to be of malignant character. In a short time this tumour increased in size, occupied a large area on the left side of the abdomen, and showed expansile pulsation. Soon after this increase began to be observed, one morning while moving in bed the patient was seen to fall back, his face became blanched, and he expired almost immediately. On *post-mortem* examination there was found to be an aneurysm of the abdominal aorta which had caused erosion of the bodies of the first and second lumbar vertebrae, and which had penetrated the left psoas muscle dissecting through the soft muscular structure, and turning it into a secondary aneurysmal cavity. The blood had then passed upwards, and passing below the diaphragm, had escaped

suddenly into the left pleural cavity; death had resulted as the consequence of this accident. Dr. Beevor remarked on the importance of observing with care apparently insignificant physical signs as a means to accurate diagnosis, and especially the comparison of one side of the body with the other, in the case of any symptoms involving sensation or any other interference with the nervous system. In discussing the case, Dr. GALLOWAY remarked on the absence of signs of referred pain along the course of the lumbar nerves, which must have been pressed on during the progress of the aneurysm. Mr. MOWER WHITE pointed out the fact that from the anatomical relations the aneurysm must have perforated the strong iliac fascia on gaining access to the psoas muscle, and inquired whether it was not possible that the aneurysm might have originated in either the first or second lumbar artery instead of in the aorta itself. After remarks by Dr. GLOVER and Dr. MORISON, Dr. BEEVOR replied, and said that there was no evidence that the aneurysm had originated in either of the two positions mentioned as possible by Dr. Mower White.—Dr. THOMAS HAMILTON related a case of Abdominal Suppuration. The patient, a man in late middle life, had long suffered from symptoms of chronic dyspepsia, with gradual loss of strength, when he developed a tumour in the left side of the abdomen about the iliac region. This increased in size with rise of temperature, and presented much difficulty in diagnosis. The patient was seen in consultation by several physicians, and the opinions differed, some being in favour of the diagnosis of abdominal suppuration, and others of malignant disease. At length on being seen in consultation with Mr. Langton, it was decided to incise the mass with the idea of exploration. On incision the tumour proved to be an abscess in connection with the descending colon, and on microscopic examination of the walls of the cavity there was found to be no evidence of malignant origin. While the abscess was being drained there appeared in the discharge a coil of sausage skin, and a bristle about $\frac{1}{2}$ inch in length. The speaker was of opinion that the abscess was associated with the presence of these foreign bodies as irritants. In spite of all efforts to prevent the spreading of the suppuration it spread over the abdominal wall, and ultimately caused death. Dr. GLOVER, who had seen this case with Dr. Hamilton, stated that in the first instance he felt quite assured of the malignant origin of the obstruction that was produced. The CHAIRMAN criticised Dr. Hamilton's supposition that the foreign bodies mentioned had been the immediate cause of the abscess. Mr. KING was of opinion that it was more probable that there had been a fecal accumulation, possibly around the foreign bodies, which had caused ulceration of the mucous membrane, with a resulting pericolic abscess.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.—At a meeting of this Society on December 5th, Dr. PORTER (President) in the chair, Mr. SKELL showed (1) a large number of stereoscopes with photographs illustrating Eye Operations and Methods of Examining Eye Patients; (2) an Electrolysis Needle; (3) a woman with Embolism of Central Artery of Retina.—Mr. RICHARD FAYELL showed Gynaecological Specimens, and gave particulars of a successful case of Nephrectomy.—Dr. SINCLAIR WHITE exhibited and made remarks on (1) a successful case of Laminectomy for Complete Paraplegia due to Spinal Caries. The paralysis had been present for upwards of a year, and had resisted seven months' treatment by continuous extension and other recognised expectant plans. The patient, a boy, aged 8 years, was operated on five months ago, and could now walk well. The arches of the fourth, fifth, and sixth dorsal vertebrae were removed, and a large cavity corresponding in extent to the body of the fifth dorsal vertebra cleared out; (2) upwards of 30 Gall Stones removed from a woman by operation. Dr. White, instead of stitching the cut edges of the gall bladder, tied them over a glass tube with a constriction at the point of ligature. This plan had answered well by saving time at the operation, and by keeping the wound from bile during its healing; (3) a child with Supernumerary and Webbed Fingers and Toes.—Dr. CLYDE HAYES showed a case of Malignant Disease of the Tongue.—Mr. CUFF showed (1) a woman with a large Venous Nevus of Tongue; (2) a boy, aged 10, with Enchondromata (two in number) on the Right Hand.—Dr.

ARTHUR HALL showed (1) a case of Melanoderma; (2) a case of Syphiloderma.—Dr. GWYNNE read a paper on the Radical Cure of Hernia. He maintained that it was one of the most successful operations of modern surgery, relieving the patient not only from grave inconvenience, but also from the ever-present danger of strangulation. He advocated Macswen's method of stitching up the inguinal opening, but thought that ligature and excision of the sac simplified the operation, and produced as good results, especially in children, as Macswen's mode of dealing with it. In Dr. Gwynne's opinion this applied with still greater force to congenital hernia. In cases of the latter he preferred closing the ring with stout ligatures, so as to restore the valvular condition of the canal and subsequently ligaturing the sac as high up as possible without excising any portion, due care being taken not to include or otherwise injure the spermatic cord. A number of cases were exhibited dating from one to five years after operation.—The President, Dr. SINCLAIR WHITE, Dr. WILKINSON, Dr. GWYNNE, Dr. BURGESS, Dr. SWENBY, and Dr. ADDISON discussed the cases and paper.

GLASGOW MEDICO-CHIRURGICAL SOCIETY.—President, Dr. W. L. REID. At the meetings of the Society during the present month the following cases, etc., have been shown: Dr. FINLAYSON narrated the case of a man who died from Rupture of the Descending Aorta, the result of violence, the patient having been able for some weeks after the accident to pursue his occupation as a quay labourer, and making little or no complaint; the wall of the artery appeared to be healthy. Dr. Finlayson also gave an account of a case of Aneurysm of the Arch of the Aorta, with diastolic murmur, the aortic valve on post-mortem examination being competent.—Dr. MACARTNEY reported on the use of Tetanus Antitoxin in two cases, in neither of which did the remedy appear to have any beneficial influence.—Dr. DALZIEL showed a specimen of Perforating Ulcer of the Duodenum, which he had removed after rupture occurred; the patient, who was a young woman, made a good recovery. Dr. Dalziel also showed a patient whose foot he had partially removed on account of a Perforating Ulcer, the result of injury to nerves; the result was considered highly satisfactory.—Dr. JOHN LOVIE showed Microscopic Preparations of the Nerves from cases of diabetic and traumatic peripheral neuritis.

INFIRMARY MEDICAL SUPERINTENDENTS' SOCIETY.—A meeting of this Society was held at the Infirmary of St. George-in-the-East on December 14th, Mr. J. R. LOWN in the chair.—Dr. M. M. BOWLAN (Medical Superintendent of St. George-in-the-East) exhibited the following cases: (1) Extensive Ulceration of Both Feet; (2) Suppuration of Knee-Joint Cured and Perfect Movement Regained by Draining and Free Irrigation; (3) Congenital Heart Disease; (4) Pityriasis Raster; (5) Jaundice associated with Ruptured Spleen.—The question of a Uniform Diet for all Workhouses within the metropolitan area was discussed and approved of, Mr. WALTER BURNER (Greenwich) pointing out that those houses which adopted a more liberal diet were favoured with the company of the professional workhouse loafer, who was a pest to society, and made these institutions unendurable to the respectable poor.—Various other administrative matters of interest were discussed, and a vote of thanks to Dr. Bowlan for his interesting series of cases terminated the proceedings.

LARYNGOLOGICAL SOCIETY OF LONDON.—At a meeting on December 11th, Dr. FELIX SIMON, President, in the chair, Mr. O. BAHR reported further on the case of Papilloma of the Nose shown to the Society on April 10th, 1895. On April 22nd the growth was removed under an anæsthetic. No recurrece had taken place by November 29th. Microscopic examination showed the growth to be a true papilloma.—Dr. J. E. HALL showed a mechaic, aged 48, with a Pedunculated Growth which in his opinion grew from the inner edge of the left vocal cord.—Dr. CLIFFORD BRACE showed two specimens of Tuberculous Infiltration of the Pharynx and Tongue.—Dr. BENNETT showed a microscopic section of a round cell Sarcoma of the Thyroid.—Mr. L. LAWRENCE showed a case of Naso-pharyngeal and Nasal Polyp.—Mr. DE SANTIS showed two pathological specimens of Tuberculous Ulceration of the Trachea, Larynx, and Pharynx.—The President brought

forward a case for diagnosis which showed some ulceration in the larynx.—Mr. SPENCER showed a case of Stenosis of the Larynx caused by chronic inflammatory thickening.—Mr. BRAN showed the case of Enlarged Thyroid he brought before the Society at the last meeting; the tumour had been removed, and the lad was doing well.—Mr. W. R. H. STEWART showed a case of very large Fibroma of the Nasal Septum. The tumour when fresh measured 4 by 2½ by 1½ inches, was a true fibroma, and was by far the largest on record. It had been found impossible to move it with an *écraseur*, so Mr. Macready had removed it by turning back the upper jaw, performing a slightly modified Mansell Moullin operation. As this seemed to be a unique case, the President suggested that a woodcut should be obtained for insertion in the *Proceedings* of the Society.—Mr. C. SYMONDS gave a further report of two cases of Lesion of the Septum shown at the October meeting.—Mr. E. B. WAGGETT brought forward a case for diagnosis, a woman aged 54, who gave a history of Impacted Fishbone, with symptoms persisting for fourteen months.—Dr. W. A. WILLS showed a case of Inspiratory Spasm of the Vocal Cord.

NEWPORT MEDICAL SOCIETY.—A meeting of the Society was held on December 4th, Dr. A. GARROD THOMAS (President) in the Chair.—The evening was chiefly occupied by an interesting lecture given by Dr. PATERSON (Cardiff) on Movements of the Heart within the Chest. The lecture was profusely illustrated by limelight views of experiments made by Dr. Paterson and Professor Hayercraft (Cardiff) on the hearts of frogs and frozen animals, showing the increased antero-posterior diameter of the heart during diastole, and decrease of the same in systole.—An exhibition of Bacteriological Specimens was given by Dr. HOWARD JONES.

Bristol Medico-Chirurgical Society.—The third meeting of the Session was held in the Medical Library of University College, Bristol, on December 11th, 1895, Mr. A. W. PRICHARD in the Chair.—Dr. WATSON WILLIAMS read a paper on the Symptoms and Diagnosis of Malignant Diseases of the Larynx, illustrated by patients and drawings.—Dr. EDGEMORTH showed a patient with Unilateral Neuritis of the External Popliteal Nerve.—Dr. PROWSE showed specimens from a case of Acute Nephritis, in which the Inferior Vena Cava was plugged with clot, leaving a small central channel; both Pulmonary Arteries were plugged with similar clots.—Dr. SKENNART showed a specimen of Diffuse Cancer of the Stomach.—Dr. MICHELL CLARKE showed a specimen of Aneurysm of the Ascending Aorta communicating with the Superior Vena Cava, and Dr. SHINGLETON SMITH and Professor FAWCETT spoke on the subject.—Professor FAWCETT read a paper, illustrated with numerous specimens and diagrams, on the Retinacula of Weitbrecht or Cervical Ligaments of Stanley. Mr. HARRANT and Dr. EDGEMORTH commented on the paper.

REVIEWS.

A MEDICAL AND SURGICAL HELP FOR SHIPMASTERS AND OFFICERS IN THE MERCHANT NAVY; INCLUDING FIRST AID TO THE INJURED. By WM. JOHNSON SMITH, F.R.C.S., Principal Medical Officer, Seamen's Hospital, Greenwich. London: Charles Griffin and Co. 1895. (Crown 8vo, pp. 350. 6s.)

It is commonly believed, or at least said, that the first mate's remedy for all ills to which sea-going flesh is liable, is "a handful of salts," and it is certain that the seamen on trading vessels often undergo a great deal of unnecessary suffering owing to want of proper medical treatment. The evil is beyond complete cure, but Mr. JOHNSON SMITH has done what is possible to diminish it by writing this book. The task could not have fallen into better hands, as by the official position which he holds he is not only brought into constant relation with the seafaring classes, but has the opportunity of keeping himself well acquainted with the improvements in surgical methods and with the increase of knowledge as to exotic diseases.

In the opening chapters of the book general topics are discussed, the contents of the medicine chest are described, and occasion is taken to recommend the use of solid drugs, tabloids being specially mentioned. The chapters on fevers, which are preceded by an account of the uses of the clinical thermometer, are extremely well done. The administration of drugs is kept well in the background, and sound advice is given as to the measures which should be taken to prevent the spread of the disease.

About one-third of the volume is occupied by chapters on the treatment of injuries, and the concluding pages deal with diseases of the eye, skin, urinary organs, and bowels, with venereal disease, with poisoning, with the treatment of insensibility and suspended animation, and with the application of bandages and other appliances. There is a short chapter on cooking at sea, with some practical receipts. The appendices contain a great deal of useful information of a miscellaneous kind bearing on health on board ship, including the statutory provisions dealing with the subject, port sanitary regulations, dietary scales, etc.

We have tested the book in various ways, and have found it neither redundant nor deficient. It is written in plain language, is thoroughly practical, free from padding or fine writing, in fact, always brief and to the point. Higher praise it would be impossible to give.

THE THEORY AND PRACTICE OF COUNTER-IRRITATION. By H. CAMERON GILLIES, M.D. London: Macmillan and Co. 1895. (Demy 8vo, pp. 236. 6s.)

ALTHOUGH perhaps hardly the same interest is taken in the subject of counter-irritation as formerly, yet its undoubted value in some cases would render a satisfactory explanation of its mode of action very acceptable.

Dr. GILLIES's book is divided into two parts—(1) Historical and theoretical, and (2) practical. The historical survey occupies six chapters, and in Chapter vii a new theory is stated and discussed. There seems to be no difficulty in accepting in general the author's contention that inflammation is a natural effort to repair an injury or a diseased state. The science of bacteriology has somewhat modified the views on inflammation, and one well-known definition at the present moment is that inflammation is the method by which the organism attempts to render inert noxious elements, introduced from without or arising from within. On the other hand, the author's reasoning is not convincing if it is intended to prove that inflammation in every phase and stage is under all conditions a reparative process. His views as regards inflammation and its relation to counter-irritation are summed up on p. 111 thus—that every process of inflammation is a natural effort towards cure, and that the beneficial effects of counter-irritation result from their facilitating or accelerating that process.

In Part II the uses of counter-irritation are discussed in general in Chapter i and in detail in Chapter iii, whereas in Chapter ii some practical observations are made on the circumstances in which counter-irritation should and should not be employed. The detailed uses given are: (1) To quicken repair, (2) to relieve pain, (3) to promote absorption, (4) to throw off diseased tissues, (5) to remove passive engorgement, (6) to rouse from a state of unconsciousness, and (7) to draw poisons from the tissues (as in dog-bite).

Objections might readily be made to some statements made under the author's allusion to the Koch treatment in the section dealing with the throwing off of diseased tissues. Dr. Gillies prefers the use of blistering fluid in the treatment of lupus to the sharp spoon. He is satisfied (p. 168) that if the health is rightly cared for the blister leaves the scraper under such conditions with far worse than no excuse. It may fairly be stated that the power of blisters to draw poisons from wounds as in dog-bite remains to be proved.

In Chapter iv, the Davies Hall treatment of acute rheumatism with blisters is interestingly discussed, and in Chapter v the various agents used as counter-irritants with their different preparations are dealt with in a very practical manner.

It will be readily admitted that the question of counter-irritation is a difficult one. It is one of those subjects which, not lending themselves directly to experimental investiga-

tion, have furnished opportunity to keen and philosophical, but almost endless, discussion without our appearing to come much nearer to the solution.

Part I of this book will be read with interest, but Part II is of greater worth. At times the thought comes to the reader (very wrongly, no doubt) as to whether in these busy days the subject might not have been treated in a more condensed form.

LEHRBUCH DER VERGLEICHENDEN PATHOLOGIE UND THERAPIE DES MENSCHEN UND DER HAUSTHIERE. [Handbook of Comparative Pathology and Treatment in Man and Animals.] Von Dr. GEORG SCHNICKENBUCH, Privat-Dozent der Tiermedizin in Kiel. 1te Lieferung. Die Infektionskrankheiten. Leipzig: Wilhelm Engelmann. 1895. (Royal 8vo, pp. 216. M.5.)

There can no longer be any doubt concerning the importance of the comparative study of diseases in man and animals. The latest developments of bacteriology as applied to the prevention of disease in animals and man, as well as to the cure of disease in man, have rendered it essential that similar infections in man and animals should be carefully studied and thoroughly understood. A further reason lies in the important subject of the communicability of disease from animals to man.

In the author's introductory remarks there is a very clear indictment as to the neglect which this comparative study has met with in the past. He laments that in Germany no University with the exception of Munich has a chair of veterinary science, such teaching being relegated to a secondary position. After this there is an interesting general account of some of the differences underlying diseases in man and animals.

The plan followed in this work is to give a general account of the infection, including the bacteriology, then a special description of the disease, first in man and afterwards in animals in their order of susceptibility. At the end of each chapter there is a valuable account of the sanitary legal aspects of the disease in question, including the police regulations. To the medical profession such infections as diphtheria, tuberculosis, hydrophobia, tetanus, anthrax, actinomycosis, will offer a more special interest, and in each case these diseases are satisfactorily dealt with. As regards the paragraphs on bacteriology, they are perhaps a little unequal. At times the description of the micro-organism is complete, including its morphology, mode of culture, etc.; at other times the information is hardly as full as it might be. Under the paragraphs on treatment there is no account of the all-absorbing topic of the serum treatment of diphtheria, and none of the antitoxin treatment of tetanus. It may be open to some doubt whether it was necessary to include diseases not known in animals, such as scarlet fever, etc. The short account given can hardly be of any value to anybody; this criticism applies specially to the treatment.

The above are but slight imperfections in an excellent book, and if the two succeeding volumes maintain the standard of the first a very valuable work will be the outcome of the author's exertions. It should supply a distinct want, and is well worthy of a place in a general medical library.

ORIGIN OF PLANT STRUCTURES BY SELF-ADAPTATION TO THE ENVIRONMENT. By the Rev. GEORGE HENLOW. London: Kegan Paul, Trench, Trubner, and Co. 1895. (F.R. 8vo, pp. 296.)

Mr. HENLOW has collected an immense number of facts, with full bibliographical references, to prove that "natural selection" has had nothing to do with the origin of species; and if he does not succeed in convincing the reader, he at least deserves the credit of having written an interesting book. His contention is that "variability and environment are the two great factors in evolution, and sufficient without the aid of natural selection." Indeed it amounts to this, that natural selection and survival of the fittest are mere dreams.

He recognises the fact that Darwin considered natural selection as distinct from adaptive variations in plants. It

is generally admitted that local conditions determine or greatly influence the nature and characteristics of the vegetation, and especially its physiognomies; but the surviving flora must surely be due to a kind of selection, and it is what we may. Mr. HENLOW argues that variations are simply incident species, and so they often are; yet he lays special stress on the fact that many Alpine forms of lowland species have not yet become fixed species, though botanists of eminence have described them as such.

Bonnier and Flahault's observations on the same species in different latitudes and at different altitudes are given in illustration. But it may be added that in a dry season such as the past, one had not far to go to find curiously reduced forms, and a succession of such dry seasons would cause the disappearance of certain species from certain localities and favour the development of others. Mr. Gaston Bonnier's latest experiments are the most interesting and instructive as to the influence of climate. He cultivated, or caused to be cultivated, at different altitudes plants propagated from one and the same individual, growing in the plains. In these experiments the soil and other conditions were as nearly as possible the same at the different altitudes, though differing from natural conditions, inasmuch as there was no struggle or competition with other plants for existence. The results were a reduction at once to the characteristic Alpine form; the size, the external morphology, and the anatomy having undergone great modifications. But we do not see how such facts—and many others that Mr. HENLOW brings forward in support of his argument—prove that there has been no natural selection in operation.

However, apart from this question, this little book is well worth reading and studying. A considerable number of typographical errors have been overlooked, and care has not always been taken to verify statements easily verified. For example, it is stated (page 191) that Spitzbergen "has no annuals at all."

SUGGESTION UND REFLEX: NEUE KRITISCH-EXPERIMENTELLE STUDIE UBER DIE REFLEXPHÄNOMENE DES HYPNOTISMUS. [Suggestion and Reflex: a Critical and Experimental Study of the Reflex Phenomena of Hypnotism.] Von Dr. KARL SCHAEFFER. Jena: Gustav Fischer. 1895. (Royal 8vo, pp. 122, 6 plates. M 6.50.)

Dr. SCHAEFFER begins by stating the conflicting views about the nature of hypnotism maintained by the school of Nancy, as represented by Bernheim, and the school of the Salpêtrière as represented by Charcot. Bernheim holds that everything in hypnotism can be explained through the action of mental suggestion, and even when no direct suggestion is made that the hypnotised person knows or guesses what the operator wants, and obediently executes it. On the other hand, Charcot indicated some phenomena which could not be explained as the result of mental influences. He instanced the contraction of particular muscles on the skin being touched, for the patients are not anatomists who know the action of particular muscles. Freud noticed that by stimulating the surface of the skin the almost diseased muscles of the ear could be made to contract.

Dr. Schaeffer, while admitting the influence of mental suggestion, maintains that there is also present in hypnotism a heightened degree of cutaneous and muscular excitability which is the cause of many curious phenomena of muscular contraction and rigidity. These he attributes to the reflex action of the grey substance of the posterior horn of the spinal cord. He tells us that mental suggestion is but a form of association, and reflex action is also a form of association. Hence he considers it fruitless to dispute whether certain phenomena in hypnotism are really of psychical or somatic character. We do see some analogy between mental association and spinal reflex action; but there is also a distinction sufficiently clear to prevent the disputants being satisfied with Dr. Schaeffer's assurance that there is a substantial agreement between them. In reality Dr. Schaeffer supports the school of the Salpêtrière. He gives in great detail a number of experiments made by Laufenauer, H. Gey, and himself, in which different groups of muscles were thrown into contractions by stimuli applied not only to the skin but to the eye, the ear, and the sense of smell, and Dr. Schaeffer

reminds us that every precaution was taken to exclude mental suggestion during these experiments. The descriptions are well illustrated by six leaves of plates taken from photographs and also by some woodcuts in the text.

MICROSKOPISCH UND CHEMISCH AM KRANKHEITSBETT [Clinical Microscopy and Chemistry]. Von Professor Dr. H. LERNHAERTZ. 3te vermehrte Auflage. Berlin: Julius Springer. 1895. (Demy 8vo, pp. 325, with numerous illustrations and three coloured plates. M. 8.)

A DEMAND for a second edition of this book in two years after its first appearance bears fitting testimony to its excellence. The examination is arranged under the following sections: (1) parasites, vegetable and animal, (2) the blood, (3) the sputum, (4) the secretions of the mouth, the stomach contents and stools, (5) the urine, and (6) fluids obtained by puncture. The importance of bacteriology is further accentuated by the introduction in this edition of a short description of cultivation media and of the mode of growth of certain micro-organisms. The work constitutes a very useful outline account of a subject of rapidly growing interest. Our much increased knowledge of the morbid changes in the blood is well reflected in the second section, which also contains an account of the blood in health. Both the general changes affecting the blood in disease, as well as those in the more special blood diseases, are described.

In each of the remaining sections the naked eye and microscope examination is fully detailed after a few general remarks. In all cases a very useful account is appended of the alteration to be found in the excretions and secretions in the principal diseases. The chemical examination of the gastric contents and the urine include the most recent information on the subject. The account of the changes in the urine brought about by the administration of certain drugs is a useful addition. There is an appendix to the section on the alimentary canal, which includes the examination both of the vaginal secretions, lochia, and products of abortion, as well as that of milk.

The information in this book is reliable and well up to date, and the methods are clearly and succinctly described. It deserves to be most cordially recommended.

L'ALCOOL. Par les Docteurs PAUL SÂRIBUX, Médecin des Asiles d'Aliénés de la Seine, et FÉLIX MATHIEU, Médecin des Dispensaires de la Ville de Paris. Paris. 1895. (Small 8vo, pp. 192.)

THE authors, whose experience and observation of alcoholism have been extensive, present a clear and comprehensive account of the various questions which cluster around alcohol. The composition and effects of all varieties of alcoholic intoxicants are set forth at length. The most noxious of the alcohols—the alcohol (ethylic) of wine—are described as paralysing the higher mental faculties, the alcohol being called a poison of the intelligence, neither restoring nor fortifying—in short, a narcotic. The uselessness of alcohol in increasing endurance and in resisting extreme cold is insisted on, and the alleged advantages from the use of alcoholic liquors are stigmatised as illusions. A chapter is devoted to the hygiene of drink, in which, after water, the best drinks are stated to be coffee, tea, cocoa, maté, and acidulated beverages. Sweet aromatic drinks made from syrups of fruits are highly commended.

The opposition to abstinence, and the opinion in favour of moderate drinking are credited by the authors mainly to prejudgments which are among the consequences of drinking. The authors contend: (1) That the use, even moderate, of distilled liquors is dangerous, and should be proscribed. (2) That the habitual use of fermented drinks (wine, beer, cider, etc.) is useless for the performance of healthy function. (3) That the moderate use of very weak unsophisticated fermented drinks can be tolerated by some persons, but only with food. (4) That weak fermented drinks ought to be withheld from children and adolescents, from women in pregnancy and lactation, from persons of sedentary occupation, from neurotics (hysterical, epileptic, and neurasthenic),

from descendants of these and of the insane, reformed inebriates, the children of inebriates and inebriates themselves; also from the obese, chlorotic, anemic, dyspeptic, the subjects of diseases of the liver, kidneys, skin, the diabetic, the arthritic, etc.

NOTES ON BOOKS.

Transactions of the Ophthalmological Society of the United Kingdom. Vol. xv. (London: J. and A. Churchill. 1895. Cr. 8vo, pp. 314. 12s. 6d.).—The first pages of this volume of the Ophthalmological Society's *Transactions* are occupied by Dr. Gowers's highly suggestive and original Bowman Lecture on Subjective Visual Sensations. It is illustrated by a large number of new drawings, some in colours, made by three patients liable to migraine. The volume contains also numerous other coloured plates which illustrate admirably the conditions with which they deal. One of the papers of most general interest is that by Dr. Argyll Robertson on a case of *Filaria Loa* in which the parasite was removed from under the conjunctiva; it is enriched by a description of the worm and by some critical remarks by Dr. Manson, and embellished by excellent coloured lithographs. Another paper of general interest is that by Mr. George Lawson on Plastic Cellulitis of the Orbit, a serious and commonly fatal malady, the exact causation of which is obscure, though there seems reason to suppose that it has sometimes been determined by operations within the nasal cavities.

REPORTS AND ANALYSES AND DESCRIPTIONS OF NEW INVENTIONS IN MEDICINE, SURGERY, DIETETICS, AND THE ALLIED SCIENCES.

A PARAFFIN SAFETY LAMP.

WE have received from Messrs. Kleson and Co. (25, Fore Street Avenue, E.C.) an improved form of their safety lamp, in which the defects we pointed out in our former notice of it are removed. The base has been widened, so that it is not so easily upset as it was before, and the communication between the wick tube and the oil chamber, to which we drew attention, has been closed. The wick tube has also been made longer, so as to reach much nearer to the bottom of the reservoir. In its improved form we believe it to be a very safe lamp. It is strongly made, and its curved wick tube is very efficient, not only for the purpose of preventing explosion, but as entirely preventing the escape of oil by the side of the wick in case the lamp is overturned. Its price also is very small, and should put it within the reach of all.

CONGRESS OF PSYCHOLOGY.—The Third International Congress of Psychology will be held at Munich from August 4th to 7th, 1896. The President of the Organising Committee is Professor Stumpf, of Berlin, and among the members are Professor Ferrier, Professor Schäfer, Professor Sidgwick, Professor Sully, Professors Bernheim and Liégeois of Nancy, and Professor Richet of Paris. The programme includes four divisions—namely, psycho-physiology, psychology of the normal individual, psycho-pathology, and comparative psychology. The general secretary is Dr. Frhr. von Schrenck Notzing, Max-Joseph Strasse 2-1, Munich.

THE PENNSYLVANIA COLONY FARM FOR EPILEPTICS.—The project of establishing a colony for epileptics, where country living and farm work, judiciously apportioned, would constitute the principal therapeutic treatment, which has been under consideration by the Pennsylvania State Legislature, has at length assumed a definite shape. The court has granted a charter for the "Pennsylvania Colony Farm for Epileptics." A gentleman of Philadelphia has offered to give 50,000 dollars for the erection of suitable buildings, providing that the farm be secured before January 1st, 1896.

REPORTS

ON

THE NURSING AND ADMINISTRATION
OF IRISH WORKHOUSES
AND INFIRMARIES.

SPECIAL COMMISSION OF THE "BRITISH MEDICAL JOURNAL."

XIII.—MULLINGAR WORKHOUSE INFIRMARY,
CO. WESTMEATH.

We were somewhat amused when we reached this infirmary to find that the medical officer, Dr. Dillon Kelly, finding that the infirmary quarters were neither commodious nor suitable for all his patients, had taken the bull by the horns, and settled the male patients in the empty fever hospital; and a very pretty settlement it is. Entering by the lodge, and passing through the dining hall, we came first to

THE INFIRMARY.

which we found quite in accordance with the medical officer's report as laid before his Board: "The infirmary is primitive in its arrangements for light, air, space, and sanitary arrangements, totally unfit for the treatment of medical or surgical cases, and positively injurious to asthma." These wards have rough surface walls, whitewashed; the roof is pitched and plastered, the floors are uneven and none too clean, the fireplaces are old, the windows small and draughty, the ventilation, by means of the upper part of the windows and small apertures in the opposite wall, neither sufficient nor easy to regulate. The beds are the old wooden frames with straw ticks, and are crowded together. The six wards hold 8 or 10 beds each, and are all appropriated to the women. There are no dayrooms. These wards are

OVER THE LUNATIC WARDS,

which are unceiled and admit of the free transmission of sound, and are within earshot of the yards used by the idiot class. These sick wards are locked at night, there is no night nurse, and no bells to the officers' quarters. We saw several serious cases in this division, two patients in advanced phthisis, one with eczema on the legs, paralysis (the patient lacked the power of retention), dropsy, a severe case of rheumatism, senile decay in all stages, etc.

THERE WERE BUT FEW COMFORTS,

the crowded and limited space does not admit of tables or armchairs. In the ward on the ground floor some attempt has been made to relieve the monotony of the whitewash by pasting some pictures on the walls. The airing courts are equally desolate, and would be improved by the addition of shelters and benches.

As we mentioned above, Dr. Dillon Kelly has placed his male patients in the

"FEVER" HOSPITAL.

Outside this hospital the doctor has laid out and stocked a small garden, and contrived a greenhouse, and here we saw the old men happily employed in gardening, and one of them showed us the greenhouse with much pride. They felt a proprietorship in the garden and an interest which it was refreshing to see. The "fever" hospital here, as in every other case, is better built and more adaptable than the infirmary, and we do not wonder that the doctor coveted these wards for his patients. The wards, four in all, are on the two floors, the administration block occupying the middle portion of the structure. On entering we found ourselves in a clean commodious hall, where there is a table with writing and other materials for the doctor's use; the nurse's room and the kitchen open out of the hall on the further side, and the wards on either hand, a wide staircase communicating with those above. There are 40 beds in all.

THE PATIENTS

were not very numerous, and the trained nurse was away for her holiday, her place being supplied by another nurse. Such cases as we saw were in much better condition than

those in the infirmary; the wards are wider, the beds not so crowded; there is cross ventilation, and more light and sunshine. There was a case of abdominal disease, advanced phthisis, some cases of chronic asthma, etc. Several of the patients were able to be up, and they were seated in armchairs or round the tables. The smooth surface of the walls was coloured in two shades; the fireplaces were more capable of warming the wards, though we could not feel that the heat would be sufficient in the winter, especially if turf were used.

THE LUNATICS

are placed on the ground-floor of the infirmary, underneath the sick wards, their apartments being unceiled. There are no cells, but the wards are dark, dreary, and uninviting, with rough walls, small windows; the inmates are dirty and neglected in appearance, have no attendants but paupers, and no outlet but the confined yard. There was nothing that indicated kindness or consideration for these unhappy creatures. There are no baths or conveniences in this division. The hospital nurse is responsible for the lunatics, who are locked in at night under the charge of a pauper, the nurse being over in the "fever" hospital. There were five men and seven women in these wards.

THERE IS ONE TRAINED NURSE

who has 120 beds under her charge; there is no night nurse, the result being that the nurse's rest is frequently broken, and if not actually called up, she must often be very anxious about her charges. Her assistants in the wards are the paupers, on whom no reliance can be placed. But we have so often in these reports described the pauper "nurse," that our readers will not need any further insistence on this point.

THE LYING-IN WARD

is a small ward in the body of the house holding three beds; it was empty when we went over the house. The room had rough whitewashed walls, unceiled rafters, a poor fireplace, and bad ventilation. The number of confinements averages about fifty in the year, and the patients are attended to by a midwife from the town, the hospital nurse being responsible for them during their recovery, though their actual attendant is a pauper woman.

THE INFIRM WARDS,

to quote again from Dr. Dillon Kelly's report, "are long, low, cold, uninviting apartments, badly lighted and heated, unceiled; they are locked on the outside at night, leaving the inmates without means of communication, even in case of illness or fire." These wards are in two-storeyed buildings, which stand at right angles to the infirmary and body of the house, forming one side of the two large yards; they answer in every respect to the above description. Both men and women are on the ground floor, the wards containing 22 beds respectively; there are no day rooms. We saw no seats for the old people other than benches. A table at the end of the wards was set out with mugs and plates; a few old women were in bed, and one old lady was washing out her cap by the stove. The ward did not look tidy.

IN THE YARD

In front of these wards were some unsavoury heaps of refuse awaiting removal, and some of the ward slops were being rinsed away, as was quite evident by the smell. This yard is much encumbered with laundry poles. On the main side the conditions were a little better; the yard was tidy and well swept, and the ward trimmer, though we could not see that in the matter of comforts the men were better off than the women. The system of pails and buckets is in force in this division, as there are no indoor conveniences.

OUTSIDE THE HOSPITAL.

We found the usual privies, quite 25 yards away from the building, a distance which makes them practically useless in bad weather or at night. The wagon receptacles are frequently emptied. The outdoor conveniences for the infirm wards can also only be used in the daytime, as these wards are locked at night. No water is laid on except in the "fever" hospital, where is a separate laundry, and more efficient means of supplying hot water.

THE SICK DIETS

are cooked in the two hospital kitchens under the supervision of the nurse; in both we found cooking ranges of modern construction. The kitchen and laundry in the body of the house remain as they were built fifty years ago; they have the large coppers of the famine period, unwieldy and difficult to keep clean, and each with its separate furnace.

RECOMMENDATIONS.

In the "fever" hospital, where the medical officer has placed his male patients, the guardians may see what are the structural requirements of a place where the sick are tended; sufficient floor space, air and light, smooth wall surface, and good ventilation; under such conditions it is more possible to keep the patients clean and to nurse them efficiently. It is evident that the sick are overflowing the space assigned them, and the demand for hospital space will increase, as the district is a populous one. As things are the men are better off than the women, and we trust that the guardians will see their way to improving the female hospital; modern bedsteads and fewer of them, armchairs and modern fireplaces, walls plastered and coloured would be no small alleviation to the lot of the sick women, but entire reconstruction of the block would be by far the most satisfactory course. The sanitary appliances require to be brought up to date, and baths with hot and cold water supply are urgently needed. But in the front of all stands the nursing question; the medical officer has no opportunity of treating the patients with one nurse to 120 patients by day and none at all by night; until pauper nursing is superseded by a trained paid staff the sick department is a hospital only in name. Trained nursing will be found the truest economy in the end.

THE IRISH PRESS ON OUR COMMISSIONER'S REPORTS.

Just over a year ago the *Irish News*, awakened in regard to the question of workhouse affairs, especially Irish workhouses, and being interested. A great deal of information was furnished in reference to the manner in which nursing, instruction, and day-work has been carried out in the workhouses throughout Ireland, in many cases the arrangements provided were found to be very inadequate, and a number of the Boards of Guardians in the country, when roused to make investigations in reply to the allegations of the Irish Medical Association frankly admitted the necessity that existed for putting their house in order, and accordingly set themselves to the task with more or less success. Some others there are, however, who have not been so quick to act in the matter. The *BRITISH MEDICAL JOURNAL*, too, has done good service by laying bare the secrets of the lunatic wards of a number of workhouses throughout the country. There is no doubt that public attention is being more closely drawn to the administration of the Poor Law and to the working of the Poor-law system. It is not to be assumed that the guardians are to blame for the onerous and disgraceful state of affairs that is now and again revealed. It is the system rather than the guardians that should bear the blame. It cannot be denied that most of those who are elected to the office of Poor-law guardians endeavour to carry out their duties in a good and humane spirit. Occasionally mistakes may be made by individual boards, and now and again hardship may be inflicted; but, generally speaking, the guardians deal in as generous and kindly a manner with the poor as the nature of the cast-iron system under which they operate will allow.

VACCINATION AND SMALL-POX IN 1894.

No. XXIV.—STOCKPORT.

THE borough of Stockport is to be congratulated on having curtailed to small dimensions an outbreak of small-pox in 1894, which at times threatened to develop into a serious epidemic. As a matter of fact the cases only numbered 37, but these comprised 14 separate introductions of the disease into the town, while of the sufferers, 12 were either tramps or inmates of common lodging houses frequented by tramps, one was an itinerant ice vendor, and one a navvy at the borough sewage outfall works, his attack necessitating the impression on his fellow workers of the expediency of re-vaccination. And in addition there were two localised outbreaks, each of which arose by reason of a mild unrecognised case, and one of which gave evidence of attempts on the part of patients to set the sanitary officials at defiance. In the first group of 9 cases the primary attack had been deemed three weeks before recognition to be chicken-pox, and the little fellow had resumed attendance at school and at a mill where he worked as a half timer. As stated, 8 other cases arose, and one adult fled on visitation by a medical man, and secreted herself in a house whence she was removed with

difficulty. An inmate of an infected household visited a public house bar, and was only removed for bathing purposes on threat of being sent to prison.

In the second group, a mild case at a mill gave rise to six others, and some of these were only found to be ailing on being bathed prior to disinfection. Indeed, the action of the Stockport authorities in securing the bathing and disinfection of all inmates of invaded houses is excellent in its results, as showing plainly very often whether the suspected individuals are sickening. The promptitude with which the officials followed up every clue, and made themselves conversant with the circumstances of all infected households, did much to stay the epidemic. The condition of vaccination of those exposed to infection also did much. Not only were vaccinated sufferers attacked very mildly in their persons, but they may be considered as having a much modified potency for harm in the spreading of infection, as mild attacks are getting to be deemed less likely to cause dissemination of the virus than those severer cases which are so frequently seen among the unvaccinated patients. Vaccination—and by this term we mean primary vaccination—certainly in Stockport last year had a vast modifying power on the cases, and the utility of the operation may be seen from the fact that all the 33 cases in vaccinated persons recovered, whilst of the 4 persons unvaccinated who caught the disease, no fewer than 3 died, their several ages being 1 year, and 34 and 45 years. No revaccinated individual was attacked.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

At a meeting of Fellows to be held at the College on Thursday next, January 2nd, the President will report that one deputation of Fellows and one of Members had been received by the Committee of the Council appointed to receive deputations from the Fellows in reference to the desirability, or otherwise, of applying for a new charter; and that the Committee had postponed its report until after January 2nd, when one of the resolutions upon which it will report is to be considered by the meeting of Fellows. A resolution carried at the annual meeting of Fellows and Members on November 7th will be considered by the Fellows. It is in the following terms:

That the number of the Council be increased to thirty-two, and that eight of these, who may be Members, shall be elected by the Members only, provided always that no Member who has not been a Member for twenty years shall be eligible for a seat on the Council.

Mr. HERBERT W. PAGE will move:

That it is desirable to give to the Members of the College direct representation upon the Council, and that for this purpose the number of seats on the Council shall be raised to twenty-eight, of which four shall be filled by eligible Fellows, who shall be elected by the votes of Members only, in such a manner and at such time as the Council may determine.

Mr. R. CLEMENT LUCAS will move:

That, in the opinion of the Fellows of this College, women should be admitted to the diplomas of the College.

Mr. TIMOTHY HOLMES will move:

That this meeting learns with pleasure that the Council of the College are represented on the Civil Rights Defence Committee in the case of Mr. R. B. Anderson.

Mr. C. H. GOLDING-BIRD will move:

That the Council be requested to consider the advisability of changing the date of the winter meeting of the Fellows to the first Thursday either in December or February from the first Thursday in January.

AN EXPLORING TRIP UNDER THE DIRECTION OF TWO MEDICAL MEN.—Dr. William H. Furness and J. H. M. Miller, both members of the class of 1891 of the Medical Department of the University of Pennsylvania, have started for the South Sea Islands, where they will spend at least a year in collecting ethnological and archaeological specimens for the University. Should the field prove fruitful, it is probable that their stay may be prolonged to two years. After arriving at San Francisco they will sail for Yokohama, touching at Honolulu. They will proceed to Singapore, and from there will take passage for the Philippine Islands, visiting other groups of the East Indian and South Pacific Archipelagos in a chartered vessel.

BRITISH MEDICAL ASSOCIATION. SUBSCRIPTIONS FOR 1895.

SUBSCRIPTIONS to the Association for 1895 became due on January 1st; and notice is hereby given, in accordance with By-law 5, that Branch Secretaries' subscription accounts close on October 31st, and all unpaid subscriptions must be forwarded after that date to the General Secretary, 429, Strand, London. Post-office orders should be made payable at the General Post Office, London.

British Medical Journal.

SATURDAY, DECEMBER 28TH, 1895.

THE EVER-GROWING BURDEN OF GRATUITOUS WORK.

To those who watch the signs of the times it is becoming obvious that the erection of State medicine into a special department of knowledge, and the demand for what is practically a separate course of study from those who elect to enter the sanitary service, is having the effect of putting a considerable strain upon that feeling of sympathy and comradeship which ought to exist between medical officers of health and general practitioners, as members of one common profession.

Dr. Arthur Newsholme has recently on several occasions referred to the wide scope which the investigations of a medical officer of health should take.

Speaking of the extension of the schedule, Dr. Newsholme said: "There is, however, the important difficulty of expense. We cannot reasonably expect local authorities to pay half a crown or a shilling (according as the case occurs in private or in public practice) for each notification of these minor diseases unless we can show some immediate practical utility." To this we would say, Why not if it is for the public good? and if it is not for the public good the whole thing falls to the ground. Dr. Newsholme says that "this difficulty might be overcome by adopting the system in vogue in some Continental countries as Germany, Scandinavia, etc., a system which works smoothly and efficiently, as I have recently had personal opportunities of observing. The chief infectious diseases are required to be notified immediately, but there is a much longer list of diseases in connection with which only a weekly list is required. No fee is given to the notifying practitioner for either of these returns." This doubtless is, from the medical officer of health's point of view, the ideal system; and without definitely advocating its adoption in its entirety, Dr. Newsholme says that it is "evident that we can expect no general extension of compulsory notification unless medical practitioners are prepared to accept as small a fee as a shilling for each certificate, and are prepared to make weekly returns of the minor infectious diseases for a modified fee." But, we ask, why should the hard-worked and ill-paid general practitioner be called upon to make this great free gift to the nation, if the resulting benefits are so far off that "we cannot reasonably expect local authorities to pay" for it?

It speaks volumes for the different points of view occupied by the health officer and the medical practitioner, that anyone in the position occupied by Dr. Newsholme should think so lightly of the medical certificate, the filling up and signing of which has cost the practitioner much thought, much anxiety, and involved him in no small responsibility, that it should even be suggested that this should be done without fee, and we cannot but express our surprise that so able a statistician should so slightly appreciate the importance of the basis and foundation on which all the deductions of health statistics rest.

It should be understood by the public, as it certainly is felt by the profession, that the signing of a notification certificate, especially in an early stage of the disease, is a most anxious matter, often involving the exercise of far more special medical knowledge and experience than the prescription of the treatment for the case. It should also be borne in mind that the difficulty and responsibility are all the greater the more indefinite the disease, and, in view of the manner in which the profession has been harassed by the injudicious action of ill-advised sanitary authorities in regard to the comparatively simple certificates hitherto required in relation to some half-dozen of the best defined diseases in the nosology, medical men may well be excused if they decline to jump at the suggestion. Even in strictly legal consequences the signing of a certificate is a serious matter; if an error creeps in the medical man is liable to action, and damages may be recovered from him for assumed injury to business, or what not arising from the action taken upon his certificate, while if he withholds it until the disease has progressed so far as to render the diagnosis certain, he is always liable to be haled before the magistrate for neglecting to certify, and even if he escape a fine, to be held up to public obloquy as a breaker of the law.

THE EMPLOYERS' LIABILITY BILL. ITS MEDICAL ASPECTS.

THERE is a general expectation that a new Employers' Liability Bill will be introduced in the coming session. It will not be Mr. Asquith's Bill, though it will contain many of its principles. The doctrine of common employment will certainly be abolished in the one as in the other, and the right of compensation for accident will probably be extended to workmen in the service of the Crown, to seamen, domestic servants, and all wage earners. Under the Act of 1880 proof of negligence upon the part of a fellow employee constituted no claim for compensation from the employer. What was required was proof of personal negligence upon the part of the employer or his superintending agents. Both Houses, however, agreed to the abolition of this requirement, and it may safely be assumed that the present Parliament will be of the same mind. Indeed, if Sir A. B. Forwood's Bill, which failed for lack of time to get read last session, be a true indication of what we may expect, even proof of negligence upon the part of a fellow workman will be unnecessary. Personal injury while engaged in the execution of the work of his employer will entitle the workman to receive compensation from his employer, unless the accident was caused by the wilful act or wilful default of the workman himself. If the liability is disputed the county court will settle the question, and the judge, if he

think fit, may appoint a legally-qualified medical practitioner to examine the claimant or otherwise assist him. In case of death or of permanent total disablement, the workman or his representative is to be entitled to a sum equivalent to the wages of the workman during the three years preceding the injury or the sum of £150, whichever of such sums shall be the larger. In case of permanent partial disablement the sum is not to exceed one-half of the amount which would have been payable in the case of death. And, lastly, in a case of temporary disablement the compensation is to be a weekly allowance not exceeding two-thirds of the workman's wages, the allowance to cease if a medical practitioner appointed by the judge certifies that the workman is able to return to his work, or if the workman declines to be examined by him.

The expression "total disablement" means loss of sight, or of both legs, or of both arms, and any other injury of such a nature as permanently to disable the workman from earning wages at the kind of work on which he was employed. "Partial disablement" means loss of one eye, or of one leg, or arm, or hand, and any other injury of such a nature as permanently to disable the workman from earning full wages at the kind of work on which he was employed. And "temporary disablement" means any injury of such a nature as temporarily to disable, for a period of not less than fourteen days, the workman from earning wages or from earning full wages at the work on which he was employed. A workman may contract out of the Act, but if the compensation in case of accident is reduced, such contract is void. If, however, after occurrence of the injury, he gives written notice to his employer that he does not claim compensation under this Act, he is then free to claim any right to which he may be entitled by common law.

It is plain, therefore, that the scope of the proposed measure is likely to be much wider than anything that has hitherto been suggested. Mining, shipping, railway travelling, and all sorts of dangerous trades are already protected by Board of Trade regulations for the purpose of preventing accidents. But accidents still happen, and one political party holds that liberal compensation, when negligence upon the part of a fellow workman is proved, would tend to make employers more careful in their choice of men and plant. It would leave the amount to be settled by a jury; it would have all men treated alike and allow no contracting out. The other party regards accidents as inevitable. Board of Trade regulations notwithstanding, no large piece of work can be undertaken without them, and all that can be done is to provide fair compensation. The negligence may be assumed without inquiry. Whether it hurt the negligent man or his neighbour, injury is done all the same; a man is thrown out of employment and his wife and children are without support.

The general relations of capital and labour do not come within the province of a medical journal. There are problems regarding the liability of employers with which medical men have little immediate concern and no special knowledge. In face of these a judicious reticence is becoming. But it would be mere affectation to fail to acknowledge our alarm lest the funds and management of our hospitals should suffer through a political dispute. It is a

custom in small manufacturing towns to exact 1d. a week from every workman for the accident hospital, and the employer is also expected to make a generous contribution. In this free and easy way £800 or £1,000 per annum are collected, all cases of accident are immediately taken to the hospital, and an untold amount of suffering is relieved. Of course, where a railway company is concerned and a large number of men are kept in fairly constant employment it is an easy matter to put all this on a thorough business footing. But smaller employers, when they find they have to pay compensation, may not be inclined to continue their contributions to the hospital, and the individual working men who receive it may be in no more generous mood. In large cities it is possible that disturbance of hospital funds may be still greater.

If householders are to pay pecuniary compensation, perhaps £150, for each accident which may happen to their domestics, they will be apt to employ their hospital subscriptions in insuring their domestics against accidents, or rather in insuring themselves against their liability. Miners, shipowners, and other employers of labour will do the same with the result that, while hospital funds rapidly shrink to a minimum, insurance companies will undergo enormous extension. No doubt a way out of this difficulty may be discovered. Possibly the workmen may have some suggestion to offer. The voluntary system of hospital support cannot continue unless the volunteers are forthcoming, and already many of our hospitals are deeply in debt.

There is another point which appears to deserve the attention of those who are now engaged in framing the new Bill. While the question of compensation is still undecided, there is a mental restlessness in some cases of accident which decidedly retards recovery. It is important therefore that the necessary legal procedure should be simple, and the amount settled at an early date. But when the accident results in internal injury it is sometimes impossible to foretell forthwith whether the disablement will be permanent or only temporary. There ought to be a way of obtaining compensation for temporary disablement without prejudice to further action when the disablement has been clearly shown to be permanent.

THE FELLOWS AND MEMBERS OF THE ROYAL COLLEGE OF SURGEONS.

On Thursday next a meeting will be held within the walls of the College of Surgeons which should be one of historic interest. The occasion is the half-yearly meeting of the Fellows of the College. Before this meeting, however, will be brought, as the main topic of discussion, the claim and petition of the Members of the College to some share and representation in the Council. The subject has been so often discussed in the past in our pages that it seems almost unnecessary to refer in anticipation to the cogent reasons on which their petition is based. During the last few years, owing to a most unfortunate conjunction of events which led to a serious miscarriage of the original well-organised effort, this claim has been somewhat in abeyance. Wisely, perhaps, and with the effect, we hope, of allowing the somewhat angry feelings which were developed in the course of

an ill-judged litigation to subside, the Members' Association had for a time desisted from any active steps. It is well that these past cases of disagreement should now be left altogether out of view, and that the proposed measure which we regard as one of simple justice in the higher sense of the word, and in any case of equitable conciliation, should be judged and dealt with solely on its own merits. Looked at from that point of view, it is clear that in the present day it cannot be regarded as other than a singular anomaly that the 16,000 Members of the College who are undoubtedly its main support, and in a large and popular sense the chief constituents of the College, should be wholly without representation, and without any kind of voice in the administration of the affairs of this great institution. The Fellows of the College have recently attained to a larger share than hitherto, and to a more distinct and audible voice in the conduct of the College affairs. It is only reasonable to expect that with the growth of liberal opinion and of that confidence in the good sense and patriotism of the great body of the profession which is now everywhere apparent, a further step shall be taken with their assistance towards liberalising and thus consolidating the government and administration of the College. Nothing will have a better effect in this direction than the admission of the Members to some share of representation in the governing body of its Council. There can be no question that both in the Council and among the Fellows this view is gaining ground, and some early steps in this direction might be looked for with confidence. Backed by the help of the Council and by that large number of Fellows who are known to be in favour of conciliatory steps, it might be hoped that the consideration by the meeting of Fellows on Thursday next of the proposal of the Members brought forward by the Council will meet with large favour. It depends on the willingness of those who are in favour of these proposals to take the trouble to attend next Thursday whether or not success will on this occasion attend the just efforts of the Members' Association. We earnestly hope that it may. In any case, we will put it to all those Fellows who desire to do justice to the Members that they should not fail personally to attend. In this way they can give effect to the excellent intentions which a large number of them are believed to entertain, and it is satisfactory to know that they will not be without considerable support within the Council itself. The Council are known largely to desire to be guided in this matter by the wish and opinion of the Fellows, and anyone who abstains from attending this meeting, and who holds the liberal views which we believe to be widely entertained, may in the end have to hold himself individually responsible for any failure to carry out the desired object.

Mr. JAMES GRIERSON GLEDHILL, M.B., C.M., I.S.A., and barrister-at-law, is a candidate for Salford and County coronership, vacant by the death of Mr. Price. Mr. Gledhill is a member of the Council of the Lancashire and Cheshire Branch, and has been jointly concerned in drafting Bills to amend Medical, Coroners, and Births and Deaths Registra-

tion Acts. He has had considerable experience with the metropolitan and provincial coroners, and is the only medical candidate in the field.

THE DIRECT REPRESENTATIVE FOR IRELAND.

At a combined meeting of the Ulster Medical Society and the North of Ireland Branch of the British Medical Association held in Belfast on December 23rd, a resolution was cordially adopted approving of the candidature of Professor Cumming for the next vacancy as Direct Representative of Ireland on the General Medical Council. A letter was read from Professor Cumming accepting this nomination. A large and representative Executive Committee was appointed. Our Belfast Correspondent telegraphs that a strong feeling exists that Dublin should not monopolise the entire representation for Ireland, and that Professor Cumming would be in all respects an admirable and influential representative of the provincial practitioners.

A QUEENLY STUDENT.

THE Queen of Portugal, who for some time past has shown a pronounced taste for the study of the healing art, has completed her second year of formal medical study, and has just successfully passed the examination for second year's students before the Faculty of Lisbon. It must need a good deal of nerve to pluck a queen, but we daresay there are more diplomatic methods of making the exalted candidate aware that a further course of study would be advisable. The study of medicine, by the way, is now about the one new thing left for the German Emperor to exercise his versatile genius upon. He might present himself for examination with a light heart, for the most Rhadamanthine of Teutonic professors would hardly care to risk ploughing him.

MEDICINE AND JUSTICE.

At the Leeds Assizes last week Annie Robinson was convicted of attempting to poison her husband with white precipitate, and sentenced to twenty years' penal servitude. It is satisfactory to know that the detection of this crime and the avoidance of a greater crime were due to the tact and judgment of a medical man. Mr. Demetriadi, the doctor in question, was called to the prisoner's husband, whom he had previously known, and found him suffering from vomiting and diarrhoea. After a short time the course of the symptoms suggested to his mind the possibility of irritant poisoning, and he made an endeavour to get some of the vomited matters or excreta for examination, but as the prisoner, who was in sole attendance upon her husband, always succeeded in defeating this object his suspicions became stronger, and he procured the services of a trained nurse, with the result that the day after her arrival a portion of one of the stools of the patient was saved for examination, and was found to contain mercury. Subsequently in two specimens of food prepared for the patient by the prisoner, and handed by the nurse to the doctor, on analysis white precipitate was found in the proportion of 68 grains to the pint in one, and 83 grains in the other. Mr. Demetriadi then applied for a warrant for the arrest of the wife on a charge of attempting to poison her husband, and, the sole cause of his illness being removed, he made a gradual and complete recovery. The parties had only been married last January, and had at first lived together affectionately; but the wife seemed to have soon tired of her husband and had formed a liaison. She had, moreover, got her husband to make his will in her favour, and had insured his life and was paying the premiums at the time of his illness. She had also told several people that her husband would not get over his illness, and that the doctor had confirmed this, which was not true. Save in one respect, but that of vital importance—namely, the result to the patient—there is a very close similarity between this case and the notorious Maybrick case, and it will be interesting to see whether any of Mrs. Maybrick's

champions—if there are still any left—can spare time to take up the cudgels on behalf of another female, who, except in the matter of youth and good looks, would appear to have just the same claims for their sympathy and support that Mrs. Maybrick had. The judge in his summing up spoke in the warmest terms of the propriety, skill, and care displayed by the doctor and nurse in this case, and we think his encomiums were richly deserved. The evidence of the prisoner's guilt was overwhelming, and the judge in passing sentence said it was one of the most heartless cases he had ever had to do with.

ABBREVIATED REFERENCES.

With the last volume of the Catalogue of the Surgeon-General's Library at Washington Dr. Billings has issued an alphabetical list of abbreviations of titles of medical periodicals employed in the sixteen volumes of that work. This list is of very great practical value; in the first place, it gives in moderate compass a list of nearly all the medical periodicals both past and present; up to the issue of this volume there has been nothing published of so comprehensive a character, especially as regards the more out-of-the-way journals published in the United States. These often have titles closely resembling some well-known journal, and much confusion is occasioned by references to the former unless the abbreviations are very carefully done. The printing of this list will easily clear up mistakes of this kind and be a great saving of time and labour. It is, however, the abbreviations themselves which will be most useful; if authors will abbreviate the titles of journals in their references in accordance with Dr. Billings's list much labour will be saved, as this will prevent many mistakes, particularly as regards journals with similar titles. These difficulties have all been guarded against in preparing this list of abbreviations, and it is sincerely to be hoped that advantage will be taken of the great labour and skill which the compilers have bestowed upon their work.

THE HUXLEY MEMORIAL.

SINCE the first meeting of the general committee on November 27th, which was fully reported by the press, two meetings of the executive committee have been held. At the first of these, at which Lord Shand accepted the office of chairman, it was reported that a number of foreigners of eminence had expressed a wish to be associated with the proposal to commemorate Mr. Huxley's distinguished services to humanity. It was resolved, in the first instance, to invite subscriptions from the members of the general committee. At the second meeting, held on December 18th, it was reported that the subscriptions, which at the general meeting had amounted to £557, had been increased to about £1,400, and it was resolved that a wider appeal for subscriptions should now be made to the friends and admirers of Mr. Huxley amongst the general public. The honorary secretary stated that in America committees were in the course of being formed to promote the realisation of an adequate fund. The committee resolved to communicate, by means of a subcommittee of their number, with Mr. Onslow Ford, R.A., who had the advantage of being well acquainted with Mr. Huxley, in reference to the statue, which it is proposed should be erected beside those of Darwin and Owen in the Natural History Museum, South Kensington. The extent to which the committee may be able to carry out the other intended objects of founding exhibitions, scholarships, and medals for biological research and lectureships, and possibly in assisting the republication of Mr. Huxley's scientific works, will of course depend on the subscriptions which may now be received. These may be sent to the treasurer, Sir John Lubbock; or the bankers, Messrs. Roberts, Lubbock, and Co., 15, Lombard Street, E.C.; or to the Secretary, Professor G. B. Howes, Royal College of Science, South Kensington. The amount received to December 20th is £1,595. The Court of

the Fishmongers' Company, in consideration of the eminent and important services rendered by the late Professor Huxley to the cause of technical education, has agreed to give a scholarship of £60 per annum to the City and Guilds of London Technical College, Finsbury, to be called "The Fishmongers' Company's Huxley Scholarship," to be held for three years by any scholar who has given evidence of high scientific attainments, to enable him to proceed to the Central College at Kensington.

THE SICK POOR IN IRISH WORKHOUSES: MULLINGAR.

WE suspect that the Medical Officer of the Mullingar Union had to cut his way through much red tape before he succeeded in appropriating the disused fever hospital of the union to the use of all the male patients in the workhouse, and we congratulate him on his energy. The female patients are already overcrowded in the whole of the old infirmary, where are the narrow, dreary wards, both draughty and ill-ventilated, the uneven floors, and the wooden framed beds with their straw bedding. It seems a pity that it was not possible to put the more serious cases, both male and female, into the far better equipped "fever" hospital, more especially as there is but one nurse, who, as matters stand, may have patients dangerously ill in both hospitals, which are quite apart from each other. We suppose however there were administrative difficulties impossible to overcome, but it does seem that the solution of some of the guardians' difficulties might lie in this adaptation of the fever hospitals, built when typhus and enteric were the scourges of the congested districts in Ireland, to the use of the non-infectious patients. For with better feeding and sanitation, and perhaps also with the thinning of the population, fever has greatly diminished, and the fever hospital, fairly constructed and decently equipped, stands empty, while the workhouse infirmary, usually totally unfit for the treatment of the sick, has all its evils increased by overcrowding. It ought not to be left to the courage and perseverance of a medical officer to follow the dictates of common sense, in spite of a distant and ill-informed authority sticking for the letter of the law. The rarer fever patients might be accommodated in temporary iron buildings, or removed in ambulances to the large fever hospitals, which if any well considered scheme of amalgamation is adopted will serve several unions. In such a scheme the old people would receive shelter in their own district, and also the sick of other than infectious disease, while special and joint arrangements would be made for the imbeciles, the children, and the fever cases.

THE PASTEUR INSTITUTE AND ITS ENEMIES.

WE have again to note certain false statements lately made as to the work of the Pasteur Institute in Paris. The Victoria Street Society has published a paper entitled "M. Pasteur's Threefold Hecatomb," and Mr. Berdoe has published a pamphlet, *What is Our Debt to Pasteur?* and a leaflet, *A Pasteur Institute for Ireland: A Letter to the Irish Public*. The Victoria Street Society gives a list of every death from hydrophobia that has occurred, in spite of inoculation, during the years 1885-95. The total number is 281; of these, 210 were inoculated in Paris, 40 in Russia, 13 in other countries. It is childish folly to publish such a paper—to count the lives that could not be saved and not to count the lives that were saved. It would be equally reasonable to collect 281 cases of death from recurrent cancer after operation, and call them "a threefold hecatomb." They say that "it is easy to make a low average of mortality when those merely licked by dogs are reckoned among the total treated." It is impossible that any impartial man, who had paid the slightest attention to the subject, could write such nonsense. Mr. Berdoe is, if possible, even worse. He says "Pasteur's average is based on all comers; that is to say, on persons bitten by really rabid, doubtfully rabid, and non-rabid

dogs." Is it possible that he is really in such dense ignorance of the *Annales de l'Institut Pasteur*? He says that M. Pasteur himself wrote, in a case of dog-bite, "There needs no other treatment than cauterization." But he does not say whether the dog in this case was rabid. Finally, getting more and more foolish as he goes on, he says "M. Pasteur's statistics are simply statistics of dog-bite or dog-lick; his treatment is a miserable delusion and a cruel mockery; nobody can prove that it has ever saved a single life." The statement that the cases bitten by doubtfully rabid dogs are mixed with those bitten by dogs proved to be rabid, is absolutely false; they are not. The suggestion that deaths, in spite of treatment, are deaths due to treatment, is worse than false. We hope against hope that Mr. Berdoo will try to understand the *Annales de l'Institut Pasteur* before he writes any more rubbish such as we have quoted. We hope, also against hope, that those who still keep the Victoria Street Society afloat will take the trouble to see for themselves what false and mischievous nonsense they help to publish.

SANITARY AUTHORITIES AND PUBLIC WATER SERVICES.

We have before referred to the autocracy of water companies, with special reference to the matter of inspection of their works. The health aspects of the subject are of vital importance. Companies having acquired rights of supply over certain areas, seem thereafter to wrap themselves up as above interference, at least in too many instances, and thus bring upon themselves an amount of suspicion which it should be their object to avert. Such suspicion need not exist if companies will only allow the moral right of sanitary bodies to satisfy themselves that the nature of the works is such as to leave no room for the entry to the distributing mains of the water service of matters of a deleterious sort. Of course, as things stand at present, there is no power by which a sanitary authority can depute its officers to visit waterworks of a private company, even though the district be wholly dependent on the works for its water. That this is wrong in principle need not perhaps be contended. And no water company with nothing to conceal need hesitate to allow visitation by sanitary officers whenever and wherever they please to come. Dr. Porter, of Stockport, insists that the power for such visits, at any time and without previous notice, should be in the hands of every health body, and we cordially agree with him. He would see bacterioscopic examination made at any rate occasionally of the water served to the public, and would have the officer deputed by his authority for the purpose in possession of the right to visit every source of water supply and every filtering bed, and so on; and he deems it well that an official of the company should be present. He set out the same idea in his special report of 1894 on the water supply of the borough, and we think he has done well to repeat and emphasize the important points in his annual report for last year.

ISOLATION HOSPITALS.

In another column an indictment against the present policy of the Metropolitan Asylums Board is urged with some apparent force. The Board, it is said, spend annually about £300,000 in the isolation of small-pox and "fever," and this with the twofold object of benefiting the patients and at the same time controlling the spread of these diseases. The former object is admittedly attained, but not the latter, according to our correspondent. It is argued that, although the removal of scarlet fever and diphtheria patients to hospitals lessens the number of foci, the seasonal rise and fall show themselves independent of all this; that the proportion of cases isolated is least during the autumnal prevalence, when the hospitals are full, and greatest in the spring when attacks are fewest, so that in point of fact the seasonal decline begins when the hospitals break down, and the

seasonal increase occurs at the time when the hospital isolation is most efficient. This is true enough, although its real significance is less than might at first sight appear. At most the facts imply that the causes which determine the increase operate in spite of hospital interference with the free multiplication of known foci, and that later on the comparative breakdown of the hospital resources does not keep alive the waning epidemic. Not all the cases are isolated at best, and it would be strange if the seasonal curve were obliterated by an isolation which after all is only partial. But no one can doubt that at every stage the hospitals limit the opportunities for diffusion, or that, however great may be the actual prevalence, it would be greater still if all the hospital cases were turned loose on the community. Granting that the present partial isolation does not hold in efficient control the seasonal prevalence, and that the difficulties in the way of complete isolation are at present insuperable, is it necessary to assume that the number of foci is a matter of small moment, and that the seasonal causes have to do with dust and dirt, with uncleanly domestic habits, and with variations—seasonal variations—in personal susceptibility? Surely not. That there are obscure factors at work is tolerably certain, and one of the mistakes that have been made in the past is the assumption that the one and only cause of scarlet fever is scarlet fever in a readily recognizable form and in *genus homo*. We have learned something about milk scarlet fever, and even bovine scarlet fever, and quite recently Mr. Shirley Murphy has taught us to look to public elementary schools for a clue to some part of the mystery. The slight cases, beyond the reach of isolation and perhaps of notification, are probably responsible for much mischief. These are but examples of variable quality of contagium and variable facilities for diffusion, all of which may be thought of as possibly affected by seasonal conditions. If all else can be excluded, seasonal variation in susceptibility may come into question, but at present it awaits proof of any kind. More thorough cleanliness and disinfection would be excellent measures in themselves, but it is not epidemiologically permissible to argue too directly from cholera to scarlet fever. The value of the work of the Metropolitan Asylums Board is, perhaps, most clearly shown in the success which they have achieved in their campaign against small-pox, although even here the seasonal variation still shows itself, and occasional outbreaks reveal the existence of undercurrents. If the statistical results are less convincing with regard to scarlet fever and diphtheria, we ought, nevertheless, to give credit to the Board for the good demonstrably done by the vast work of isolation which they are carrying on. It is no fault of theirs that the isolation of scarlet fever and diphtheria is at present less complete than that of small-pox.

THE METROPOLITAN ASYLUMS BOARD.

At a special meeting of the Metropolitan Asylums Board held on December 21st it was decided to open the Gore Farm Hospital for the reception of convalescents recovering from scarlet fever. In the course of the discussion the correctness of the comments on the situation which appeared in the *BRITISH MEDICAL JOURNAL* of December 2nd was demonstrated almost to the letter, notwithstanding the somewhat astonishing protest raised against the assertion, made by "a medical journal," that a divorce had taken place between the work of the sanitary authorities and the management of the infectious diseases of the metropolis. In regard to what we said as to the point of view from which the managers of the Asylums Board regard their duties to the public, it is interesting to record that one speaker, the mover of the amendment against the opening of Gore Farm, definitely stated that their duty was towards those patients who were in their wards, and that the Board had no responsibility in regard to those whom they were unable to take in. This of course is just the view which we knew was taken by many of the managers, and it is worthy of note that it was

not till nearly the end of the discussion that any protest was made against this way of looking at the matter. We have stated that the real root of the trouble lies in the divorce which has taken place between the work of the sanitary authorities and management of the infectious diseases of the metropolis. The truth of this is obvious to any one who considers for a moment that hardly a sanitary authority in London has a hospital for infectious cases, and that as a fact the management of these cases is undertaken by the Asylums Board on which no sanitary authority is represented except through the Poor-law guardians. We have said that it is the system that is at fault, and as an illustration of the way the system works we would point again to the statement to which we have already referred, a statement made at a meeting of the Board on whom, *de facto*, falls the hospital treatment of all the fever of the metropolis, and one which we believe to be literally true, namely, that the managers have no responsibility in regard to those patients whom they are unable to take in.

LIBRARIES AND INFECTIOUS DISEASES:

It has been deemed necessary on several occasions to close the Brierley Hill Free Library during an epidemic of infectious diseases because of the danger of the spread of infection by borrowed books; and the Committee have now considered it wise to issue with their new catalogue a list of special rules dealing with cases of infectious diseases in their relation to the uses of the library. The rules, which have been approved by the Urban District Council, are as follows: 1. The sanitary inspector shall ascertain if any books from the free library are in infected houses. 2. The sanitary inspector shall be empowered to retain any books found in infected houses until such books have been disinfected or destroyed, as required by the medical officer for the time being. 3. The inspector shall report any fresh cases of infectious diseases, such as small-pox and scarlet fever, to the librarian at the free library on the Tuesday and Friday nights in each week during the prevalence of any epidemic of such diseases, and the librarian shall keep a list of the same. 4. The inspector shall furnish the librarian with the library volume number of any book or books disinfected or destroyed, in accordance with Rule 2. 5. That all books belonging to borrowers having infectious diseases in their homes should be impounded by the librarian until the expiration of such period of time as the medical officer may consider necessary. 6. That any borrowers not having books from the free library at the time of any seizure of infectious diseases at their homes shall not be permitted to obtain books from the free library until the expiration of such time as the medical officer may direct. 7. Any borrower having books from this library who shall transfer his or her books to the home of any person known to be seized with any infectious disease, such as small-pox or scarlet fever, shall be liable to forfeit the privileges of the library during the pleasure of the Free Library Committee.

INSECURITY OF POOR-LAW LIFE APPOINTMENTS.

A FURTHER illustration of the insecurity of the position of district medical officers engaged in Poor-law practice is afforded by the case of a correspondent, who states that, owing to the alteration of the boundaries of several of the medical districts of the union in which he holds a life appointment his district has been so altered as to leave him with an additional area and also with additional population, and he states that this will without doubt cause him additional work. He tells us that when he consented to the proposed change being made, he did so with the full expectation that he would have an equitable increase of salary. This the guardians now refuse to give; he naturally thinks that he has not been justly treated, and asks for our opinion. If the facts are as stated, and we have no reason to doubt this, his application for an increase of salary is only reason-

able, and any other public body but a parsimonious Board of Guardians would so regard the question. Unfortunately for our correspondent, his Board appears to study economy without any regard for equity. This case is one which points strongly to the necessity for some steps to be taken to render life appointments (so called) really such, and only to be determined by the guardians for serious neglect of duty, or with due compensation for loss of office.

ST. ANDREWS AND DUNDEE.

In connection with a request from the Universities Commissioners for information as to a basis of negotiations for a union between St. Andrews University and Dundee University College, the University Court of St. Andrews has, by a majority of 9 to 3, passed a resolution declaring that it is useless to enter into any discussion regarding a new agreement until the defenders in the action of Metcalfe and Others v. Cox and Others withdraw their defences, and allow judgment to be given against them.

LORD CHANCELLOR'S VISITOR IN LUNACY.

DR. DAVID NICOLSON has been appointed one of the Lord Chancellor's Medical Visitors in Lunacy in succession to Dr. Lockhart Robertson, who has resigned the office. Dr. Nicolson, who is a graduate of the University of Aberdeen, held several appointments in the Prison Medical Service before his appointment as Superintendent of the State Criminal Lunatic Asylum at Broadmoor, in succession to Dr. Orange, C.B. Dr. Nicolson is at the present time President of the Medico-Psychological Association, and the announcement of his appointment as Visitor in Lunacy will be received with much satisfaction by medical psychologists in this country, by whom he is highly esteemed. Dr. Nicolson is an active member of the British Medical Association, and has rendered considerable services as a member of the Parliamentary Bills Committee.

ADULTERATED MEDICINE.

ACCORDING to a report of proceedings under the Food and Drugs Act at Birmingham, four cases were brought before the police magistrates, in which persons described as retail chemists were charged with selling medicinal preparations which were not of the nature, quality, and substance of the articles demanded by the purchasers, namely, tincture of aloe and tincture of iodine. These are both preparations of the *British Pharmacopœia*, and by the provisions of the Pharmacy Act, 1868, qualified chemists are required to compound them according to its formularies. But the evidence given by Dr. Alfred Hill, the local medical officer of health and public analyst, showed that the articles sold were not in any instance properly compounded. Some of the ingredients were present in much larger proportion than the *Pharmacopœia* directs, and as the preparations are intended for internal administration, the consequences of taking an overdose might have been dangerous. In three of the cases the defendants were convicted and fined, while the fourth was withdrawn by reason of a technical informality. Two of the defendants had previously been fined for similar offences. One of them admitted that he was not a registered chemist, and that seems to be the case with the other three, as their names are not on the *Register* of persons qualified under the Pharmacy Act. All the defendants appear, therefore, to have been unlawfully carrying on the business of chemist and druggist without having satisfied the requirements of the law as to necessary technical knowledge. Although the adulteration proved was not of a fraudulent nature, it showed ignorance calculated to be detrimental, for the purchasers of drugs or medicinal preparations cannot protect themselves, as they might do to some extent in buying ordinary articles of food, but must rely upon the honesty and accuracy of the chemist, who is alone qualified

to deal in such articles. In this respect the Pharmacy Act appears to be defective, and to fall short of providing for the safety of the public by merely prohibiting the sale of actual poisons by any but qualified persons. In the supply of medicine it is no less important that the persons engaged in that delicate and responsible business should possess competent skill and knowledge to justify the confidence which the customers must of necessity have in them. It is fortunate that the Food and Drugs Act can be applied to make up for the deficiencies of the Pharmacy Act, and the Birmingham authorities are to be commended for the activity they have shown in the public interest by instituting these prosecutions.

HOMICIDAL LUNACY.

Referring to the recent articles in our columns on murders committed, and attempts to murder recently made, by persons mentally affected, we may briefly refer to two cases reported within the last few days, in one of which the murderer was found to be insane, and in the second of which the killing was done by one who, according to the reports published in the daily press, was stated by the neighbours to have been drinking heavily for some time, and to have been not considered sane by many people. We do not jump to this conclusion, of course. The former was a man named McQueen, who murdered his uncle recently, and was found insane by the High Court of Glasgow the other day. It was found that he was under a delusion that he was ordained by God to be the instrument of vengeance on materialists and sensualists. In pursuance of this mission he appears to have taken his uncle's life. People with "missions" and sane, or supposed to be sane, are a public nuisance, but lunatics with "missions" are a deadly danger to the public. If retaining their freedom, they are able to devote the considerable powers of mind still possessed by lunatics of that type to the logical carrying out of their delusions or of their pious obedience to their hallucinations in the form of "spiritual" or "heavenly" commands by the accomplishment of some homicidal or dangerous act. The second case recently came before the Southwark police court. A labourer's wife cut the throat of her baby, aged 3 months, with a table knife during the morning, and almost in the presence of her daughter, aged 11 years. When arrested immediately afterwards, she made references to suffering from jeers, and other statements which serve to indicate that a very close investigation into her mental state, just before and at the time of the commission of the act, is necessary as the basis for determining the question of responsibility or irresponsibility on the ground of disease.

THE PRESS AND PRIVATE LUNATIC ASYLUMS.

Our attention has been called to a recent article in a daily contemporary on the subject of private lunatic asylums. The writer of it starts with the Lanchester case as his text. He takes it as constituting an "exposure of the methods pursued by private asylums and the lunacy doctors," and as showing that "it is time something was done to protect the public from this insidious danger." For the sweeping statement that the case exposes the methods pursued by private asylums (that is, by all) there is no ground whatever; it does not expose the methods pursued even by a single asylum; for the published evidence shows that, whatever the rights or wrongs of that particular case may be, the only action that took place that could be so much as publicly called in question was that of the friends and certifiers, inasmuch as they alone had the opportunity of acting on previous personal knowledge. Then the writer proceeds to give a sort of explanation of an alleged frustration of all attempts at thorough reform; and in doing so he falls foul of what he calls "the three most gigantic and conservative trade unions that exist in this country"—namely, the lawyers, the doctors, and the per-

manent Government officials. The last are the worst; but "the influence of the legal and medical professions is only a little less insidious and powerful than that of the permanent officials. The lawyer finds his profit in keeping up the old legal forms as much as possible, so that its terms cannot be understood by the plain man; the doctor in making as much business and as many well-paid official positions for himself as he can." And this, too, in spite of all the achievements of preventive medicine. And this is taken to explain why the attempted reforms have been no reforms at all. But we are immediately enlightened as to part of the basis for the conclusion that the reforms urged by the writer are necessary—namely, "the exposures of the iniquitous methods pursued by the private asylums made by the late Charles Reade." It is really too absurd that the sensational writing of Charles Reade on this subject should be taken seriously. Nor would anyone who really knew the facts concerning asylum "methods" think it possible that, but for her position, Miss Lanchester might have remained "a prisoner for life, a sane denizen of a madhouse." The hearsay case, related at some length, would not be of any value until all the facts in connection with it were threshed out by those who could obtain, and are competent to sift, the evidence—and full and sufficient evidence—from all sides. A few years ago a Royal Commission sat on this subject and took volumes of evidence upon it. The investigation extended over a long space of time. All who considered themselves aggrieved were allowed to come forward and state their case, and their doing so was facilitated. But, on investigation, all the charges made broke down, and the members of the Commission reported to the House of Parliament, by which they had been appointed, that no case of unlawful detention had been made out. This is an asylum question, but not specially a private asylum question. Probably just as large a proportion of public asylum patients as of private consider themselves unjustly detained or placed in an asylum; certainly, considering their lack of means to bring legal actions, the percentage of pauper cases among the total of those instituting legal proceedings against those who placed them in asylums is very large. No system will get rid of it. For patients with certain forms of insanity are sure to believe themselves to be improperly and illegally sent to and detained in any asylum; and some of these are most dangerous lunatics.

THE SALE OF INFECTED MILK.

The epidemic of enteric fever at Plumstead during May and June, 1895, reported by Dr. Sidney Davies to the Society of Medical Officers of Health, exhibits in a striking manner the defects of the 71st Section of the Public Health (London) Act and the corresponding Section 4 of the Infectious Diseases (Prevention) Act, which, while enabling a magistrate, after a number of legal formalities have been gone through, to prohibit the sale "within the district" of milk which has been proved to his satisfaction to have been the cause of spreading dangerous infectious disease, implicitly permits its sale in any other district, in accordance with the real meaning of the legal dictum, so generally misunderstood, that "the exception proves the rule." In the provinces such milk would in all probability be sent up to London to swell the quantity of so-called "accommodation milk" sold at the railway termini to casual customers and dealers whose regular supplies happen to be insufficient. The source of such milk, should inquiries be instituted, it is always difficult to trace. In this instance it was sent with impunity, but with disastrous results, to the adjoining district of Woolwich, to a retail dealer who had all along been supplied from the dairy in question. As to the connection of the fever with the milk there could be no reasonable doubt, though the mode of the infection of the milk remained obscure, for with the exception of some secondary cases due to personal transmission, and a few which, owing to the dairyman's irregular conduct of his

business, keeping no books, and allowing the utmost latitude to his men, could not be positively shown to have drunk this milk, the cases were exclusively among his customers, regular or casual. There is no knowing how far the consequences might have spread had he kept within the letter of the law instead of acquiring such notoriety, first by defying the order of the magistrate, and afterwards evading it by selling his milk to his own men at the railway station to be hawked about the place in alleged ignorance of its origin, and by other fraudulent procedure, as to find himself at length compelled to break up his establishment and dispose of his stock in the open market. The omission of the words "in the district" would render the section really effective for the prevention of disease.

A BLOCK FOR ISOLATION PURPOSES AT THE POPULAR HOSPITAL.

THE Chairman of the Poplar Hospital for accidents made an appeal a short time ago for £3,000 to provide an isolation block. He stated that the hospital was full of accident cases, that scarlet fever had broken out in the wards, and that there were no means of isolating nurses or patients; the hospitals of the Metropolitan Asylums Board being full, the fever patients had to be sent back to their own homes. The Poplar Hospital did not long remain in want of the money asked for, as the *Daily Chronicle* took the matter in hand, and the amount was raised within a week. The subscription list was closed on December 13th, on which day our contemporary was able to congratulate its readers upon the fact that this result had been so speedily achieved.

OVER-SUPPLY AND DIMINISHED DEMAND.

A DOUBLE suicide which, says the *New York World*, shocked Paris the other day, brought to the attention of the public the financial straits in which, it is said, a majority of the physicians of that city live. Dr. Arnaud de Langlard, an old physician who had been decorated by the Government for brave conduct during the cholera epidemic many years ago, committed suicide with his wife because his practice had dwindled to the vanishing point, and starvation was staring them in the face. In commenting upon the tragedy several newspapers asserted that in Paris not more than one doctor out of five is able to make more than the barest living. Among the causes of this poverty among physicians is the destitution of most of their patients. Medical science has made such great strides, too, that maladies of all sorts are more quickly cured, and such precautions are taken to prevent the spread of contagious diseases that epidemics are becoming practically unknown. The number of doctors, on the other hand, has rapidly increased. Another reason why there is not practice enough to go around is that in many of the hospitals people can be treated for nothing or at a very nominal figure. Many of these hospitals have training schools which are free, in which are taught the rudiments of medicine and surgery. These schools are largely attended, and many sick people are taken in hand at their own homes by some member of the family who has profited by this instruction.

PRIZES OF THE ACADEMIE DE MEDECINE.

THE annual distribution of the prizes of the Paris Académie de Médecine took place on December 10th. The list is a long one, and only a few of the principal prize winners can be mentioned here. The Barbier prize of £80, offered every year for the discovery of a remedy for an incurable disease, such as hydrophobia, cancer, epilepsy, cholera, etc., was not awarded to any of the ten competitors, but an "encouragement" of £20 was granted to M. E. Legrain for his work on the sero-therapeutic treatment of typhoid, and smaller sums were awarded to five others. The Henri Buignet prize of £60 for the best work on the application of physics or chemistry to medicine

was awarded to Dr. Chabré, for his memoir on the Chemical Transformation of the Fundamental Substance of Cartilage during Ossification. The Adrien Buisson triennial prize of £420, offered for the discovery of a remedy for a disease hitherto looked upon as incurable, was divided among the following: £240 to Dr. Jarre for his work on the Cure of the Douloureux of the Face by a New Surgical Method; £80 to Dr. Chervin for his memoir on Stammering and other Defects of Pronunciation; £40 to MM. Wurtz and Marciano for their essay on Leprosy: its Prophylaxis and Treatment; £20 to Dr. Guillard for his work on Pneumo-thorax; £20 to Dr. Christiani, of Geneva, for his researches on the Thyroid Body; and £20 to Dr. Calvin, of the Medical Department of French Army, for his work on Chronic Paludism. The Chevallier Prize of £60 for the best work on the treatment of cancer was awarded to Dr. Robin for his work entitled *Contribution to the Study of a New Method of Treatment of the Malignant Inoperable Tumours: Tactotherapy*. The Dauvel prize of £40 for the best work on myxodema was divided between Dr. Combe, of Lausanne, and the Drs. Cristiani (M. and Madame), of Geneva. The Desportes prize of £52 for the best work on practical therapeutics was divided between Dr. Thibierge (*Therapeutics of Diseases of the Skin*) and Professor Delorme (*Disappearance of Neuritic Disorders, etc., by Localized and Forceful Compression*). The Huguier prize of £120 (triennial) for the best work on diseases of women, especially their surgical treatment, was awarded to Drs. S. Bonnet and P. Petit for their *Practical Treatise on Gynaecology*. The Laborde Prize of £200 was divided, Drs. Gouguenheim and Glover being awarded £100 for their *Atlas of Laryngology and Rhinology*; Dr. Chipault £60 for his *Operative Surgery of the Nervous System*; Professor Reverdin, of Geneva, £20 for his essay on *Surgical Antiseptics and Asepsis*, and Dr. Delbet £20 for his *Surgical Anatomy of the Bladder*. A prize of £40 (Prix Adolphe Monbinne) was awarded to Dr. L. Petit for his book on *The Consumptive in the Principal Countries of Europe*. The Perron Prize (£152) was divided among six candidates, Dr. Sabouraud getting the lion's share (£72) for his work on *Human Trichophytoses*.

PREHISTORIC TREPHINING IN RUSSIA.

MR. D. G. BRUNTON, writing in *Science*, calls attention to an article by General von Krahmer in the *Globus*, Bd. LXVII, No. 11, in which he describes an amulet obtained in 1886 from a neolithic burial in Russia. It was of bone, and on examination proved to have been taken from a human skull. Ten years later the archaeologist Biellachewski, in exploring a deposit on the banks of the Dnieper, exhumed a human skull from which a precisely similar fragment must have been removed. Careful inspection showed that the trephining had been performed after death, the spot selected for the operation being the right frontal bone. The instrument must have had a sharp cutting edge, but there is evidence of lack of skill in the use of it. The skull must have belonged to a comparatively young person, probably a woman. Such examples are said to be extremely rare in Russia. Among the skulls in the Anthropological Museum of Moscow there is but one showing evidence of ancient trephining, and it is catalogued as coming from the Caucasus. The evidence brought forward by General von Krahmer showing that this operation was occasionally practised in order to obtain amulets from the parietes of the skull is valuable as illustrating a primitive superstition which prevailed in several widely separated tribes.

PRESENTATION.—Dr. J. B. Brown, Division Surgeon G.P.O., was on December 13th presented by the pupils of his ambulance class (New Wandsworth Branch, St. John Ambulance Association) with a handsome clock, bearing a suitable inscription expressing gratitude for his instruction. This is the second occasion on which Dr. Brown has been the recipient of a similar testimonial.

A NATIONAL SYSTEM OF REGISTRATION OF SICKNESS.

As will have been seen by the reports published in our columns, Dr. Newsholme has brought before recent meetings of the Society of Medical Officers of Health and the Royal Statistical Society a subject of considerable general interest, and one which is almost new in this country—the need for a national system of registration of sickness.

Many attempts have been made in this country to secure a national system of registration of sickness, and it is gratifying to know that the British Medical Association took an active part for many years in pressing upon the Legislature the importance of the subject. On two occasions departments of the Government have undertaken the tabulation and circulation of returns of sickness: first in 1857-58, when the then General Board of Health undertook to print and circulate the weekly and quarterly returns of sickness of all kinds attended at the public expense in hospitals and dispensaries and by Poor-law medical officers in the metropolis; and, secondly, since 1889, when the Local Government Board have undertaken the task of circulating the returns of infectious disease received from a large number of towns, and thus securing the internotification of the notifiable diseases. These precedents have an obvious value in arriving at a conclusion in favour of a larger official scheme on similar lines.

The local voluntary efforts made to secure the registration of sickness in London, Manchester, and several other towns have not been permanently successful, notwithstanding the enthusiasm and pertinacity of those who projected them. As Dr. Ramsey long ago pointed out, "the voluntary principle has invariably proved quite unequal to the regular, constant, and universal performance of laborious official duties without any hope of profit or of praise." Gradually the plea for compulsory notification of infectious diseases took the place of that for the more general notification of sickness.

In addition to the immediate utility connected with isolation of the sick, disinfection, and removal of insanitary conditions, medical knowledge might be expected to benefit by increased acquaintance with the natural history of the various infectious diseases, and with the conditions governing the occurrence of epidemic and interepidemic periods. The statistics obtained by means of compulsory notification were likely to be extremely valuable, as increased knowledge must eventually lead to improved and extended measures for the prevention of disease. Hence the compulsory notification of all infectious diseases was advocated, and the extension of notification to such diseases as phthisis, rheumatic fever, and pneumonia.

As to the expense of compulsory notification of sickness, Dr. Newsholme showed that a weekly return of cases would for many diseases be almost as valuable as an immediate return, and that by this means the expense of extended notification might be minimised. In the next place, he stated that in Scandinavian countries and in Germany there was a wider schedule of diseases than in this country, but no payment for notification was made. This, Dr. Newsholme admitted, could not be tolerated in England, unless the medical profession received as complete protection from vexatious prosecutions and from unqualified practitioners as is accorded to their Continental brethren.

Dr. Newsholme advocated a central office in London, probably in connection with the General Register Office, at which sickness statistics should be tabulated similarly to the death statistics. The sickness statistics should however, in the first instance, always be sent to the medical officer of health of each district for his immediate use. These statistics should comprise (1) returns of all new cases of sickness treated among the parochial poor; (2) returns of all new cases of sickness at hospitals and dispensaries; (3) similar returns of the sickness in connection with friendly societies—these returns to be made weekly to the medical officer of health, and to comprise a limited list of fifteen to twenty diseases, all others being classified under one heading. An extension of present machinery would be required, but gradually by this means a very valuable mass of sickness statistics would be collected. For some years they would undoubtedly be imperfect, but this was a strong argument in favour of an early start.

From the debate at the Society of Medical Officers of Health it would seem that, in the opinion of those well qualified to speak, a national system of registration of sickness is not yet within reach; still the possibility and the usefulness of such a system hardly admit of doubt; and if it is ever to be attained in this country it must necessarily be gradually, as Dr. Newsholme showed. At present about 93 per cent. of the people of England and Wales are placed under compulsory notification—that is, in the area represented by this large proportion of the population eleven diseases (small-pox, cholera, diphtheria, membranous croup, erysipelas, scarlatina, typhus, typhoid, relapsing continued, and purpural fevers) are notifiable. Already some seventy local authorities have added measles to this list, about twenty have added whooping-cough, several have added autumn diarrhoea, a few German measles and chicken-pox, and at least one authority has added hydrophobia. Why the line should be drawn below these seventeen diseases is difficult to explain.

The notification to the health officer of any of the following would surely be useful: Mumps, influenza, cerebro-spinal fever, dysentery, ague, remittent fever, glanders, erysipelas, septicæmia, purpura, tuberculosis, pneumonia, and acute rheumatism; and some of them would have been made notifiable had not the Local Government Board withheld their approval. Doubtless, in time, most of them will be notifiable, and certainly cases of anthrax and poisoning by arsenic, phosphorus, or lead. This will involve the repeal of Section 29 of the Factories and Workshops Act, so as to provide for notification being made to the medical officer of health instead of to the inspector of factories.

Perhaps, after all, what would help on as much as anything the establishment of a national system of registration of sickness might be for some medical officer of health, possessed of enthusiasm and perseverance, to show what can be accomplished in one district, by getting in and tabulating all the returns which Dr. Newsholme has pointed out, are available, and may be had with little trouble and practically no expense.

THE TREATMENT OF CHILDREN MENTALLY DEFICIENT.

AN address on this subject was given at a meeting of the Union of Teachers of the Deaf on the Pure Oral System on December 12th by Dr. SHUTTLEWORTH, formerly Medical Superintendent of the Royal Albert Asylum, Lancaster, the Rev. Dr. STAINER presiding. The lecturer traced the connection with institutions for deaf mutes of early efforts for the amelioration of the mentally defective class. Referring to the labours of Itard in his attempts to reclaim the *Sauvage de l'Aveyron*, he showed how, notwithstanding an unsatisfactory result, the scientific observation of the sensory and mental deficiencies of this case and the consequent indications for treatment led to an appreciation of the means afterwards found serviceable in the training of idiots and imbeciles. The lines set forth by Itard were:—(1) to develop the senses; (2) to develop the intellectual powers; (3) to develop the affective functions. Following a similar plan, his pupil Seguin undertook in 1867 the training of a young idiot in the children's hospital of Paris, and having achieved signal success, became, as instructor of the imbecile children at the Asylum, the pioneer of the physiological system of education now followed universally in training institutions for the mentally deficient. Whilst there were some analogies between the deaf mute and the mentally deficient child (and Dr. Shuttleworth illustrated this by reference to family histories showing alternating instances of the occurrence of deaf mutism, idiosyncrasy, and insanity in the pedigree, and also to a certain correspondence of the causation of the two classes of infirmity), there were, of course, distinct differences in the treatment respectively suited to those deprived merely of one sense and to those suffering from imperfections or imperfect action of the nervous centres, sometimes indeed of the whole nervous system. In the case of mentally feeble children dumbness might be due to deafness, but more frequently lack of language was owing to lack of thought. Sometimes there was lack of power to co-ordinate the complex mechanism of speech, more

rarely there was imperfect development either of the cerebral centres (Broca's convolution, etc.) or of the organs necessary for articulation. Speech had been made a basis for the classification of idiots and imbeciles, but it was not an unerring standard of discrimination between different degrees of intelligence. At the Royal Albert Asylum about 20 per cent. of the 600 inmates were either dumb, or could make only a few articulate sounds, and about 15 per cent. spoke distinctly, whilst less than 40 per cent. spoke well, and less than 30 per cent. only fairly. Only 4 were completely deaf (deafness being a bar to admission), and about 40 others had some deficiency in hearing power. Whenever practicable, improvement of speech by oral methods was attempted, though want of intelligence and of power of continuity rendered the task difficult. With mentally deficient children, however, the first need was for sensorial training, following the principle pointed out by Seguin, that the organs of sensation are within our reach, and those of thought out of it. "The former are the first we can set in action," the senses of touch, sight, hearing, and even taste and smell were methodically cultivated and exercised. The regulation of the muscular activities, whether in abeyance as in some low grade cases or in unruly excess as in the nervously irritable class, and their subordination to voluntary control formed the next step in the educational ladder. Ordinary school exercises were at length reached, but all instruction had to be conveyed in as concrete a form as possible, the feeble idealising power of the pupils rendering them unable to comprehend that which was abstract. Examples of methods and of apparatus used were given, and it was stated that inasmuch as the fingers often formed the best avenues of approach to the brain, manual training was of the utmost importance. This, when judiciously carried out so as to prove attractive, was most efficacious in fixing the attention and promoting continuity of thought and steady application, and the lecturer urged its importance in connection with the system pursued in oral schools for the deaf, where he thought that without some such relief there was risk of overstrain from too continuous efforts at lip-reading. With regard to the difficult class of imbecile deaf mutes, or still worse, of deaf-mute idiots, he ventured to question whether, after a sufficient trial of the pure oral method, recourse might not with advantage be had to signs, though he fully admitted the great superiority of oral teaching in improving mental action and breaking [up] isolation whenever there was sufficient basis of intelligence to work upon. Still, it must not be forgotten that "feeble gifted" children were often more nimble with their fingers than with their brains; and industrial training should not be neglected in favour of fruitless and too protracted efforts to teach articulation. The proportion of "feeble-minded" deaf-mutes was very differently stated in different national statistics on the subject, varying (according to Mygind) from 1.3 per cent. in Danish institutions to about 10 per cent. in those of North America; our Transatlantic cousins were perhaps setting up a somewhat high standard for "cuteness." The address closed with a reference to the good work done in the centres for the special instruction of backward and defective children under the London School Board, and a suggestion that, with the spread of compulsory and assisted education for the deaf, it would probably be advisable to form separate departments for institutions and teaching centres for deaf-mute children also mentally defective. The need for moral training was not to be lost sight of, and the most successful teaching both of deaf-mutes and of mentally defective children would depend not only upon the skill and enthusiasm, but upon the persevering loving interest brought to bear upon the work.

An animated discussion followed, speeches being made by Mr. VAN PRAAGH, Mr. ARTHUR KINSAY, the Rev. Dr. STAINER, Dr. HILL (St. Mary's), Dr. STILL (Children's Hospital), and others.

Specimens of the manual work of patients at the Royal Albert Asylum were exhibited.

DR. D. ARGYLE ROBERTSON has resigned his seat at the Board of Managers of the Edinburgh Royal Infirmary, and his place has been filled by the election of Emeritus Professor Struthers.

ISOLATION HOSPITALS.

[FROM A CORRESPONDENT.]

According to the last annual report of the Metropolitan Asylums Board upwards of £300,000 was expended in the year ending September 30th, 1894, on the isolation and treatment of fever and small-pox cases in their hospitals. This is a very large sum. According to the last edition of Burdett's *Hospital Annual*, the ordinary expenditure of all the general hospitals put together (not merely the big hospitals with schools) amounts to under £430,000. In other words, while the ratepayers cannot pay a penny towards the treatment of the most disastrous and distressing case of ordinary illness, they pay this enormous sum for the treatment and isolation of a particular class of disorders. The reason for spending this money, and it may be added the sole excuse for spending public funds on the maintenance and treatment of persons who are confessedly quite able to pay both for the one and the other, is that it is hoped and intended, by isolating the individuals attacked, to prevent the spread of the disease to the healthy.

How far is it true that infectious diseases spread in proportion to the number of foci of infection, or, in other words, what relation is there between the number of existing cases, from which the disease may be spread among the rest of the people, and the tendency shown by the malady so to extend?

It is easy to understand, and not difficult to believe, that the removal of a first case or the isolation of the whole of the first group of cases occurring in any community might have the effect of preventing any further spread of the disease. But that is not now the question. As it affects London and all large centres of population, the question is whether, by merely diminishing the number of cases which are unisolated, the spread of the disease is checked at all in proportion to the expense involved in so doing. It is impossible to shut one's eyes to the phenomena presented by what is known as the "seasonal prevalence" of such a disease as scarlet fever. Epidemic prevalence is another matter, for since the hospitals have been brought into general use we have had no epidemic worthy of the name by which to test their efficacy, the outbreaks of 1893 and of the present year having been slight compared with the epidemics of twenty or thirty years ago. We have then to fall back upon the seasonal variation, the ordinary yearly oscillation in the prevalence of the disease. So far as one may judge by the mortality returns, there is a far greater prevalence of the disease in the autumn than there is in the spring. Although the curve varies somewhat in contour year by year, and varies enormously in range, still we have, as one of its most marked features, this tendency to rise in autumn.

Now the Asylums Board hospitals, notwithstanding the magnitude of their resources, have hitherto failed to cope with this autumnal rise, so that, although a gradually-increasing proportion of all the cases occurring in each year have been isolated in hospital, the proportion so isolated in the spring has far exceeded that isolated in the autumn. In 1893, as again this year, the beds were absolutely full in the autumn, and so it happened that at the very moment when the epidemic was at its height the proportion of cases being isolated was at the smallest, and then, when the number of infectious cases scattered over London was greater than it had been for several years, the epidemic took a turn, and quickly fell to such a degree that in the year following, namely, in 1894, the total of the cases did not amount to half as many as had occurred in 1893.

There is then no reason to suppose that the rise in that epidemic had anything to do with the number of foci from which the disease could spread, or that its fall had any relation to the number of cases isolated by the Asylums Board hospitals. The epidemic rose notwithstanding that the hospitals were doing well, and it fell just when they failed. It is not suggested that the hospitals do not do much good, or that they are anything but a blessing to those individuals who, when attacked by fevers, are fortunate enough to gain admission to their wards. But then, so far as the individual is concerned, a person suffering from bronchitis or pneumonia is equally benefited by hospital treatment, yet no public funds are set aside to treat the sufferer from bronchitis unless he is a pauper. Great then as is the good done by the fever

hospitals, it is not the particular sort of good for which the public money is expended.

If this were a matter merely of dealing with scarlet fever and diphtheria, and if free treatment were offered only to those who were not in a position to pay, things might well be left to find their own level, and the ratepayers might well be content to put up with even a considerable expenditure for the sake of getting a large number of poor children safely through a very serious disease. But this is not the case. Led on by the theory—or rather the assumption, for it is not even an explanation of the facts—that the spread of fevers can be controlled by limiting the number of foci of infection, it is now seriously proposed to admit measles into hospitals for isolation, and already the Asylums Board hospitals are freely open to the richest if suffering from scarlet fever or diphtheria.

To understand in any full degree the magnitude of the task thus suggested, it must be remembered that the deaths from measles in London last year were more than three times as numerous as those from scarlet fever, and outnumbered even those from diphtheria. It is high time, then, that the dogmas now current regarding the proper methods of controlling epidemics should be reconsidered.

The spread of infectious diseases is largely, if not mainly, influenced by two factors—the infectiousness of the disease, and the susceptibility of the patient. The attention of those responsible for their management in London has been given almost exclusively to the former, whereas the whole history of the epidemic points well nigh exclusively to the latter, including in it the effect of season on the constitution as the active factor in their development.

Whatever may be done in the future, it is quite certain that the attempt to isolate scarlet fever in London has hitherto been a failure; even although its prevalence has during the experiment been comparatively light, the death-rate from the disease having in 1870 been five times, and in 1888 nearly six times, as high as in 1893.

In the meantime more knowledge is required. It may be doubted whether we yet know with anything like exactitude what are the conditions of health, and what are the conditions of environment, which favour the spread of either scarlet fever or diphtheria, although we do know some of the conditions which determine whether outbreaks of measles shall be virulent or mild. It is not that too much attention has been paid by sanitary authorities to drains and water supply, but that too little has been paid to dust and dirt, and to uncleanly domestic habits.

It is by no means certain that far better results would not be attained than at present follow our one-sided efforts to deal with epidemics by isolation, were something like the "sanitary column" so successfully employed by Dr. Mason, of Hull, during the cholera outbreak in that town introduced into our ordinary sanitary machinery, and were every removal of a patient to hospital immediately followed by a methodical attack on dust and dirt by an official body of cleaners, and by a real disinfection of the house and its contents, a disinfection very different from the farcical burning of sulphur with which so many sanitary authorities save their consciences. But for this purpose the hospitals must be at the disposal of the sanitary authorities, who will be responsible for the other measures, besides more removal, necessary for the control of epidemics, and must not be wasted, as they are at present, by being left open to anyone who chooses to send for the ambulance. As things are at present, people may throw upon the community the whole expense of the maintenance and treatment of their children, while they may themselves neglect the most ordinary precautions for rendering their houses innocuous to others. Under existing arrangements it may happen that a parent may send to hospital child after child, who may not only be treated at the public expense, but may be maintained, perhaps for three months, so that on their return they shall not carry back with them any infection, and yet the same man may all the time keep at home one pot child suffering from the fever, and thus may render nugatory all the efforts of the Board to prevent the spread of the epidemic.

That the Metropolitan Asylums Board spends its annual income carefully and well in the treatment of its patients cannot be doubted, but that the money is spent to the best

advantage for checking the spread of scarlet fever and diphtheria is another matter, and one open to serious question.

THE POOR-LAW SCHOOLS COMMITTEE.

THE Departmental Committee of the House of Commons to inquire into the working of the Poor-law schools, appointed by Mr. Shaw Lefevre last year, have, after many months' hard work, nearly closed their labours.

The investigation has been extremely thorough, and witnesses have been called from every well-informed quarter who could throw light on the subject. The first witness was Mr. Ernest Hart, Chairman of the Parliamentary Bills Committee of the British Medical Association, who made a statement on behalf of the deputation at whose instance the Committee was appointed, and who gave a full account of the charges brought against the present system of administration.

The inquiry necessarily ranged over the whole question of the existing defects in the great associated or barrack schools, the injuries to physical health, especially in respect to developmental affections and the spread of ophthalmia, the allegations of inefficiency in inspection, the merits and demerits of the boarding-out system, and the discussion of the methods of control.

Mr. Mundella has stated that the report may be expected before the meeting of Parliament, and that it will be laid on the table immediately after Parliament has assembled. Nothing can exceed the assiduity, patience, and intelligence with which the inquiry has been conducted by the highly competent Commission selected, and the report is likely to be a very thorough and satisfactory document. It is believed that it is likely to affect not only the metropolitan schools with which it is more immediately concerned, but the whole system of Poor-law school administration throughout the country.

LITERARY NOTES.

ACCORDING to the *Athenaeum*, Mrs. G. J. Romanes has completed the memoir of her late husband, which will be published by Messrs. Longman in January or February. The memoir will consist chiefly of letters, including a large number from Charles Darwin.

Dr. Morrison Legge's book, entitled *Public Health in European Capitals*, which has just been published by Messrs. Swan Sonnenschein is the result of personal observations during the past two years and a-half. The cities dealt with are Paris, Berlin, Brussels, Christiania, Stockholm, and Copenhagen.

The West London Medical-Chirurgical Society has decided to issue a quarterly journal, to be entitled *The West London Quarterly Journal*, in place of the biennial publication of its proceedings. Mr. Percy Dunn has been appointed Editor, and Mr. Leonard A. Bidwell, Editorial Secretary, of the new journal. In addition to the papers read before the Society and full reports of its meetings, the *West London Quarterly Journal*, among other features, will contain a "Mirror of Practice," or full notes of interesting cases occurring either in hospital or in private practice. The first number will appear on January 1st, 1894.

To the last published part of the *Klinische Zeitsung* *Stratfragen* (ix, p. 117) Dr. Ladislav Hasek has contributed an obituary notice of the late Professor Charcot. At the end of the article, the author gives a classified bibliography of Professor Charcot's works, which will be found very useful for purposes of reference. The number of papers, etc., enumerated is exactly 320.

During the past year the number of medical journals published in Paris has increased from 177 to 199. It would be interesting to know how many subscribers there are to the majority of these, but as they continue to increase and

multiply. It is to be supposed that they serve their purpose in some way or other.

In *The Gillmans of Highgate*, a book (recently published by Stock) from the pen of Mr. Alexander W. Gillman, grandson of the medical practitioner who befriended Coleridge for many years, special reference is made to two inaccurate statements made and repeated by some biographers of the poet. One is that Coleridge was never thoroughly cured of his opium habit; the other that he paid for his board and lodging during the eighteen years that he lived under Mr. Gillman's roof. The author states that he was frequently told by his father, the Rev. James Gillman, the eldest son of Coleridge's friend, that although the poet might have contributed something at first as a return for the medical care and advice he received, he "practically lived as a guest at the invitation of Mr. Gillman for these eighteen years. Besides which many of his friends were weekly entertained at dinner, etc., no doubt to the great pleasure and edification of his host and hostess." Concerning the opium habit, it has been asserted by De Quincey and others that Coleridge continued to obtain supplies of laudanum surreptitiously through the doctor's boy. Mr. Gillman's assurance, however, was that the habit was thoroughly conquered, and the boy, Mr. Thomas Taylor, now one of the oldest inhabitants of Highgate, is called as a witness. He states "that he never procured any opium for Mr. Coleridge, nor did he ever hear of his alleged habit of taking it;" but, he added, "he was a great consumer of snuff, and I used to bring him a pound of 'Irish blackguard' (his favourite snuff) at a time, with which he smothered himself."

The *Minster* has passed into hands of the Artistic Publishing Company, Limited, and the first number of the new series will be issued on December 28th. The magazine in its new form will be practically a new publication, for the cover, the size, the nature of the contents, the policy, and in fact everything but the title will undergo a complete transformation. In future the *Minster* will be a magazine of "light humorous literature, contributed by the best authors and illustrated by the best artists."

THE CASE OF DR. LIONEL SMITH.

IN the JOURNAL of December 21st we published an appeal for funds from Dr. James F. Goodhart and Dr. de Havilland Hall, to enable Dr. Lionel Smith to take up the appointment of District Surgeon in Zululand, which has been offered him by the Secretary of State for the Colonies.

As we stated last week, Dr. Smith has suffered great hardship at the hands of the West Australian Government, and his attempt to obtain redress from the highest court of appeal in this country was defeated on legal grounds. His resources have thus been seriously reduced, and the case is one which we strongly recommend to the generosity of the profession.

The following subscriptions have already been received and forwarded to Dr. de Havilland Hall:

	£	s.	d.
Sir Edwin Saunders	...	2	2 0
Dr. Walter A. Satchell	...	1	1 0
Dr. John C. Galton	...	1	1 0
A Seedling	...	0	5 0
Dr. Frank Godfrey	...	1	1 0

PRESENTATION.—Dr. R. N. Wallace, of Cravenhurst, Stamford Hill, has been presented with a solid silver salver by a number of medical men in Hackney as a token of their regard and esteem.

THE DIAGNOSIS OF GLANDERS.—The French Minister of War has issued important instructions in regard to glanders and tuberculosis in horses, and the value of mallein as a diagnostic agent to prevent the danger of transmission to the officers and men, and in fact to all those brought into contact with horses. The animals are to be divided into three groups after the test is applied. Full particulars of the procedure to be carried out are embodied in the War Minister's instruction, and may be read in the *Union Médicale* of October 26th.

ASSOCIATION INTELLIGENCE.

COUNCIL.

NOTICE OF MEETING.

A MEETING of the Council will be held in the Council Room of the Association, at No. 429, Strand (corner of Agar Street), London, on Wednesday the 13th day of January next, at 2 o'clock in the afternoon.

FRANCIS FOWKE, General Secretary.

December, 1895.

NOTICE OF QUARTERLY MEETINGS FOR 1896. ELECTION OF MEMBERS.

MEETINGS of the Council will be held on January 15th, April 15th, July 8th, and October 21st, 1896. Candidates for election by the Council of the Association must send in their forms of application to the General Secretary not later than twenty-one days before each meeting—namely, March 26th, June 18th, and October 1st, 1896.

Any qualified medical practitioner, not disqualified by any by-law of the Association, who shall be recommended as eligible by any three members, may be elected a member by the Council or by any recognised Branch Council.

Candidates seeking election by a Branch Council should apply to the Secretary of the Branch. No members can be elected by a Branch Council unless their names have been inserted in the circular summoning the meeting at which they seek election.

FRANCIS FOWKE, General Secretary.

LIBRARY OF THE BRITISH MEDICAL ASSOCIATION.

MEMBERS are reminded that the Library and Writing Rooms of the Association are fitted up for the accommodation of the members in commodious apartments, at the offices of the Association, 429, Strand. The rooms are open from 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 2 P.M. Members can have their letters addressed to them at the Office.

BRANCH MEETING TO BE HELD.

LANCASHIRE AND CHESHIRE BRANCH.—The annual meeting of this Branch will be held in the Medical Institution, Liverpool, on Wednesday, January 8th, 1896. Agenda: Report of the Council of the Branch on the Midwifery Nurses Registration Bill as drafted by a Subcommittee of the Parliamentary Bills Committee and amended by a Committee of the Branch Council. Report of the Committee of the Branch appointed March 8th, 1894, "to watch the progress and to oppose any proposed legislation for the registration of midwives." Mr. H. H. Preston will move and Dr. G. H. Broadbent will second, "That a Vigilance Committee of the members of the Branch be at once elected, with power to add to their number, to watch the progress of any legislation for the registration of unqualified persons to practise medicine, surgery, or midwifery without the supervision of those already registered under the Medical Acts." Mr. Walter Whitehead will move a resolution standing in his name as to the present system of government of the British Medical Association. Mr. Colin Campbell will move and Dr. J. Brassey Branch will second, "That this Branch contribute £50 to the fund which is being raised to repay Dr. R. R. Rentoul his expenses incurred in defraying the first and second Midwives Registration Bills." All notices of motion and amendments for the meeting, and applications for membership of the Association and the Branch, should at once be sent to the Honorary Secretary, JAMES BARR, M.D., 79, Rodney Street, Liverpool.

SPECIAL CORRESPONDENCE.

ST. PETERSBURG.

Pirogof in the Crimean War.—*Maladministration and Attempts at Reform.*—*The Employment of Sisters of Mercy as Nurses in War and Peace.*—*New Russian Medical Journal.*—*New Medical Faculty in Odessa University.*—*The Cholera Epidemic.*

THE anniversary of the death of the great Russian surgeon Pirogof, was kept by a commemorative meeting, held in the hall of the Red Cross Society, of the four principal medical societies in St. Petersburg, the Pirogof Surgical Society leading the way. The anniversary was marked by an address to the prizes already instituted in the name of Pirogof, a new set, consisting of gold medals, will be offered for the best

works upon some surgical subject. The movement is opportune to recall some of the events which were happening just forty years ago, and the part which Pirogof played in the Crimean war. He was ordered to Sevastopol in October, 1854, and remained there all that winter, and until the following June, in full charge of the principal military hospitals on the north side of the harbour.

The maladministration, disorder, and disgraceful abuses which he found prevailing everywhere seem to have deeply affected him, and in June he returned to St. Petersburg with the object of representing to the central authorities the crying needs for improvement and reform. In this he was unsuccessful, and after a short stay in the capital he was ordered back to the seat of war. He was permitted to take with him a certain number of young surgeons of his own choosing, and among these was the late Professor Botkin, who had then but recently qualified. By the time they arrived in Sevastopol the south side of the harbour had already been taken, and the hospitals of the northern side were full to overflowing with sick and wounded. From September to December, 1855, Pirogof was in Simpheropol; thence he was ordered to visit and inspect the hospitals, about seventy in number, in Perekop, Kherson, Ekaterinoslav, Khar'kov, and other towns. He found the hospitals crammed with patients, some wounded, others ill with typhus or typhoid fever or dysentery, and a large proportion suffering from frozen limbs, for they had been brought from the seat of war in open sledges, with the thermometer a dozen or more degrees below zero Fahrenheit. "This frightful time," Pirogof himself wrote, "I shall never forget to the end of my life." He instituted important reforms.

Among these was the introduction of female nurses into field hospitals. Primarily the honour of introducing this great reform in Russia is due to the Grand Duchess Helena Pavlovna, the sister of the Emperor Nicholas. The Emperor himself, ever avowed to innovations, was sceptical as to the possibility of women nurses being sent to the actual theatre of war, but he yielded to his sister's entreaties, and allowed the experiment to be tried. The Grand Duchess turned to Pirogof to aid her in carrying it out. At that time the employment of women as nurses was scarcely known, even in civil hospitals, and the new proposal had to overcome many prejudices and much inertia. The Grand Duchess herself set an example by bandaging with her own hands a patient who had been operated upon in Pirogof's clinic; after that the prejudice rapidly disappeared, and many women came forward and offered their services as Sisters of Mercy. Pirogof himself at first scarcely knew how to regard the innovation. He had only seen the employment of women as nurses in the Paris hospitals, and had no practical acquaintance with such a system. In his own words, it was "more by instinct than from experience" that he was convinced of the great boon their services would be in nursing the sick both in war and peace. It is from the time of the Crimean war that the general employment of women nurses in Russian hospitals dates.

A number of new Russian medical journals are announced for next year. *Contemporary Medicine and Hygiene*, a monthly magazine, will be edited by Professor Afanasief, who has severed his connection with the journal called *Practical Medicine*. *Reports of the St. Petersburg Biological Laboratory* will appear quarterly, edited by Dr. Loebschaft. *A Review of Pathology, Neurology, and Experimental Psychology* will be published monthly under the editorship of Dr. Bekhterev; and *the Russian Sanitary Journal* twice monthly, under the editorship of Dr. Dmitrieff.

The question of founding a medical faculty in the University of Odessa, which had been long under discussion, has finally been decided in the affirmative. The municipality of Odessa has generously offered to double its grant for the new faculty, raising it from 250,000 to 500,000 roubles, that is, to over £100,000.

The cholera outbreak seems to be rather spreading than subsiding in St. Petersburg. Between November 11th and 18th there occurred 47 cases and 14 deaths; between the 18th and 25th, 73 cases and 46 deaths; between noon on the 25th and noon on the 26th, 14 fresh cases were admitted to hospital and 6 patients died; there remained 59 under treatment. On November 26th, in the week ending November 4th, there

occurred 230 cases of cholera with 110 deaths; in the following week there were 220 cases with only 94 deaths. In the Government of Kiev in the same two weeks the figures were 72 cases with 26 deaths and 101 cases with 34 deaths respectively. In that of Orel, 16 cases with 6 deaths occurred between October 22nd and November 18th. All the above-mentioned dates are according to the old style.

FLORENCE.

The Maternity Department of the Sta Maria Nuova Hospital.—Laparotomy for Myomata and for Extrauterine Pregnancy.—Vaginal Hysterectomy.—Laparotomy for Inflammatory Conditions.—Conservative Operations on the Fallopian Tubes.—Caesarean Section.—Symphysiotomy.—Treatment of Normal Labour.—Clinical Institute at Pisa.—A Medical Archaeologist.

A TABLET in the cloisters of the Sta Maria Nuova Hospital states that it was adapted to the reception of parturient women, the treatment of obstetrical cases and of indigent sick children by Leopold Pasqui in the year 1578. The maternity section provides for attendance at the patients' homes as well as in the hospital. The first floor is devoted to the maternity department, the second floor to that of diseases of women. The corridors and wards are spacious, airy, and clean. On admission, each patient has a warm bath, which is repeated when labour begins. The following statistics have been kindly furnished to me by Professor Pestalozza, Director of the Clinique of Obstetrics and Gynecology of the Florence University. They extend from January, 1894, to October, 1895 (twenty-two months), during which 2,167 cases were admitted.

Laparotomy was performed 135 times. In 18 cases for large fibromata and combined with hysterectomy—in one case it was performed after Caesarean section with success both as regards mother and child. Smaller fibroids are removed *per vaginam* with or without hysterectomy. Ten laparotomies were performed for extrauterine foetation, all making good recoveries. In these cases the aim is to remove the sac entire. In one case the pregnancy went to full term, and ten months after the operation mother and child are both well and healthy. In this case hysterectomy was combined with the removal of the sac, as the placenta was in the folds of the broad ligament. In a second case the fetus was in the folds of the omentum, and was partially mummified. In a third case there was coexistence of extra- and intrauterine foetation, and after removal of the tubal sac hysterectomy was performed. For cancer of the uterus Professor Pestalozza prefers to operate *per vaginam*, but four times he operated by abdominal section. All four cases recovered, but in one there was recurrence after a few months. A large number of ovariectomies were done, and in one case pregnancy occurred five months after the operation, and ran a normal course. The majority of inflammatory conditions of the appendages are treated by medicaments and expectancy. In the case of voluminous tubal tumours and suppurations Professor Pestalozza prefers abdominal section to vaginal operation. If suppuration is bilateral the removal of the tubes is combined with hysterectomy. Of eight such cases there were seven recoveries.

In 4 cases laparotomy was performed as a conservative measure. The appendages were freed, the adhesions, foci of disease, and cystic portions of the ovary excised, the ovaries replaced in position, and the obliterated lumen of the tube rendered patent. In cases of hamatocoele demanding operative interference laparotomy is performed unless there is suppuration.

Caesarean section was performed three times, twice for pelvic deformity and once for fibroma. Child and mother were saved in each case.

Symphysiotomy has been done three times in two years. Two cases recovered and one case died of hemorrhage. Professor Pestalozza does not regard this operation with favour.

In normal labours only external disinfection is practiced, and no douches are administered in puerperium. Of 1,155 midwifery cases conducted in the hospital there has been no death from puerperal inflammation, although all cases are examined frequently by students and student midwives. This department gives post-graduate courses of practical instruction of which foreigners may avail themselves.

The new building of the Institute of Clinical Medicine of Pisa is spacious and specially adapted to modern requirements. Congratulatory letters were received from many illustrious members of the faculty, among whom may be mentioned Professor Grocco, who was Professor Queirolo's predecessor in the chair of Clinical Medicine at the University of Pisa before his promotion to that of Florence.

Cavaliere Dr. Alfonso Ademello, who has occupied the post of Sanitary Director of the Hospital of Grosseto for forty years, died recently. For many years he interested himself with excavations at Grosseto, and has written much about the Maremma. Dr. Ademello fought in the war of independence in 1848, and was taken prisoner.

ALGIERS.

A CORRESPONDENT writes: Algiers promises to be fuller than ever. The season so far has begun well, and we have been much favoured by good weather, of which there is every promise of continuance. In many respects my experience in practice for the last few years has been more favourable than I expected as to the effects of the climate here. It is less hot than many of the African winter resorts and by no means conserving, and a variety of excellent climates might be had by due selection. The town of Algiers is improving every year in sanitation and in buildings. It has, moreover, the great advantage for those who are seeking freedom from English wet, cold, and fogs, and the pleasures of winter sunshine without suffering from any severe ailment, and being essentially a pleasure town where museums are abundant, and where there is a large European colony always willing to welcome any new comers and admit them to a share of the abundant outdoor recreations and pleasures of the place. One of the best hotels is the Hôtel de la Régence, which has recently been completely renovated, and is under the care of Mr. Harly. It offers the exceptional comforts of a first-class house at exceptional prices—12 francs a day covers all expenses; and as there are now many English physicians here, I hope I may be permitted to put in a good word for this delightful winter resort, which has perhaps been hardly sufficiently mentioned of late, and is apt to be overlooked by English visitors for newer, but in many respects less desirable, resorts.

CORRESPONDENCE.

THE PHYSIOLOGY OF THE CARBO-HYDRATES.

SIR.—I should be obliged if you could find room to publish the enclosed copy of a letter which I have been constrained to write to Dr. Pavy.—I am, etc.

Cambridge, Dec. 21st.

M. FOSTER.

"Shelford, Cambridge,
"December 21st, 1895.

"DEAR DR. PAVY.—I have to acknowledge the receipt of your book, entitled, *The Physiology of the Carbo-hydrates: an Epitome*, which you have done me the honour to send me. I have carefully read the Preface, the appearance of which has set me free to say in regard to myself what could not be said in official correspondence.

"I have the leave of the President of the Royal Society to state that since your first letter to them the President and Council have received legal advice confirming your contention that in taking steps with regard to the publication of Dr. Paton's paper before it was read they acted in contravention of the statutes. In their anxiety to shorten the delay, always in part unavoidable, attending the publication of papers, they have been led, not only in the case of Dr. Paton's paper but also in many other cases during recent years, to adopt a mode of procedure which they now learn contravenes the statutes, but they have decided on taking steps so to amend the statutes as to remove a limitation which, in the interests of the Fellows and of science, is clearly undesirable.

"This point conceded, the whole of the rest of the action taken in regard to Dr. Paton's paper was conformable to the statutes. The President and Council sitting as Committee of Papers, authorised the officers to 'refer' papers during the

recess, and under this authority Dr. Paton's paper was referred to certain Fellows of the Society who, since they were 'knowing and well-skilled in the particular branch of science to which the said paper' related, seemed likely to have been chosen referees by the Committee of Papers had it been sitting. The reports being favourable, the paper was, under a like authority, ordered for publication in accordance with the reports. This action of the officers being reported to the Committee of Papers at its first meeting after the recess was approved and confirmed. By that decision the President and Council sitting as Committee of Papers, took from my brother officers and myself all responsibility; had the President and Council thought that the referees had been unwisely chosen, it was in their power, and was indeed their duty, to undo what had been done, and to reconsider the question of publication. They did not do so.

"I at once and freely accept your explanation that by the words 'contrary to what is considered ethically becoming' contained in your first letter, you meant 'biased.' Will you allow me to say that I fully recognise the grave responsibilities attaching to my office of Senior Secretary to the Royal Society and the injury to science attending on a 'biased' action on my part. No man is free from 'bias'; and my action has at times, probably often, been other than it should have been. But, so far as I know, I have not consciously allowed myself to be unduly influenced by personal considerations, save, perhaps, when I have urged against the hostile criticism directed towards some communications made to the Royal Society that these should be judged not only in respect to their absolute value, but also with regard to the position and reputation of the authors.

"The last paragraph in your Preface embodies a suggestion as to the nomination of the referees on Dr. Paton's paper, which I venture to hope you would not have published had you fully realised that refereeing being strictly confidential I am prevented from making any answer whatever to it.

"Your Preface being a public matter, I shall send a copy of this letter to the medical papers, and in conclusion, let me ask you not to think me discourteous in desiring not to continue the correspondence.—Yours faithfully,

"Dr. Pavy, F.R.S., etc.

M. FOSTER."

THE CHELSEA HOSPITAL FOR WOMEN.

SIR.—In the necessarily very condensed account you give of the meeting of governors of the Chelsea Hospital for Women on November 18th my remarks read as if I stated that the patient in question might have bled to death before Mr. O'Callaghan's arrival if the resident medical officer had not interfered.

The actual words I used were these: "As Mr. O'Callaghan and myself both live in the same street and three miles away from the hospital, one of our patients might well bleed to death before we could arrive if the resident medical officer was not to touch the dressings." By inserting this correction you will oblige.—I am, etc.,

Harley Street, W., Dec. 21st.

WILLIAM DUNCAN.

QUININE FOR THE ASHANTI EXPEDITION.

SIR.—Now that our troops have begun their active march to Ashanti, it will be the duty of the Commissariat to see to it that they are all supplied with quinine. Upwards of fifty years ago, when acting as surgeon on the Welland Canal in Ontario, Upper Canada, there were many thousand navvies employed in digging and widening the canal, and of that large number of Irishmen who were exposed to the malaria of the swamps between Toronto and the Chipaway Creek all along the level of the canal where there were hundreds of wooden shanties, I had large numbers daily under my care for ague; often hundreds were sick at one time. The point I wish to emphasise is that of the contractors and officials who were not exposed to the wet and sun, myself amongst the number, all who lodged at the hotel at Port Robinson duly took their morning dram with 5 grains of quinine, not one suffered from the ague. I attribute their exemption from the attack which laid up so many of the navvies to their daily dose of this powerful medicine.—I am, etc.,

Brodick, Arran, Dec. 18th.

J. A. JAMIESON, M.D.

THE DISCOVERY OF THE ANTITOXIN OF SNAKE POISON.

SIR,—No one has accused Professor Fraser of claiming priority for his results published in June, 1895, over those of Calmette, published in May, 1894, and over those published by the same investigator in April, 1895. Such a proceeding on Professor Fraser's part would, indeed, have been rash.

What I have drawn attention to is that when publishing a detailed account of experiments identical with those already published by Calmette, and when drawing conclusions from them similar to those already formulated by Calmette, he omitted to refer to Calmette's published work in such a way as to fairly direct attention to the fact that he (Fraser) had been completely anticipated by the French observer. I showed that this had led other persons not conversant with the progress of this branch of scientific inquiry to claim for Professor Fraser the priority which it would certainly have been unwise for him to have claimed for himself.

I supposed that Professor Fraser would have been glad of the opportunity of expressing regret for his omission, regret which others must feel, though apparently he does not. The theory put forward by Professor Fraser—that it is not usual in communications to the proceedings of a learned Society extending to twenty-seven pages octavo in length, to give more than the very briefest allusion to the latest work on the subject, carried out and published by another worker and anticipating all that you have to say—is not, I think, admissible.

Especially, it seems to me, is it unusual that the reference to an immediate predecessor's work should be so brief as to appear contemptuous and so expressed as to be actually misleading (even when read by experts) in regard to the total absence of novelty in the experiments and conclusions which you are about to record as your own work.

Professor Fraser read one paper to the Royal Society of Edinburgh on June 3rd, and a second on the same subject on July 15th. It is impossible to imagine how many such "preliminary" statements Professor Fraser would allow himself to publish and how long a time he would allow to lapse before making the statement, which one would have thought should have been "preliminary" to them all, namely, that the experiments have been already made, and the results published by Calmette.—I am, etc.,

Athenium Club, Dec. 22nd.

H. RAY LANKESTER.

LORETIN: A POSTSCRIPT.

SIR.—I am forced to supplement my paper on Loretin in the *BRITISH MEDICAL JOURNAL* of December 21st by pointing out a peculiar quality which the six months' experience gained since the July meeting has shown me it possesses. While taking first rank as a non-poisonous, non-irritating, odourless antiseptic and deodorant, I find that when dusted on a raw surface it relaxes the blood vessels. Hence the wound is prone to become subsequently filled by a clot, which, however, does not suppurate, as would be the case under almost any other circumstances, but is eventually reabsorbed. The incident is not desirable, and I now apply loretin only to the skin surface, never dusting it into a cavity unless there be special risk of suppuration, and then only very sparingly. I would take leave to add that long experience has shown me the ideal condition in which to leave any operation wound to be the utmost attainable maximum of dryness, avoiding all swabbing with fluids, however antiseptic. It is probable that the efficacy of iodoform, loretin, and the like is very largely due to their capacity for absorbing moisture, without which microbe proliferation does not occur.—I am, etc.,

Gloucester Place, W., Dec. 22nd.

HENRY SNOW.

INDIAN SANITATION.

SIR.—In the *BRITISH MEDICAL JOURNAL* of November 9th just received, a copy of an address given by Mr. Ernest Hart before the meeting of the South Indian Branch at Madras on February 9th, 1895, is published, and a note is added to explain why it seemed desirable to publish this now. In the same issue with the proceedings of the Council a protest from the South Indian Branch is also to be found.

I desire to point out that the erroneous statements referred

to in this protest do not exist in the address now published, but in that published by Mr. Hart before the Public Health Section of the Association at its late meeting in London. If anyone who voted in this Section of the Association meeting, or who is interested in the matter, will compare the address now published with that to be found in the *JOURNAL* of August 3rd last, he will have no difficulty in understanding why the members of this far-away Branch have read the latter with much surprise, and should have entered a vigorous protest against any resolution founded on it. Shortly, in the one address nothing can be said good enough for the work of the medical services in India, and in the other nothing sufficiently severe.—I am, etc.,

Madras, Nov. 27th.

A. M. BRANFOT, M.B. Lond.

* * Warm praise of individuals is by no means inconsistent with severe condemnation of the system under which they are compelled to act. The two addresses were printed in order to afford the means for comparison which our correspondent suggests.

THE MALARIAL PARASITE.

SIR.—While agreeing with Dr. Daniels's remarks contained in his letter in the *BRITISH MEDICAL JOURNAL* of October 26th last, that in many cases of malarial fever terminating fatally very few, or even no, intracorporeal bodies may be found in the peripheral circulation, whilst one organ such as the brain may contain a large number of corpuscles infested with parasites, I must take a decided objection to the last paragraph of his letter.

My own experience of malarial fever in British Guiana, so far as it at present goes, is shortly as follows:

1. The large majority of cases belong to the tertian type—mild and malignant.

2. It is in these cases of mild tertian fever exceedingly easy to demonstrate the typical parasite; and it is no exaggeration to say of this particular parasite, "a child may recognise it." Nor would it be a vain boast on my part to say that in any such case I never fail to find the parasite when looked for, and usually after the examination of one slide only of fresh blood.

3. It is much more easy to demonstrate the parasites in the ordinary cases than in the more severe forms, obviously because the tertian and quartan parasites are very much bigger than the quotidian and malignant forms.

4. Cases of Marchiasava's and Bigland's summer-autumn fevers, with their typical parasite, occur here throughout the year, and therefore the term "summer-autumn" should be abolished, and that of "malignant tertian" adhered to. The reason why I obtain different results from those of Dr. Daniels is, I think, contained in paragraph No. 3 of his letter.

He admits that in a crowded hospital only the cases of urgency are admitted; and his experience, I believe, is derived almost wholly from his observations in the crowded Public Hospital of Georgetown, Demerara.

My experience is almost entirely derived from cases occurring amongst East Indian immigrants on sugar estates, and no case of fever is denied admission to an estate hospital under my control. Also my experience is rural as opposed to Dr. Daniels's urban experience. Consequently I am in a position to study all classes of fever, from the mildest ephemeral fever to the most malignant fatal type.

I am very sceptical as to there being "many fevers in warm climates which are not malarial, and which do not fall into line with the recognised types"—at any rate so far as British Guiana is concerned. Thanks to Laveran's brilliant discovery, however, we shall soon be able to discover such fevers if they exist.

I may add that I am keeping chart records of such cases as time permits me to go into, on the admirable plan suggested some time ago by Dr. Patrick Manson.—I am, etc.,

Demerara, Nov. 27th.

A. T. OSLAND,
British Guiana Medical Service.

A THEORY OF OXALURIA.

SIR.—In the *BRITISH MEDICAL JOURNAL* of December 14th, p. 1407, there is a report of a paper on Oxaluria which I read at the Edinburgh Medico-Chirurgical Society. As there are

several inaccuracies in that report, I venture to write and point them out.

1. I did not state that calcium oxalate was found "in octohedral form and in dumb-bell crystals, the latter soluble in acetic acid." What I did state was that calcium oxalate was seen in the urine in one form only, that being as octohedral crystals, and that the dumb-bell crystals found in urinary sediments being soluble in acetic acid were not composed of oxalate of calcium.

2. As to the precipitation of oxalate of lime in urine, I said that it might be due to the presence of an excess of either of these substances, and I explained why I considered that it was to excess of oxalic acid and not to excess of lime that it occurred.

3. A diet free from oxalic acid abolished the excretion of oxalic acid, not merely caused a "deficiency in excretion."

4. I stated that the average excretion of oxalic acid in urine was 17.2 mg. per diem.

5. The report mentions the two factors influencing the excretion, which I stated, but does not state that these were both found to increase the excretion.

6. The symptoms of "oxaluria," when critically considered along with the physiology of the excretion of oxalic acid, and with the results of treatment were shown to be a strong argument in favour of the theory that cases which have been described as "oxaluria" were really cases of hyperacid dyspepsia.

The theory of the excretion of oxalic acid in urine which I supported is (1) that it is normal and constant; (2) that it is dependent on the absorption of oxalic acid, oxalic acid being a constituent of the common food stuffs; (3) that oxalic acid is not produced in the metabolism; (4) that a precipitation as calcium oxalate occurs very frequently in healthy urines, and indicates the presence of a comparative excess of oxalic acid; and (5) that the presence of calcium oxalate in urine as a diagnostic sign is valueless. I am, etc.,

Edinburgh, Dec. 14th.

JAMES C. DUNLOP.

MEDICAL MEN AND POLICE FEES.

Sir,—Being a medical practitioner in a very poor District in London, not near any hospital, and a considerable distance from the divisional police surgeon, I receive not infrequently a "police call." Now for some time past I have had a difficulty in getting the usual "certificate for surgeon's charges," and have either had to call at the police station or write for it, and sometimes my claim has been disputed. Quite recently I had a night call, the constable coming to my house stating that he was afraid a person was dying in the street, and I returned with him at once to the case. The next day, instead of bringing me the usual certificate for attendance, he left a slip of paper bearing the name and address of the patient, and said that the person would come and see me, which he did some three days afterwards. I told him the police fee, and asked him if he could pay it, and he said No, as he was very poor and out of work at the time, and could not possibly pay more than one third the amount, so I declined to take any money from him.

As you are doubtless aware, all these cases are urgent, and there is not time either to send for the divisional surgeon or convey the case to hospital, so the policeman walks into one's surgery or pulls one's night bell, and demands services at once for any length of time whatever one's engagements. If the police authorities afterwards find that a person is able to pay, surely it is for them to look after it, and not leave the medical man anything they choose to offer.

Of course, when any accident occurs, or anyone is taken suddenly ill in the street, there are half a dozen people off at once for the nearest medical man, stating they have been sent by the policeman, and even if the police have charge of the case, my experience has been that the first greeting from the constable is, "I did not send for you, Sir."

I have recently spoken to several medical men on this subject of police calls, and find they have exactly the same grievances; and it seems to me that if we got four questions satisfactorily answered, we should know better how to deal with them:

1. What constitutes medico-legally a police case?
2. If a constable requires medical aid, is he supposed to apply personally for it, or send a written request?

3. Is a medical man bound to respond to a police call, and what would be the consequences if he refused?

4. When the police call for the services of a medical man, is he legally entitled to the usual police fee?

I have addressed the first two questions more than once to the authorities at Scotland Yard, but have received no reply; and as I cannot get the information from the source whence it should come, I trust it will be supplied through your valuable columns.—I am, etc.,

December 9th.

M.D.

ANÆSTHETICS IN THROAT CASES.

Sir,—During the administration of chloroform and also of ether for operations on the mouth and throat it has often appeared to me that the muscles which close the jaws are later in relaxing, and require, in fact, a condition of more profound general narcosis than is required for the relaxation of the body muscles generally.

If this observation is correct, the fact is one of the very greatest practical importance, because it may serve to explain in part the danger of anaesthesia, and especially of chloroform anaesthesia, in such operations as the removal of adenoid growths.

If the administrator pushes the anaesthetic till the muscular relaxation allows the mouth to be easily opened, there is great danger that the respiratory centre may be so depressed that the cough reflex will be abolished, and if chloroform is being administered—the heart so depressed in addition, that suffocation may occur from very slight causes, such, for instance, as a very little blood entering the trachea. Death may then occur quite suddenly, essentially from asphyxia, but from asphyxia so masked by the action of the anaesthetic that there will be no dyspnoeic movements or cyanosis, the heart stopping, apparently, simultaneously with respiration.

It appears to me, therefore, that in operations on the throat the patient should be regarded as "ready" when the skin reflexes are abolished, and the limb muscles relaxed; but that if some muscular resistance to the opening of the mouth occurs, it should not be regarded as an indication for pushing the anaesthetic.—I am, etc.,

ALEXANDER B. BOYD, M.B. Oxon.

Christchurch, New Zealand, Oct. 30th.

MEDICAL TITLES QUESTION.

Sir,—It was the earnest desire of the late Sir George Paget, M.D., K.C.B., F.R.S., a former President of the General Medical Council, to see legislation accomplished which would settle the medical titles dispute. He considered it the most important duty which could engage the attention of the General Medical Council, and he was instrumental in inducing the College of Physicians to pass their resolution on the subject.

It appears to me that the difficulty should most appropriately find its solution in the efforts of the parliamentary representatives of the Universities, assisted by the General Medical Council. Finding the Dublin University electors bringing out such a strong candidate as Mr. Lecky, I wrote to him on the subject, and the following information will no doubt be interesting to your readers:

In the course of a correspondence, illustrating from my own case the injustice complained of, I wrote: "I would have been content to remain for the time without becoming a doctor of medicine if I could have practised on equitable terms with other practitioners who were not doctors of medicine, but most of such practitioners placed themselves at an undue advantage over me by assuming—in spite of official medical opinion—the title of doctor. I therefore became a doctor of medicine at a cost of time, expense, and extra study to enable me to conscientiously compete with practitioners who had not given this extra study, expense, and time. If official medical opinion be right, it should be legally enforced, but a clause might be added, exempting from the operation of the Bill practitioners already registered. If official medical opinion be wrong, then Parliament should by statute authorise the title of doctor for all qualified practitioners. In either case legislation is required or the injustice will continue."

Mr. Lecky, in reply, stated that "he hoped to consider the

matter very carefully and favourably when it was introduced into Parliament, as it, no doubt, would be by some experienced member speaking on behalf of the medical profession."

That opinions may differ as to the general lines and details of a Bill is natural, but I venture to hope that I have stated the case, proving the necessity for a settlement sufficiently clearly to establish a consensus of opinion among authoritative bodies that, whichever direction it may lie in, a remedy must be found.—I am, etc.,

Liverpool, Dec. 3rd.

GLYNN WHITTLE.

TREATMENT OF MALIGNANT TUMOURS BY TOXINS.

514.—The publication of the paper of Dr. James Swain in the BRITISH MEDICAL JOURNAL of December 7th, on the Treatment of Malignant Tumours by the Toxins of the Erysipelas Streptococcus, in which he records an unsuccessful case, induces me to piece on record the fact that I have lately used this method of treatment in two cases. One was a boy whose leg I amputated for sarcoma of the tibia, and who developed six months later a secondary growth in the sigmoid notch of the lower jaw, which extended too deeply for removal. The injections were commenced early in the growth of the tumour, but it grew rapidly during their use, and finally attained an enormous size before death. The second case is still under treatment, and I will reserve any record of it until a future time. I have abstained from the publication of the first case, as it is impossible to judge of the value of this method of treatment by one or two cases only, seeing that not more than nine out of Coley's thirty-eight cases of sarcoma were cured, and I explain to patients to whom I propose the method that only a quarter of the cases have been cured by the injections in Coley's hands. The evidence of its beneficial action in carcinoma has not been strong enough to induce me to advise its trial in such cases. I would, however, call attention to the fact that the "reactions" following the injections are often severe; and although I have not had any suppuration (as in Dr. Swain's case) as a result of the injections, I have had great local swelling, with redness and oedema of the skin, lasting for a few hours after the injections when they have been made into the subcutaneous tissue in the neighbourhood of the growth, rather than into the growth itself. In both my cases, although I began with the smallest dose, the first general reactions were very severe, reminding me of the most marked reactions which occurred during the tuberculin treatment.—I am, etc.,

NAVAL AND MILITARY MEDICAL SERVICES.

ARMY MEDICAL STAFF EXCHANGE

The chance for inserting notices respecting Exchanges in the Army Medical Department is 2d. Clk., which should be forwarded in stamps or post office order with the notice. The last post on Wednesday is the latest by which these communications can be received.

A MEDICAL OFFICER who is going home next trooping season is willing to exchange either with a Surgeon-Captain or Surgeon-Major to remain another year in India.—Address, stating terms, to Modicus, care of William Watson and Co., Bankers, 8, Hornby Road, Bombay.

ARMY MEDICAL STAFF

BRIGADE SURGEON LIEUTENANT COLONEL R. H. CASEW, D.S.O., becomes entitled to promotion to the rank of Surgeon Colonel by the recent death of Surgeon Major J. A. D. Jones.

Surgeon Major (Colonel) Edward Benson, M.D., died in battle on November 26th, at the age of 41. He was appointed Assistant-Surgeon, March 1st, 1880, Surgeon, March 1st, 1881, and Surgeon-Major, March 1st, 1882. He quitted the service on retired pay, April 26th, 1888. He was engaged in the Boer war in 1899, and had received the South African medal.

THE ATLANTIC EXPEDITION

REMOVED COLONEL W. TAYLOR, in command of the Medical Department, landed at Cape Cod, with the 100th and 11th, and with the 1st and 2nd, and they inspected the hospital in course of construction at Cotuit Hill. The Commander-in-Chief declared himself well pleased with the progress of the work.

Surgeon W. R. Henderson has been appointed Medical Officer in Charge of the Colonial Forces.

The latest transport vessel from Gibraltar, with the 2nd Battalion West Yorkshire Regiment, arrived all well at Puerto de Terra Leona on December 18th. And the P. And O. commenced, with the special service

Corps for Ashanti, including 3 officers and 254 men, and 16 Royal Engineers, and one man of the Army Pay Corps, arrived on December 1931, in time for the 1931-32 season.

The West India Regiment landed at Cape Coast Castle on December 10th, with 20 men sick, also 4 white soldiers on the sick list; 3 of the latter have recovered, but 24 men of the West India Regiment, according to accounts dated December 22nd, are now down with malaria. Some of the cases are dangerous.

The ships *Amber* and *Coronado* sailed from Freetown, Sierra Leone, for Cape Coast Castle on the night of December 2nd.

VOLUNTEER AMBULANCE SCHOOL OF INSTRUCTION

[illegible]

THE "DRESSING PACKET" IS FIRST AID TO THE WOUNDED

critical survey of the means adopted in ancient and modern warfare for affording the first aid to the wounded. He considers that the medical equipment of the army of the future will consist of a mule and a pair of medical containers per battalion in the first line, and in the second a large number of sanitary formations specially arranged with a view to the maximum of convenience and portability. These latter will be the true field hospitals, the former being reserved for services near the front, more adapted to give courage than help. Above all the wounded soldier will no longer have to travel entirely to the ambulance, he will be carried first of all to help.

This is the object of the packet of dressing now used in the French and German armies. Three great dangers threaten the soldier in the field. The first two in order of vital importance or of a great vessel, cause the immediate mortality in battle. They are unpreventable, and affect 3 per cent. of the combatants, leaving a fifth to a quarter of the wounded. The third danger—septic infection of the wounds, which cause 50 per cent. of the mortality—can be stopped by attention to two things—cleanliness and rest. It was formerly found it possible to ensure these by preserving the wound from manipulation until the injured man had been brought to the ambulance and washed with the remainder of the active treatment. This was effected by the use of the diagnostic card, which for severely wounded and amputees, porous cases, red for others, in which the first aid man saw the patient could write down his name and save him the trouble of telling the name himself when received. The packet was a water-tight bag intended to be torn open and washed, and the only other thing solution of the problem is seen to be the provisional dressing. This is collected by means of the packet devised by the German surgeon Port. It consists of a little bag always to be carried in a soldier's pocket, containing the packet, and having in the outside floor and sides a layer of gauze for the use of the contents. These comprise a flannel of two or three layers, a compress of band of the gauze, a piece of waterproof canvas (to be the main bagging, which has been proved in the field to be a very handy piece. All these elements are divided so as to be used for two wounds. The soldier must be specially instructed in the use of the packet beforehand, to compress the contents as little as possible, to spread them first the wound with his hands, and to keep it as much as possible from contact with his clothes and share all with the rest. The packet considers that a valuable addition in this packet would be an elastic band

age or ligature, preferably an India-rubber ribbon which could be worn over the shoulders like braces, or round the waist as a belt. By this means the dangers of hæmorrhage would be greatly reduced, leaving only the wounding of a vital organ as a residuum not to be eliminated.

MEDICO-LEGAL AND MEDICO-ETHICAL.

MIDWIFERY ENGAGEMENTS.

His Honour Judge Edge delivered judgment at the Tynes County Court on December 17th in a case heard at the last Court, in which Dr. Woodridge of Hartlepool, sued A. Willing, publisher, of Ashington, for 3 guineas professional fee. Plaintiff was engaged by defendant to attend to his wife in her confinement, but defendant actually called in another medical man. The question was whether plaintiff was entitled to recover his fee. No authorities were cited, said his Honour, to help him in coming to a decision, and he had to consider the case upon the usual principle where there was a contract. In the present case there was a contract, which was broken by defendant. It was perfectly clear that plaintiff was not entitled to his full fee because he had not rendered the service, but he was entitled to some compensation because he had been deprived of his opportunity of making a profit. Looking at the circumstances, he thought the justice of the case would be met by making an order against defendant for a guinea, half the full fee claimed.

POISONING BY MISADVENTURE.

A BIRMINGHAM manufacturer died recently, from taking strychnine supplied to him by a retail chemist. It was shown at the time that the retail chemist supplied only that which had been furnished to him by Messrs. Wyleys, wholesale chemists. At the present Birmingham assizes an action was entered by the widow of the deceased to recover damages. Both the wholesale firm and the retailer were sued. When the plaintiff's case was opened counsel stated that terms had been arranged. The record was withdrawn, Messrs. Wyleys paying the plaintiff £2,500 and taxed costs, the retailer paying his own costs. Mr. Jeff, for Messrs. Wyleys, explained that how the case arose was a mystery, and the defendant desired to act honourably. Mr. Justice Day expressed his satisfaction with the terms as stated.

HYGIENE AND ETIQUETTE.

RATHER NOT IN A CASE for an opinion on the following: A. and B. see a case in consultation which they diagnose as scarlet fever, notify it as such to C., who is medical officer of health, and also physician to the hospital. The patient is seen the same night by C., and removed to the hospital the following day, where it remains under C.'s care for thirty-one days, when it is sent out at the request of C., and is taken home in a cab taken at random from the cab stand. A. is again called in to see the case, and finds the patient desquamating freely. He is asked to see the case again, and he also decides that the patient is desquamating. A., acting on the advice of B. and D. (another practitioner), writes to the sanitary inspector calling his attention so that the necessary precautions should be taken, and also that the cab may, if possible, be found and properly disinfected. D., who also saw the case after it came from the hospital, was of opinion that the patient was desquamating. Would you say that there had been a breach of etiquette on the part of A. for not writing to C., the medical officer (with whom he is not on friendly terms), instead of to the sanitary inspector, whose duty it was to look after the disinfecting of the cab?

"* An unbiased review of the points involved in our correspondent's communication leads us to the conclusion that, in view of the assumed urgency for the disinfection of the cab, fortified moreover by the deliberate opinion of the two old experienced practitioners B. and D., he acted prudently in requesting the attention of the sanitary inspector to the case in question; at the same time, and notwithstanding the interruption of friendly feeling between C. and himself, we are of opinion that it would have been ethically judicious to have transmitted to the medical officer of health (C.) transcript of the note addressed to the sanitary inspector.

MIDWIFERY EMERGENCIES.

NEMO writes: A. and B. (surgeons) live in a working class village. A. is taken ill, and is obliged to go from home; his assistant does his work in his absence. The latter is called to a confinement; things go on slowly, and he finds it necessary to deliver, but does not like applying the forceps. He sends for B. (who is friendly with A.) to come and help him. B. delivers with forceps, and sees the patient four times afterwards at the assistant's request. All goes well. A. comes back, and B. asks about his fee, and suggests a division (guinea fees are the rule), that is, 10s. 6d. for each. A. says, "Oh, no, send your own bill, they should pay you." What is the proper thing in this case?

"* The following rule is that by which our correspondent's case should be governed, to which we deem it well to state that if A. or B. will refer to the *Medico-Chirurgical Tariffs*, it will be found that an extra half-fee is suggested as a fairly just one for a case necessitating delivery by forceps:

"When a practitioner is called in, or otherwise requested to attend, at an accouchement for another, and completes the delivery, or is detained for a considerable time, he is entitled by custom (except in the case of illness, etc., provided for by Rule 3) to one-half of the fee; but on the completion of the delivery, or on the arrival of the pre-engaged accoucheur, he should resign the further management of the case. In a case, however, which gives rise to unusual fatigue, anxiety, and responsibility, it is right that the accoucheur in attendance should receive the entire fee, etc."—*Code of Medical Ethics*, Chap. II, Sec. 5, Rule 13

CANVASSING FOR SUCCESSOR.

NO. 90 writes: A., holding several appointments, sells his practice to B. Is it unprofessional on A.'s part to endeavour to obtain the appointments for B. by canvassing, etc. A. knowing that some of the medical men in the town are seeking the appointments, and who are also canvassing?

"* Under the circumstances related we see no valid objection to A. canvassing on behalf of B.; indeed, it would seem only natural in his own interest as well as that of B.

THE RED LAMP.

I. asks if there is anything objectionable in his having a plain red lamp attached to the wall of the house inside the garden near the front door.

"* Although there is no written ethical rule condemnatory of the use of a red lamp as proposed, nevertheless any such deviation from general prescription and usage is, as a rule, viewed by the profession with more or less distrust, and almost invariably induces disparaging remarks, and should therefore be carefully avoided. If, however, the locality of the house be so dark as to render more light desirable, we would suggest that an ordinary or other selected gas lamp, with or without a reflector, should be so arranged as to throw the light upon the door or nameplate, or, as an alternative, to paint or otherwise display the name on the glass of the fanlight over the door illumined from behind by a gas jet.

EMPLOYERS AND ASSISTANT: FEES OF WITNESS.

F. M. B. writes that he engaged an assistant who signed the usual bond "to devote the whole of his time and attention in assisting him to carry on his profession, etc." We gather that while acting as assistant the latter attended at the magistrate's court to give evidence in a case in which the defendant was committed for trial, and the assistant was bound over to his own recognisances in the sum of £20 to give evidence at the sessions. The question asked is as to who is entitled to the fees.

We do not quite understand whether the fees in question are those for giving evidence before the magistrates or at the sessions; but we think that if at the time the assistant attended to give such evidence he was in the employment of our correspondent, the fees belong to the employer. It may be taken as a general rule that the earnings of an employee (in the time of the employer) belong to the latter; and we are not aware of any custom in the medical profession which overrides this rule.

M. C. asks a very similar question to that of "F. M. B.," and he will gather our opinion on the subject by referring to the reply given to "F. M. B."

REMOVALS.

A MEMBER writes: If a medical man is removing from one part of a town to another, is there anything unethical in replacing the plate on the gate of the house he is leaving for a few weeks with one such as this:

Dr. _____
(Removed to _____ Street).

I have seen it done in the London suburbs.

"* There can be nothing unethical in the course proposed. It seems to be the custom in London.

A MEMBER of the British Medical Association and a correspondent signing himself "Lex" have sent us medico-ethical questions, but do not authenticate their letters.

T. G. K.—A courteously worded note to the assumed offending practitioner, we need scarcely observe, called for a like reply; and X's omission to respond thereto leads to the inference that he had no defensible explanation to offer, or was more or less imperfectly acquainted with the courteous obligations of life.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF CAMBRIDGE.

THIRD M.B. EXAMINATION.

Part II. Pathology and Medicine.—Bennett, B.A., Joh.; Bliss, B.A., King's; Burnett, B.A., Joh.; Coombe, M.A., Gonv. and Cal.; C. D. Edwards, B.A., Joh.; E. L. UNIVERSITY OF EDINBURGH.

THE various medical classes rose for the Christmas recess on Friday, December 28th, and will meet again on Tuesday, January 7th.

SOCIETY OF APOTHECARIES OF LONDON.

PASS LIST, December, 1895. The following candidates passed in Surgery.—S. B. Blomfield, Westminster Hospital; E. C. Bond, Royal Free Hospital; A. P. Coker, Middlesex Hospital; F. O. Langford, Charing Cross Hospital; A. C. McLean, King's College Hospital;

J. G. Owen, (Charting Cross Hospital); C. J. Palmer, Birmingham and Liverpool; F. E. Jenner, Medical University; E. T. V. von Humpo, Royal Free Hospital; R. J. Wareham, Charing Cross Hospital.
Medicine, Forensic Medicine, and Midwifery.—T. Jones, Manchester; A. T. Morgan, Bristol; A. C. Thornton, St. Thomas's Hospital.
Medicine and Forensic Medicine.—P. R. Wallis, University College Hospital.
Medicine.—R. Goulden, Manchester; G. G. R. Hein, St. Thomas's Hospital; W. A. Montgomery, St. Thomas's Hospital; J. H. R. Pigeon, Bristol.
Forensic Medicine and Midwifery.—E. R. Bowen, Brooklyn and Bristol.
Forensic Medicine.—H. Clapham, Sheffield; J. Hoppe, Leeds.
Midwifery.—C. C. Preston, Manchester.
 To Messrs. Nisbet, Colker, Hain, Hepple, Langford, Montgomery, Owen, Palmer, Pigeon, Preston, Warcham, and Miss von Humpo was granted the diploma of the Society.

PUBLIC HEALTH AND POOR-LAW MEDICAL SERVICES.

THE TYPHOID EPIDEMIC AT DUNBAR.

THIS epidemic shows few signs of abatement. It appears that many of the inhabitants, in face of the repeated advice of the local authorities, persist in using the contaminated water unboiled. The mortality is already 17 per cent. of the cases. We understand that Sir Henry Littlejohn's report has been received by the authorities, who ought to have published it in *extenso*. The reason why they have not done so is alleged to be the fear of destroying the reputation of the place as a summer resort. If this be the reason, it is a most ill-advised one. It would have been a thousand times better to have taken the public into full confidence in a matter of this kind, and to have indicated the way in which the local authority meant to make the recurrence of such an appalling state of affairs impossible. We understand that Sir Henry Littlejohn has absolutely condemned the water supplied to the place. It appears that the sewage of two farmsteads and sundry cottages has drained into the open burn or stream of its tributaries from the first. Then later, apparently, the sewage from the caravan hospital with its typhoid patients, steps are being rapidly taken to get a supply of water from a source beyond the possibility of such pollution, and it is expected that this will be available in the course of a month or so.

A SANITARY STAIN IN STOCKPORT.

IT argues well for a sanitary district and for its sanitary officials when such outspoken utterances can be written and expressed as those which find place in the annual report of Dr. Charles Porter in 1894 in respect of the sanitary borough of Stockport, concerning the matters of excrement disposal and removal. That a town of the size and importance of Stockport should seek to rid itself of its excremental and other household filth in the speediest and best fashion is to be expected, and therefore to read of the 5,000 or 6,000 privy pits still existing in the borough is rather startling. We learn that mills and large schools have these objectionable contrivances for storing excrement, and that some privies actually drain to the river or on to the banks in an offensive manner. Further, we learn that the pits are not watertight, that they are often situated near dwellings, and that in some instances they abut on the house walls, polluting the very foundations, and in almost all cases in the town give rise to extensive soil pollution. Moreover, the location of pits under the floors of living rooms is not unknown, and pollution of air, of yards and streets, of gardens, drains, and sewers is also mentioned as inseparably connected with the abominable system still so much in vogue. There are in Stockport some 25 houses, from the privies of which the contents can only be removed by cartage through the dwelling. Nor is this all, for we witness a real odour of the excrement of 84 new buildings in 1894 with the nuisance-creating receptacles as adjuncts permitted in the town. This seems to us to be a death-blow to any comprehensive action for the abolition of these foul accumulators; at any rate, it will be if the course be persisted in during time to come. So far as we can gather there will be no excuse for continued permission to builders to construct privies for new houses. But the nuisance of these pits does not cease with their use, great as this is, since there is the added objectionable method of removal of their contents. The privies are generally of immense size, and whilst their cubic capacity is such as to necessitate only infrequent emptying, it at the same time creates the dangerous elements of storage at fermenting filth, and this of itself is distinctly dangerous to public health. Dr. Porter tells of pits emptied only at intervals of six and even twelve months instead of at fortnightly intervals. To some extent this fact can be gauged when we state that each emptying of a privy pit in 1894 meant on the average three loads of filth. The health records of Stockport show a persisting high infantile diarrhoea death rate, and that for the ten years 1884-93 the typhoid fever death rate was twice that of England and Wales, and that from diarrhoea was, compared with the whole country, as 121 to 13 per 1,000 population. The excrementally polluted subsoil is an ever-present danger to the community, and the method of cartage adopted in the town is such as to further and materially add to the danger of organic matter finding suitable breeding ground. The contents of the pits are not directly removed from the pits to the carts, but are actually removed in barrows on to the roadways, and thence placed in the carts—a method which compounds itself as lending considerable aid to the disease-disseminating action of any specifically contaminated privy. Then, again, the emptying is a costly as well as a disagreeable undertaking, and, as Dr. Porter says, its cost would go far to cover the expense of meeting half way the conversion of the privy system into the water carriage system, for which the borough

seems now to be ready. We most sincerely hope that when Dr. Porter has next to report on the annual progress of his district it will be to say that his Council have wisely resolved to set about the thorough emptying out of this stain on their citizenship, and that the necessary loan for the purpose has been obtained, in common with several large towns, such as Leicester, Leeds, and Salford.

PLENUM VENTILATION AT THE Huddersfield INFIRMARY.

AMONG the various alterations which have recently been made at the Huddersfield Infirmary is the introduction of Key's system of ventilation, according to which the air for the whole of the wards is drawn in at one spot, where it is washed and warmed, warmed by passing over steam coils and then driven by a fan 4 feet in diameter into the ducts leading to the different parts of the building. The air is delivered into the wards by upright shafts, and where the main ducts auxiliary heating coils are placed so that a certain variation of temperature can be secured at will according to what is required for each room. The air is extracted from the wards at the floor level. The system has now been in operation for two months, and is said to have given every satisfaction. The experiment will be watched with interest, and it is to be hoped that careful records will be kept of the amount of air which is driven by the fan and of the total expense. Much hinges upon this, and it is very desirable to obtain accurate records on the subject, for there is reason to believe that improved mechanical appliances have rendered the expense of mechanical ventilation much less than it used to be. There is a gradually growing experience as to the efficacy of mechanical ventilation, both in hospitals, schools, factories, mines, and public buildings, and if architects and hospital managers are once assured that it is reasonable and inexpensive, it is needless to say how enormously the planning of hospitals will be facilitated. It is conceivably possible that by aid of the fan the great cubic space which is now demanded in the interest of the patients may be found to be unnecessary.

DISRUPTION OF A COMBINED DISTRICT.

SINCE the death of Dr. Fox, who held the post of medical officer for the Mid-Cheshire district, efforts have been made to induce the urban and rural councils interested to join in the appointment of a medical officer for the same combined district. It seems, however, as yet, and the combination is now regarded as entirely broken up. The Ashton Rural Council and the Northwich Rural Council have appointed Dr. Garsington, of Northwich, the former at a salary of £300 and the latter at £400 per annum. The Northwich Urban Council have decided to appoint an officer at £200 per annum, and the Winsford and Middlewich Councils will probably adopt the same course.

MEDICAL NEWS.

At a meeting of the Border Counties Branch at Carlisle on January 10th, Professor Macewen, of Glasgow, will give an address.

A SUM of £3,200 has been granted to the Imperial Institute of Experimental Medicine, St. Petersburg, towards the expense of the preparation of diphtheria antitoxin.

A SCHEME for the establishment of an asylum for inebriates has been drawn up by the St. Petersburg Society for the Suppression of Intemperance, and has received the sanction of the Russian Government. The Society is collecting funds for the purpose.

THE dinner of the old Belfast medical students presiding in and around Manchester was held in the Victoria Hotel, Manchester, on Tuesday, December 17th, Dr. J. Watson Browne (Belfast) presiding. There was a large attendance, and it is intended to make the dinner an annual function.

MRS. SARAH EDEN, the Warwickshire milkmaid who was sentenced to death at the last Warwick Assizes for the murder of Mrs. Minister, who died after an illegal operation had been performed upon her, has been reprieved, with a view to her sentence being commuted to penal servitude for life.

INEBRIETY IN AMERICA.—The *Quarterly Journal of Inebriety* estimates the number of drunkards in the United States at what it apparently considers to be the "modest" figure of 1,600,000. As there are about 25,000,000 adults in the States, this means that 1 in every 16 citizens of the great Republic of the West is a slave to inebriety.

THE Alvaronga Prize for 1895 of the Medical College of Stockholm has been awarded to Count K. A. H. Mörner, Professor of Chemistry at the College, for an essay on "The Proteids and Albumen-reducing Substances in Normal Urine." The prize is of the value of about £61.

THE Art Annual for 1895, published by Messrs. Virtue and Co., contains a full page etching of Luke Fildes's picture entitled "The Doctor."

The annual dinner of the Edinburgh Royal College of Physicians was held on December 19th. Covers were laid for 150. The function was not quite so prolonged as in some former years. The speeches were all fairly interesting, but there was no brilliant oration.

The annual Kitchen Concert was given by the residents of the Edinburgh Royal Infirmary on December 18th, and was as usual a success. The tradition used to be that former residents in and about Edinburgh were invited, that seems no longer to hold.

THE WOMAN'S HOSPITAL, NEW YORK.—The fortieth anniversary of the foundation of this institution was held on November 21st. During the past year 927 patients were treated in the hospital, and 4,704 in the outdoor department. There were 48 deaths in the institution. The receipts from all sources amounted to 50,340 dollars, and the expenditure to 73,880 dollars.

MEDICAL STUDENTS IN FRANCE.—The constant increase in the number of medical students in France is proved by the following figures, taken from the report of the Budget Commission for 1895. They show the numbers inscribed on the official register on January 15th in each of the years named: 1891, 6,212; 1892, 7,069; 1893, 7,589; 1894, 8,897; 1895, 8,936.

PRESENTATION.—Surgeon-Lieutenant-Colonel Baines, V.D., M.D., has been presented by the officers, past and present, of the 1st Middlesex Volunteers Royal Engineers with a silver bowl and illuminated address on the occasion of his retiring, after thirty-six years' service. The presentation was made by Field-Marshal Sir John Lintorn Simmons, K.C.B., the Honorary Colonel, on December 13th, after the annual distribution of prizes.

MEDICAL GRADUATION IN GERMANY.—The total number of candidates on whom the degree of Doctor of Medicine was conferred by the universities of the German Empire in the course of the academic year 1894-95 was 1,102; of these 516 were conferred by Prussian universities, and 586 by universities outside Prussia. The largest number of medical degrees (163) was conferred by the University of Berlin, next came Würzburg with 143, Munich being third with 139.

ROYAL INSTITUTION OF GREAT BRITAIN.—The lecture arrangements for the coming three months are the following: The Christmas Lectures on "Sound, Hearing, and Speech" (adapted to a juvenile auditory) will be six in number, given on Tuesday, Thursday, and Saturday, and commencing to-day (Saturday) at 3 P.M. They will be delivered by Professor J. G. McKendrick, of Glasgow. On Tuesdays in January, February, and March, Professor C. Stewart will lecture "On the External Covering of Plants and Animals: its Structure and Functions." In February Professor H. Marshall Ward will deliver three lectures "On some Aspects of Modern Botany." In February and March Lord Rayleigh, F.R.S., will give six lectures "On Light." Lectures will also be delivered by Mr. P. H. Wicksteed, by Bishop Barry, D.D., and others. The Friday evening lectures before Easter will be given by Lord Rayleigh ("More about Argon"), Professor Burdon Sanderson, Mr. S. Lee, Mr. J. J. Arncliffe, Dr. E. Frankland, Dr. John Murray, Mr. Bunnie, Mr. W. S. Lilly, Professor T. E. Fraser, and Professor Dewar ("New Researches on Liquid Air").

MEDICAL VACANCIES.

The following vacancies are announced:

BRIDGNORTH AND SOUTH SHROPSHIRE INFIRMARY.—House-surgeon, duly qualified. Salary, £50 per annum, with board and lodging in the infirmary. Appointment for one year, but eligible for re-election. Applications to the Honorary Secretary, Oldbury Rectory, Bridgnorth, by December 31st.

BRIGHTON AND HOVE LYING-IN INSTITUTION AND HOSPITAL FOR WOMEN, 74, West Street, Brighton.—House-Surgeon, unmarried, and under 30 years of age. Salary, £50 per annum, with furnished quarters and board, gas, coals, and attendance. Applications to the Honorary Secretary before December 31st.

BRISTOL INCORPORATION.—Medical Officer for the Workhouse at Stapleton; doubly qualified. Salary, £500 per annum, with residence

and rates and taxes free, together with vaccination fees. Applications to J. J. Simpson, Clerk to the Guardians, St. Peter's Hospital, Bristol, by December 31st.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn Road, W.C.—Assistant Registrars. Applications to Richard Kershaw, Secretary, by January 15th, 1896.

COUNTY BOROUGH OF CARDIFF.—Resident Medical Officer of the Brompton Hospital for Infectious Diseases, unmarried. Appointment for one year. Salary, £50 per annum, with board (without stimulants) and residence in the hospital. Applications to Dr. Walford, Medical Officer of Health, Town Hall, Cardiff, by January 1st, 1896.

COUNTY BOROUGH OF WIGAN.—Medical Officer of Health and Medical Superintendent of the Sanatorium. Salary, £285 per annum, payable monthly; must reside within the borough. Applications, endorsed "Medical Officer," to J. J. Charnock, Town Clerk, Municipal Buildings, Wigan, by January 8th.

DENTAL HOSPITAL FOR LONDON, Leicester Square, W.C.—Assistant Dental Surgeon; must be L.D.S. Applications to J. Francis Pink, Secretary, by January 6th.

DENTAL HOSPITAL FOR LONDON AND LONDON SCHOOL OF DENTAL SURGERY, Leicester Square, W.C.—Demonstrator. Honorarium, £50 per annum. Applications to J. Francis Pink, Secretary, by January 6th.

DEVON COUNTY ASYLUM.—Assistant Medical Officer; single. Salary, £120 per annum, with board, lodging, and washing. Applications to Arthur E. Ward, Clerk to the Visitors, 9, Bedford Circus, Exeter, by December 31st.

HOLLOWAY SANATORIUM HOSPITAL FOR THE INSANE, Virginia Water.—Junior Assistant Medical Officer (Lads), for ladies' side. Applications to Dr. Philippe, Virginia Water.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton.—Four Clinical Assistants in the Out-patient Department, and Clinical Clerks to the In-patient Physicians. Applications to the Secretary by December 31st.

OWENS COLLEGE, Manchester.—Junior Demonstratorship in Physiology and Histology. Salary, £100 per annum. Applications to the Registrar by January 4th, 1896.

POPLAR AND STEPNEY SICK ASYLUM DISTRICT.—Second Assistant Medical Officer for the Asylum at Bromley, Middlesex. Salary, £50 per annum, increasing £10 yearly to £100. Applications, on forms provided, to be sent to Robert Fookett, Clerk to the Managers, Bromley, Middlesex, E., by January 2nd.

SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN, Marylebone Road, N.W.—Surgeon to the Out-Patient Department. Applications to the Secretary, George Scudamore, by January 15th, 1896.

TAUNTON AND SOMERSET HOSPITAL.—Assistant House-Surgeon. Appointment for six months, without salary, but board, washing, and lodging in the institution provided. Applications, endorsed "Assistant House-Surgeon," to J. H. Middleuph Pinchard, Secretary, 13, Haunnet Street, Taunton, by December 31st.

VICTORIA HOSPITAL FOR SICK CHILDREN, Queen's Road, Chelsea, S.W.—House-Surgeon to the In-patients; appointment for twelve months; must be F. or M.R.C.S. Eng. Honorarium, £50 per annum, with board and lodging in the hospital. Also House-Physician to the In-patients; appointment for eight months. Honorarium at the rate of £50 per annum, with board and lodging in the hospital. Applications to the Secretary by January 15th.

WESTMINSTER GENERAL LIEU-SARY, Gerrard Street, Soho, W.—Resident Medical Officer. Applications to the Secretary by December 30th.

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL, Wolverhampton.—Resident Assistant. Appointment for six months. Board, lodging, and washing provided. Applications, inscribed "Application for Resident Assistant," to the Chairman of the Medical Committee by December 30th.

YORK COUNTY HOSPITAL.—Assistant House-Surgeon, doubly qualified. Salary, £50 per annum, with board, rooms, washing, etc. Applications to Fred. W. Howell, Secretary and Manager, by January 1st, 1896.

MEDICAL APPOINTMENTS.

BUNCOMBE, W. D., L.R.C.P. Lond., M.R.C.S., appointed Medical Superintendent of the City of London Union Infirmary.

CAMPBELL, R. D., L.R.C.P., L.R.C.S. Edin., appointed Medical Officer for the Wallingford District of the Hadden Union.

CARR, Gerald, M.D., appointed Non-Resident House Surgeon to the Royal Ear Hospital, Fifth Street, Soho.

COLLINS, W. G., M.R.C.S., L.R.C.P., appointed Medical Officer for the Aylesford District of the Malling Union.

COOKE, William H., M.D. Brux., M.R.C.S., L.R.C.P., L.S.A., appointed Resident Medical Officer to the Royal United Hospital, Bath.

DIARY FOR NEXT WEEK.

WEDNESDAY.

ONSTETICAL SOCIETY OF LONDON, 8 P.M.—Specimens will be shown by Dr. Stubb (introduced by Dr. Griffith) and others. Papers: Professor G. E. Curatulo (introduced by Dr. Griffith): On the Influence of the Removal of the Ovaries on Metabolism in connection with Osteomalacia. Dr. Leonard Remfrey: The Effects of Lactation on Menstruation and Impregnation.

LETTERS, NOTES, AND ANSWERS TO CORRESPONDENTS

QUESTIONS.

A. B. asks if there is an Association of Railway Surgeons or Society of Railway Medical Officers in existence?

"* We are not aware that any such association or society exists. The medical officers of the Great Western Railway Co. have, we are informed, a private Association of their own.

THE INTERNATIONAL MEDICAL CONGRESS AT ROME.
DR. G. CRICHTON (Brixton, S.W.) asks for information about the Transactions of the Eleventh Congress International at Rome. I sent, he writes, P.O. about April, but have heard nothing. I sent also a post-card of inquiry, but received no reply.

THE PASTEUR FILTER.

DR. C. D. WHITE (Lancashire, Lancashire) asks where the Pasteur filter can be obtained.

"* The Pasteur filter is made by J. Debries and Sons Limited, of Hounslow, London, who would no doubt furnish a list of their agents on application.

ACID SALIVA.

A. B. C. would be glad of suggestions as to the treatment of erosion of the teeth in a rheumatic patient whose saliva, and chiefly the parotid, is persistently acid to litmus paper. The acidity is said by the dentist to be the cause of the erosion. The saliva is most acid on waking, slightly acid, neutral or slightly alkaline towards midday, and acid towards evening. Saliva, and especially parotid, has been administered, and mouth washed with bicarbonate of soda tried without any permanent effect.

HOME FOR BOYS OF DEFECTIVE INTELLIGENCE.

A. D. asks to be recommended a suitable school or home institution in the north of England wherein two boys of dull intellect would be admitted. They are able to attend to themselves, but one suffers from nocturnal enuresis, and has done so from 2 years of age. This boy is 15 years of age, the other about 9. Their parents are able to pay.

"* Probably the best place for the two boys to be sent, as they must go to a school in the north of England, is the Royal Albert Asylum for Idiots and Imbeciles, Lancaster. All the private institutions which admit boys of dull intellect are situated, we believe, in the south of England.

SCARLET FEVER IN SCHOOLS.

PARENT asks whether the principal of a small school, having a few scholars and more day scholars, is justified in not notifying to the parents of the day scholars the occurrence of scarlet fever in one of her boarders. Directly the diagnosis was certain the child was removed to the isolation hospital. There had not been any careless exposure to infection to account for the case, nor could it be traced, and the onset was seven weeks after the commencement of term. It is asked further whether the parents ought not to insist upon a certificate from a competent person that the drains were not at fault, and whether, in case of refusal of this on the part of the principal, a parent would not be legally justified in withdrawing his child without the usual notice.

"* The principal ought to have informed the parents, and, under the circumstances, many other precautions besides removal of the patient were necessary. But examination of the drains is not among the most important in this particular, however desirable in itself. Few authorities would hold that faulty drainage is a sufficient explanation of an outbreak of scarlet fever, and the (concealed) occurrence of scarlet fever would be a stronger ground for immediate removal of a scholar than the absence of a drainage certificate. The question is one for a collector, and is not covered by any of the public health statutes.

PURSION OF TASTE.

DR. A. B. WEAVER (Bath) writes: Amongst the numerous persons of the British Medical Journal there may probably be some who have had a case of taste such as the following, and who might be able to give some hint upon the cause, treatment or prognosis. A lady, of much general health, between 40 and 50 years of age, consulted me regarding symptoms of a most distressing and disagreeable nature. She complained that for the last six weeks and half (without exception) when she ate the food produced a peculiar, nauseous, disagreeable, the taste, something like that of decomposed meat, so bad that she was forced to eject it. This disgusting taste is principally confined to the mouth, and rarely produced by food. It is so bad that she drops putting any food into her mouth, and is losing flesh. There is no sense of disagreeable odour accompanying the apparent perversion of the function of the gustatory nerve. The tongue is clean, and there is no inflammation, but constant gastric eructation. I should add that the patient is not taking any very hot or very cold food, and occasionally suffers from dyspeptic symptoms.

ANSWERS.

A. B. MANSFIELD. We have forwarded the enclosure sent together with a previous communication of the same kind to Dr. Mansfield, the able and reliable general secretary of the Medical Defence Union, who we understand is at present occupied with the post on the subject. We hope that this action will have a good effect.

J. B. P. might perhaps communicate with Dr. Miles Bramwell, 1, Abchurch Lane, Street, Cavendish Square, W., who has had a good deal of experience in the matter referred to.

DISINFECTION AND DISPOSAL OF MANURE.

DR. C. R. LINDSAY (Birmingham, B.M.) writes: "R. J. C." and "D. H. B." should get the solids of "indio hydropy" of Messrs. Burroughs, Wellcome, and Co., and note the superior results in anti-septic action.

SACCHARIN.

DR. N. HENRY K. KANE (Kington Hill, Surrey) writes: In answer to "R. W. W." I have been led to doubt the absolute harmlessness of saccharin by only one isolated case, so the value of my doubts is not very great. But I would refer to the case of a patient who had been treated by the British Medical Journal of May, 1896, p. 101. It is two years since were not examples of prolonged use of saccharin in small doses, but of large doses (the last grammes daily) continued for periods of one or two months. These cases show conclusively that saccharin is safe under certain conditions, and also that it offers a different picture of toxicity. In the case in my own practice to which I have alluded the patient has been taking saccharin in tea and in all his coffee for four years, and is suffering from severe symptoms affecting the gastric and pancreatic distribution. It is true that the symptoms of the drug has not after a month produced great amendment in the symptoms, but this is unfortunately the case in various other patients.

THE EFFECT OF CARBONIC ACID IN MINERAL WATERS ON BACTERIA.

J. H. P.—The effect of carbonic acid gas on bacteria in mineral waters and under other conditions in which it is under pressure has been elaborately investigated by d'Arsonval, and an account of his researches will be found in the *Comptes Rendus de l'Académie des Sciences*. With regard to some effects on the specific germs of typhoid fever and cholera, some account will be found in the report lately presented by Dr. Bacton to the British Government, he as well as d'Arsonval has found, speaking generally, that carbonic acid under pressure is fatal to all bacteria provided that they do not exist in the spore form. On spores the effect is absolutely nil, even on those of stercorial bacteria.

TETANUS ANTITOXIN: MAILING.

IGNORAMUS.—We do not know of any English account of the method of preparation of the tetanus antitoxin as described in the *Revue Médicale*. The original paper, dealing with the same subject, was by Dr. Vignani & Pecherich. With regard to mailing, the *Revue Médicale* No. 10, 1896, contains a contribution by Dr. Vignani & Pecherich, and Dr. Loth on mailing in the diagnosis of glanders. This was translated in the *Journal of Comparative Pathology*, vol. 6, June, 1896, p. 107. In September, 1896, Professor Loth, of the Veterinary School, contributed an article to the *Revue Médicale*, also translated in vol. 7 of the *Journal of Comparative Pathology*. At the same time there are results of experiments published by M. P. Loth and M. Loth. In vol. vi, p. 35, McFadyen gives results of further experiments. At pp. 144 and 349, Dr. Penberthy gives some results. In the March number (1896) of the same journal there are two references, one as to the compulsory use of mallein in Switzerland, the other the report of a French veterinary surgeon.

FEMALE MEMBERS OF MEDICAL CLUBS.

DR. ALBERT WEINLAND (Chelsea Park, N.W.) writes: In a recent issue of the *BRITISH MEDICAL JOURNAL* a request was made for any statistics bearing on the amount of female members of medical societies or clubs affecting the payments which should be required from female members of clubs. For some years while a member of the staff of the Grosvenor Hill and Maiden Head Provident Dispensary I kept accurate statistics of the members under my care, and of the number of visits made to them. The average results were these: Each adult male required 1.2 visits per annum, each married woman 2.1 visits per annum, each single woman 2.0 visits per annum, and each child 1.6 visits per annum. Visits after confinement are not included in these figures. The visits to children are only approximate, as the books of the institutions did not accurately indicate the number of children included in membership; the other figures may be relied on as approximately accurate. From these and other facts relating to cost of drugs and dispensing I arrived at the conclusion that in clubs and provident dispensaries a contribution of 1d. per week from each married couple, and one of 1d. per week from others, including children, and not charging for more than three children in any one family, would be fair to the members and fairly remunerative to the medical attendance. Such a scale would make 1d. per week the highest contribution, surely not an excessive sum for any man in fairly regular employment to pay for medical attendance and medicine for himself, his wife, and his family.

NOTES, LETTERS, Etc.

A DISCLAIMER.

FROM letters received by Mr. Ernest Hall, the Editor, it would appear that his name has been added to the Committee of the Association Internationale pour le Progrès de l'Hygiène, des Sanitaires, et de l'Assainissement (Belgium). Mr. Hall desires to give notice that he knows nothing of the institution referred to by the Association, and has given no authority or consent to the use of his name.

CHANGING THE ASSOCIATION.

WHY should anti-vaccinationists say longer than now that a new man pays has given to vaccination vaccination? It is possible to see that a man with any other name would do as much, but it is not a man with a name which we have long favoured, that the Association of the Vaccinationists, do not know that their name is not any other name would do as well, for among the grounds for changing it is an investment in

put forward the "ideal" appropriateness of the name for advertising purposes. In support of this, attention is drawn to the "enormous" amount of patent medicine poisoning alternative nations. An instance of this "enormous" poison, which he has noted refers not to their success in curing disease but in drawing money from the public, attention is directed to such cases recorded as Pink Pills for Pale People, French Purgative Pills, and Burdock's Blood Purifier, and so on. In the numerous cases that the success of such preparations depends on choice of name rather than of ingredients we can well believe them. It is not without interest that in a sceptical age the company promoter should have such faith in the public, and the public in the company promoter as to bring it within the bounds of reasonable probability from a "cold" point of view, that a company can be started with a share capital of £1000 for the sale of some unadorned Vaccine Virus vaccine, a treatment the taking of which renders vaccination safe by destroying any poisonous germs in the vaccine lymph as well as curing in children or adults any diseases which can be traced to vaccination.

ERRATUM—In Dr. Haffkine's article on Vaccination against Cholera, published in the BRITISH MEDICAL JOURNAL of December 21st, p. 1543, in the table referring to the inoculations at Gaya Goal, under the head of the first period of five days, the third line should read 22 vaccinated, had 3 cases (2.25 per cent.), with 4 deaths (1.80 per cent.).

THE CHELSEA HOSPITAL FOR WOMEN.

Mr. Robert O'Callaghan, F.R.C.S., writes to point out that although 100 votes were polled at Wednesday's meeting only 57 persons voted, so against him and 17 for him. Neither he nor his wife voted although entitled to do so. The result in votes is brought about by the system of cumulative voting prevailing at the hospital.

THE PATHOGENESIS OF CANCER: A CORRECTION.

Mr. W. L. Williams, F.R.C.S. (Preston) writes: In your abstract of my communication on this subject to the Manchester Medical Society there occurs a small but important misprint, which I should feel obliged if you will rectify. I am represented by the "printer's devil" as having said that "the process by which cancers and other tumours arise might be regarded as a kind of abnormal generation." The error is in the last word of this sentence, which should be "generation," and "generation."

CASES TREATED BY BINOIDE OF MERCURY.

Dr. C. R. ILLINGWORTH, M.R.C.S. (Ritcher Road, S.W.) writes: 1. A collier was crushed by a fall of "roof," about a ton in weight. His head was pinned to the ground by one end of a large stone, making a large breach in the left occipital arch an inch in depth, which bled profusely. He walked home after being rescued from his perilous position, and an hour afterwards I found him laid down, and very faint from loss of blood. The hemorrhage had ceased, and the wound was about level with the skin with blood clot. I stitched nothing, and simply gave a half pint bottle of 1 in 2,000 biniodide of iodine lotion. Improvement began at once, and was uninterrupted. In a week the clot was organised, and bled on being scratched. A large amount of swelling remained, but passive movements of the jaw having been begun at the end of four or five days, gently, no stiffness eventually remained. Not a drop of pus and no discharge worth naming ever appeared.

2. A collier received a scalp wound down to the bone, seven inches long, and covered with coal dust, which could not be removed entirely. The wound was washed with 1 in 1,000, and six catgut sutures were used to bring the edges together. No other dressing; to be kept dry and undisturbed for three days. Then sutures removed, and wound found permanently united firmly throughout. One dressing only.

3. Loose cartilage in the knee joint of a collier. Refused chloroform but accepted cocaine. The patient held the cartilage himself whilst I made an incision of an inch in length into the joint. I caught the loose cartilage with a pair of catch-forceps dipped into 1 in 2,000, and easily removed it. I then poured in about half an ounce of the same into the joint, and told the patient to move the knee until the blood, air, and lotion frothed out of the lips of the incision; sutured. Dressing on lint with 1 in 2,000 and gutta-serena tissue; kept aseptically; next day temperature normal, and so on for five days. Got up and removed splint of own accord and then went out. No further facts to record except that he was at work on the sixth day.

PILLS AND THE STOMACH PUMP.

A medical missionary who has spent the last twenty years in China, and has just returned on short furlough, tells some amusing incidents of his work, which may serve to illustrate the attitude of the Celestial mind towards Western surgery. A patient was treated one day for a disease which involved the taking of two small pills, and he was charged the nominal sum for a single consultation. A few days afterwards the man returned to the hospital in restored health to complain that his brother had the previous day been treated for another disease and had been given a box of ten pills. Our friend demanded a refund of 20 per cent. of the fee paid by him, on the plea that he ought to have been charged for ten pills. Quite recently another patient was brought by some friends who expected that he had been swallowing uncomfortable things. While the doctor was making use of the stomach pump the patient's friends rushed through the house and entered a watch and some silver spoons. Subsequently discovering his loss, the doctor sent a message to the effect that if the articles were not returned at once he would mention the facts to the Judicial Mandarin. The delinquents came and denied all knowledge of the whereabouts of the missing property, whereupon the missionary said, "There is only one place they can have disappeared to. I shall stomach pump every one of you." With a hasty movement, the Celestials dived into their pockets, and the lost property lay intact upon the table.

RED LIGHT TREATMENT OF CORYZA.

Dr. JOHN McMULLIN (Southport, Lancs.) writes: After reading Dr. Nels H. Finson's article on the Red Light Treatment of Small-pox, I

venture to mention a case of coryza which may be of interest, as it is evident the chemical rays were causing the complaint. I was called to see a young lady in June last, who was supposed to be suffering from hay fever. She had a severe attack of coryza, with a profuse discharge from the nasal mucous membrane and ocular congestion; daylight and especially sunlight made the discharge more profuse. I suggested the hanging of a red blind in her sitting room; this was done, with a marvellous result—she was cured in three hours. When she left her sitting room the discharge reappeared. I prescribed red glasses, with the result that she could walk in the sunlight with impunity. The peculiarity in her case is that she could dispense with the glasses in August.

WOMEN DOCTORS FOR INDIA.

L.R.C.P. & S. Ed. writes: At the present in the North-West Provinces and Oude there exists a very strong and widespread prejudice against the admission of male practitioners, English or Indian, to the women's quarters of an Indian household. My assertion is based on five years' experience of medical mission practice divided between two of the largest cities of North India. There are numbers of native doctors and hakims (the latter practising according to Eastern methods) who can, with some degree of truth, call themselves family doctors, but it will be enough to refer to my experience of the Indian "family practitioner" in the departments of obstetrics and gynaecology alone. Very soon after beginning practice in India I was initiated into the mystery of the male medical attendant of the zenana. I was asked on several occasions to consult with a native doctor over the case of a high caste Hindu lady. The preliminary interview always took place in the men's quarters, and only the male friends of the patient were present. An account of the subjective symptoms of the patient was given, followed by the explanation that "As custom does not admit of our examining the patient internally I have employed a *dhat*" (native midwife), and the diagnosis supplied by the *dhat* was given, and the line of treatment adopted described. The *dhat* employed was utterly untrained in Western methods, yet she was supposed to be able to recognise any and every gynaecological abnormality and disease. My assistance was wanted because this partnership of practice had not been successful in bringing the case to a satisfactory conclusion. After being conducted to the women's quarters, where I was instructed to make a minute examination, I had a second interview with the Doctor Babu, in which he questioned me as to the condition of the patient and discussed her further treatment. In only one or two instances did he ask me to take over charge of the case, usually I never saw or heard anything more of it; he and the *dhat* continued to co-operate as before, only that the treatment was modified by the new or improved diagnosis. After a good many experiences of this sort, I refused any further "cat-and-mouse" consultations. It may be urged by some that the conditions of life in the Indian zenana do not subject the inmates to the more complicated and serious forms of disease. A glance at our statistics for the last twelve months in the departments of obstetrics and gynaecology alone shows that out of a total of 155 native patients no lower than 30 were submitted to major operations. The majority of these were forceps, removal of retained placenta or membranes, and curetting after incomplete or mismanaged abortions. They also include 2 Porro's operations, 2 cases of placenta previa for which turning and extraction were done, 3 craniotomies, 2 decapitations, 3 removals of large uterine fibroid polyp, 3 vesico-vaginal fistulae, and several operations for the removal of urinary calculi. I am thankful to say there is no death recorded among this number. Many of the operations were rendered necessary by the gross mismanagement of *dhat*s, and it is certain that if no woman doctor, trained in Western methods, had been available the majority of the midwifery cases would have proved fatal.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(3) Etiology of Rickets.

HAGENBACH (Zur. Klin. Woch., May 27th, 1895) discusses the etiology with special reference to rickets being an infective process. Theories attributing the disease to deficiency of bone salts, to lactic acid, are no longer tenable. Rickets, like other certain circumstances is disposed to admit various micro-organisms as the cause of rickets. Possessing due to micro-organisms can readily be supposed to set up the lesions found in the disease. The temperate zone is the one in which rickets abounds. The cases of rickets increase at the beginning of the cold season, when children are kept in the house. The greater the altitude, the less frequent is rickets. The infective theory would explain the prevalence of the disease in children, and its infrequency in pure, well-nourished. Both rickets and rachitis are most developed in large towns and in particularly unhealthy districts. Infection of the individual by acute or chronic diseases predisposes to both diseases. Rickets also predisposes to both. In early age chronic infective processes are frequently noticed in the bones. There is nothing in the clinical picture of rickets against the view of its being an infective disease. Acute rickets is known. The spleen is frequently enlarged. The observations in the view are that in some cases has been found, and that acute rickets in some may be produced experimentally in animals by withholding lime salts. The author thinks that the disease set up in this way is not identical with rickets, nor does he think that acute rickets has been shown to be identical with the ordinary disease. He would look upon defective feeding, with atrophies, acute and chronic infective diseases, as predisposing causes only.

(4) Acute Tuberculosis of the Broncho-pneumonic Form.

BOGIN AND LEROUX (Arch. Gén. de Méd., June, 1895) relate a case in a man, aged 40. The illness lasted about seven weeks. The onset was fairly rapid, with epistaxis, fever, and later diarrhoea. Phosphaturia was noted only in the disease. There was some distension of the abdomen and the spleen became enlarged, but there were no spots. The temperature was fairly constant. The pulse was not very rapid until towards the close. There was very much cough, and no dyspnoea. The expectoration was small in amount. The abnormal physical signs in the chest were almost limited to the bases behind, and were such as to lead to the opinion that the pulmonary lesion was secondary. There was great wasting towards the end of

the illness. At the necropsy the tuberculous lesions were found chiefly in the bases of the lungs. The authors draw special attention to the facts that there was no predominance of signs over the apices of the lungs, and that there was no dyspnoea and no haemoptysis. Possibly an examination of the sputum for tubercle bacilli might have cleared up the case. It was not that form of acute phthisis (*granulæ*) which often gives rise to diagnostic difficulties, nor a case of caseous pneumonia of the lobar variety. The lesions found were caseating broncho-pneumonic foci. This form of tuberculous broncho-pneumonia is not infrequently seen in the child; it then produces some cyanosis and dyspnoea, and auscultation and percussion usually give some precise information. Phosphaturia is fairly constant in tuberculosis, whereas it is seen only during defervescence in enteric fever. Herpes, noted in this case, is very uncommon in acute tuberculosis; it is also rare in enteric fever.

(5) Gastropathia Xiphoides.

MIRACOL (Gazz. Osped., March 26th, 1895) draws attention to a form of dyspepsia due to displacement of the xiphoid cartilage. Just as affections or slight displacements of the coccyx may induce severe backache and pelvic pain, so displacement of the xiphoid may reflexly or directly set up gastralgia and a kind of atonic dyspepsia. Not every displacement of the xiphoid causes gastric symptoms; it depends partly on the rapidity with which the displacement takes place, the proportional development of the apophysis itself, the shape of the thorax, etc. Shoemakers with marked xiphoid depression frequently suffer from gastralgia. Symptoms occur most often in anemic and enfeebled girls, and remain unrelieved by ordinary iron treatment, whilst they yield promptly to treatment directed to the xiphoid. This treatment is massage applied so as to raise the xiphoid into position, followed by the application of a pad and bandage for two or three days, or longer if required. The author has found much benefit accrue from this line of treatment when other methods had failed.

(6) Subphrenic Abscess.

LANE (Mach. med. Woch., May 11th, 1895), remarks that the etiology of this disease is varied, his own 7 cases illustrating five different groups. It may be secondary (a) to a gastric lesion the most frequent cause, as in Cases i and ii; (b) to perityphilitic processes (Cases iii and iv); (c) to injury, as in Case v; (d) to disease of the female generative organs (Case vi); or (e) to a thoracic lesion, as in Case vii. All the cases were operated upon except Case iii, which was practically moribund on admission. Cases i, ii, and iv died, whereas Cases vi and vii recovered. Case v, after a very severe illness, was on the way to recovery. Short details are given of the 7 cases. (1) In a man, aged 25, the abscess was due to the rupture of a gastric ulcer on the

posterior wall of the stomach, near the pylorus. Suppurative peritonitis was present. (2) A man, aged 35, had paid in the operation and vomiting four and a half weeks previously. The abscess was situated near the greater curvature and the abscess in the lower part of the stomach. (3) A man, aged 35, who had long suffered from constipation, was suddenly seized with abdominal pain and fever. Somewhat later there was jaundice and pain in the hepatic region, suggesting biliary colic. The end of the vermiform appendix was gangrenous; the inflammation had extended upwards behind the caecum, kidney, and liver, and had caused an abscess in the right subphrenic region. (4) In a boy, aged 14, the subphrenic abscess resulted from the rupture of a hepatic abscess. There were two perforations in the caecum, as well as one in the appendix, together with a perityphilitic abscess. The hepatic abscess was the result of a suppurative phlebitis, the origin of the infection being the vermiform appendix. (5) This case occurred in a man, aged 30, and was, apparently, the result of a blow. (6) In a woman, aged 35, the uterus was scraped out on the second day of an incomplete abortion. The pain in the upper part of the abdomen began on the seventh day. (7) A man, aged 23, had a metapneumonic empyema, and he spat up a quantity of pure pus. After this there was improvement, but later he had pain in the lower part of the chest and in the abdomen. The perforation in the diaphragm was made out at the operation. There was no gas formation in any of these cases. A serous pleurisy was present in 3 cases, which the author looks upon as of diagnostic value. The history of inflammatory lesions in the abdomen may also be of assistance.

(7) The Influence of Syphilis on Locomotor Ataxy.

CARDARELLI (Gazz. d. Osped., May 18th, 1895) says that possibly a third of the cases of locomotor ataxy may be of syphilitic origin. Ataxia occurring on twenty or thirty years after primary syphilis, and not preceded by any decided syphilitic manifestations during this time, is probably not syphilitic. So-called syphilitic ataxia has no definite characteristics of its own, such as belong to cerebral syphilis. Antisyphilitic treatment as a rule does more harm than good in ataxia, and in any case in which this form of treatment did no good in fifteen to twenty days, the author thinks it useless to persevere with it. On the whole Cardarelli thinks that the importance of syphilis as a cause of ataxia has been greatly exaggerated.

SURGERY.

(8) Excision in the Rectum.

E. FRANKEL (Zur. med. Woch., June 1st, 1895) discusses the question of excision of tumors of the rectum leading to ataxia, basing his remarks on a study of nine cases, all occurring in women. The operation occurs in

the ampullary part of the rectum, but not within 3 or 4 cm. of the anus, at least in the early stage. The naked-eye appearances are characteristic. The mucous membrane is entirely absent mostly round the whole gut, exposing the submucosa, or even the muscular coat. The base of the ulcer is smooth. There are no nodules or characteristic structures, either in the ulcer itself or in its usually sharply cut edge. A considerable narrowing with loss of elasticity is present in this normally very distensible structure. Not infrequently one or more perforations are present, which may lead to phlegmonous or putrid inflammation, to suppuration or gangrene of the perirectal tissues. Healing leaves dense scars. Adhesions may occur between the rectum and uterus. This ulceration is mostly looked upon as syphilitic. Other syphilitic lesions are frequently found in the body, including smooth atrophy of the base of the tongue, to which the author calls special attention. The microscopical evidence is also in favour of syphilis. The foci of infiltration follow the course of the vessels. Miliary gummata have been described. There are cases in which neither the history nor the minutest clinical examination reveals any evidence of syphilis. It has been suggested that gonorrhoeal infection may give rise to it, but of this there is no evidence. Reasons given to account for the disease being so much more frequent in women are unsatisfactory. The author draws attention to the fact that women are very prone to constipation; that erosions or superficial necrosis may be caused by the pressure of feces, and that thus the mucous membrane of the rectum may become a place of lessened resistance. As regards treatment, the author has never seen complete healing. He thinks that extirpation of the diseased gut, as proposed and carried out by Sick and Schede, is the only really satisfactory treatment.

(7) Excision of the Vas Deferens for Prostatic Hypertrophy.

PAYON (II *Poliolínico*, June 1st, 1895) has made a series of experiments on dogs with regard to the effects of removing the testes or the vas deferens alone. He finds that bilateral excision of the vas deferens in dogs brings about the same atrophy of the prostate as castration. Drawings of the microscopic appearance of prostates after castration and excision of the vas deferens respectively show that practically the same changes occur after both operations. The author therefore recommends excision of the vas deferens for prostatic hypertrophy in preference to castration as being a simpler operation, causing less mutilation and less mental shock to the patient, and giving equally good therapeutic results.

(8) Treatment of Pancreatic Cyst.

REIDBROW (*Boston Med. and Surg. Journ.*, March 31st, 1895) publishes a case of pancreatic cyst as large as an adult head, in a man aged 26, which

was successfully treated by laparotomy, and free incision and drainage of the tumour after it had been stitched to the edges of the wound in the abdominal wall. The author, who found drainage effectual in two previous cases, states that many other observations confirm his opinion that complete healing takes place after this plan of treatment in most cases, and that the danger is slight. He thinks, therefore, that it would be well to follow this treatment generally. If the cyst can be easily separated from its attachments and thoroughly extirpated without excessive hemorrhage, it might be best to attempt such a procedure in view of the possible reaccumulation of fluid, with its remote dangers. The attempt at enucleation should be abandoned, however, as soon as it becomes evident that the cyst is so thoroughly incorporated with the surrounding pancreatic tissues that it can be separated only by cutting.

(9) Surgical Treatment of Hydatid Tumours.

RUDALL (*Australian Med. Journ.*, January 20th, 1895) says that much of the success which has been obtained in the surgical treatment of hydatid tumours is due to the thoroughness of evacuation and to the employment of the shortest route to the surface of the body in carrying out the evacuation. He relates the following case as illustrative of these remarks. A male patient, aged 28, suffered from a swelling in the right side of the chest, which extended upwards as far as the top of the fourth interspace. On aspiration with a fine trocar fluid was withdrawn which contained pus cells and hooklets. There were no symptoms of lung affection. The diagnosis was thought to be a hydatid tumour of the liver, which had encroached to a very considerable extent upon the thoracic cavity. There did not seem to be any likelihood of dealing with the tumour effectually by an abdominal incision, and on this account it was decided to reach it through the chest wall. After the patient had been anesthetised an incision was made from near the right nipple downwards and outwards across the ribs, and then about 2 inches of the sixth and seventh ribs were resected. The pleura was then opened, and the lung was found to have been pushed upwards towards the apex of the chest cavity. The liver containing the tumour, and covered by the diaphragm, occupied the greater part of the chest. The diaphragmatic and costal surfaces of the pleura were sewn together with sutures of silkworm gut, and then a fine trocar was passed inwards in several directions. At first watery fluid escaped, and then it became opaque. On this account it was thought that more than one tumour existed. The diaphragm was next cut through and a large hydatid cyst opened. This contained opaque fluid and daughter cysts, some of which were filled with clear fluid. The liver substance overlying the cyst was broken down with the finger so as to allow the escape of the contents of the cyst, and also the

cyst itself, which was drawn out apparently entire. The liver tissue around the opening was stitched to the margins of the wound in the diaphragm, so as to shut off the peritoneum from the field of operation. The cavity in the liver was washed out with a weak sublimate lotion and a glass drainage tube introduced. A week after the operation there was a little bleeding from the wound, which lasted for several days, when a small piece of cyst wall was washed out. After this the wound healed. A little later two swellings formed in the right hypochondriac region, which were treated in the same way, and the patient recovered completely.

MIDWIFERY AND DISEASES OF WOMEN.

(10) The Pelvis in Lame Female Children. Prouvost (*Revue Obstét. Internat.*, May 21st, 1895) has studied this question, which is of grave importance. The obstetric prospects of little girls troubled with lameness are compromised, and as this, like many worse infirmities, does not always exclude the sufferer from marriage and impregnation, the extent to which the pelvic bones may become involved is a matter of interest to the obstetrician. Prouvost holds that in order to safeguard the pelvis the child must never walk without the aid of two crutches. In seven cases where no support was used, the child hobbling about without crutches or even a stick, there was distinct flattening of the pelvis on the side corresponding to the lame leg. The use of a stout stick or even of one crutch was found insufficient, in all observed cases, to ensure thorough development of the pelvis even when the deformity began at about the fourteenth year. In short, the crippled girl must make use of crutches till she is at least sixteen. In his paper Prouvost discusses the orthopedic aspect of the question very thoroughly.

(11) Ovariectomy. Eighty-eight Quarts of Fluid Recovered.

REIFSNYDER (*Amer. Journ. of Obstet.* April, 1895) describes two cases of ovariectomy performed on native Chinese women in the Margaret Williamson Hospital, Shanghai; both patients recovered. In the first case the patient was 23; the tumour weighed 80 lbs. The second patient was 25 years of age; she married at 19, and soon afterwards her abdomen began to enlarge. She had never been tapped. She was 4 ft. 8 inches in height, and the circumference at the umbilicus was 5 ft. 7 inches. She passed about 16 oz. of urine in twenty-four hours, free from albumen; its specific gravity was 1026. Her appetite was good, and the bowels acted once or twice daily. She had been unkindly treated as a sterile woman unfit for domestic work. After numerous precautions, ovariectomy was performed. Chloroform was given; her head and shoulders had to be somewhat elevated; she took but little of the anæsthetic. Eighty-eight quarts of fluid were

removed: the tumour consisted of one large and one very small cyst; there were free adhesions superiorly. The empty tumour weighed 6½ lbs. There was no ascitic fluid in the abdominal cavity. The pedicle was long and about 2½ inches broad. The abdomen was washed out, then the wound closed with twelve silk sutures. There was much shock at first. After the first day, she passed urine voluntarily, and her bowels were moved forty-one hours after operation. On the second day, there was flatulent distension, the pulse rising to 102°. Rochelle salts were given. Her second night was the worst; she had two hypodermic injections of digitalin (½ grain), brandy by the mouth twice, one turpentine enema, and a capsule of turpentine taken by the mouth. Afterwards she did well. Her weight, two months after the operation, was 92 lbs.

(118) Mytero-myomectomy.

CABLE (*Ref. Med.*, May 28th, 1895) during the last six years has operated 160 times for uterine fibroids. In 13 cases he performed vaginal hysterectomy; in 11 enucleation and morcellation, with good results in each case; he would, however, reserve this method for submucous fibroids of moderate size. As a general rule, he prefers operating through the abdomen, and with this method his mortality sank to 1 in 54, whilst with other methods it rose to 7 per cent. Placing the patient in Trendelenburg's position, he makes a fairly large abdominal incision, divides the utero-ovarian vessels between forceps, makes a circular incision at the fundus of the tumour, comprising the serous and superficial muscular layer, works his way with finger or point of forceps to the serous involucre, ligatures the uterine arteries at their point of ingress with the uterus. The tumour can then easily be drawn up into the wound, and dissected away. A ligature is placed just below the os uteri, so as to exclude any vaginal secretion, and an incision made above. The edges of the wound are disinfected with the thermo-cautery and united so as to leave a transverse line of suture at the bottom of the pelvis. The author has operated on 54 cases by this method, with one death; some of the tumours weighed as much as 12, 15, and 16 kg., and presented other operative difficulties.

(119) Pelvic Abscess communicating with Intestine.

MARK (*Rec. de Thérap. Méd. Chir.*, March 15th, 1895) records an operation on a woman, aged 41, long subject to symptoms of pelvic inflammation. She had not been pregnant for 13 years. On December 8th, 1894, there was extensive parametric deposit, with indistinct fluctuation in the left iliac fossa. By December 17th this fluctuation had become quite distinct: the pain was intolerable. On the next day vaginal hysterectomy was performed. Large abscesses were thus laid open. The appendages could not be removed. One

very large collection of pus was opened on Hilton's method. About a pint escaped. It was bluish, and smelt fecal, but no fecal matter was found in it. A T-shaped drainage tube was placed in its cavity. On the tenth day a quantity of faeces was found in the vagina. For a fortnight motions passed both ways; when there were scybala in the rectum more faeces escaped through the vagina. Much fluid had to be thrown up the rectum before any of it returned through the vagina, hence the communication must have been high up. It could not, however, be detected by the finger passed into the abscess cavity. By February 18th, 1895, the patient was in good health. A little pus still escaped from the vagina, but all pain had disappeared.

(120) Double Vagina: Hysteroscopes: Stenosis Uterina.

MURET (*Semaine Médicale*, May 8th, 1895) operated under the following circumstances on a young girl, aged 18. The period had been established for several months, but the show was irregular. She complained of dysmenorrhoea, and an elastic tumour had developed, rising above the symphysis and projecting below into the vagina, which was very narrow and blind—as it seemed—superiorly. The tumour was tapped from below; 4 pints 6 ounces of treacly viscous blood came away. The pain disappeared and menstruation became regular. After recovery the patient was examined under ether. The vagina was found to be double. The right half, which had contained the blood, was the most developed; it contained a septum with a wide eccentric aperture. The vaginal part of the cervix was small but, like the rest of the uterus, well formed. The left half of the vagina, which was naturally open, contracted above, but was now found to communicate by means of an orifice with the right half of the vagina. Contrary to rule, the atresic half was morphologically the best developed. The appearance of the catamenia before the operation was explained by the communication between the two halves of the vagina.

THERAPEUTICS.

(121) Serum Treatment of Malignant Disease.

EMMERICH and SCHOLL (*Deutsch. med. Woch.*, May 30th) reply to Bruns's strictures on the serum treatment (see *EPITOME*, June 15th, par. 464). They complain that a case in which Bruns reported to them a decided diminution in the growth is omitted; that the serum was sent to him for preliminary trial during a time when its exact method of preparation was not decided on; and that too many cases were treated with too little of the serum. They further state that the serum used in some of these cases had become infected and spoilt (after transmission), and they express surprise that it should have been used after it had become flocculent.

They have treated cases with much larger doses than Bruns with no unpleasant after-effects. The alarming symptoms produced were due to the injection of the serum into the vessels of the growth. They advocate equally with Bruns early operation.—Before the Munich Medical Society (*Munch. med. Woch.*, May 21st, 1895) Angerer maintained that Emmerich's serum had no specific curative action. Emmerich treated five cases in the author's clinic. In the first two cases no histological changes could be found, the injections having been given before operation. In the third case erysipelas came on and threatened the patient's life. Neither the injections nor the erysipelas had any effect on the tumour. In the fourth case (No. 1 in Emmerich's paper, *EPITOME*, May 11th, 1895, par. 367) a diminution in the nodules was observed, but the erysipelas which supervened might account for it. The subsequent history showed that after the patient's discharge from hospital new nodules appeared, and death occurred from cachexia. The subsequent history of the fifth case (No. 2 Emmerich's) was also unfavourable. The author emphasises the fact that great caution must be exercised in drawing conclusions. Zimmermann then reported a case in which a diminution in the tumour took place. An alebrie erysipelas appeared on the fifth day, and lasted two days. Emmerich himself was unable to attend the meeting.—Coley, of the New York Cancer Hospital, relates (*Med. Record*, May 18th, 1895) his further researches into the use of erysipelas toxins and erysipelas serum. They confirm his first conclusions. He has improved his method of treatment by using the blood serum of a horse subjected to the action of erysipelas. He relates the following cases: (1) A patient with a rapidly recurring and inoperable carcinoma of the breast was treated for several weeks with the toxins; the growth of the tumour was checked, but there was no decrease in size. The serum was then injected for two weeks, but without any apparent effect. (2) A woman, aged 50, had an enormous inoperable carcinoma of the breast. The injections produced a diminution in the size of the tumour; later erysipelas toxins were substituted for the serum. In two months the growth was reduced to one-half its size. Then uncontrollable and fatal hemorrhage was produced by the erosion of a vessel. (3) In a case of probable carcinoma of the neck and sternum, the tumour ceased to grow and became less fixed and slightly smaller. The author observes that the doses have not been pushed to anything like the probable limit of safety. He is now using much larger doses in eight cases of carcinoma and sarcoma. The author then relates three cases of epithelioma similarly treated. In one case, already published, of inoperable epithelioma of the chin, lower jaw, and floor of the mouth he could find no evidence of the disease eight months after the injections had

been discontinued. In the second case of recurrent epithelioma of the face the growth entirely disappeared. In a third case of inoperable epithelioma of the tongue the growth became smaller and less firm.

(14) Salophen.

P. MARIN (*Soc. Méd. des Hôp.*, May 31st; *Sem. Méd.*, June 5th) has studied the therapeutic action of salophen in a variety of cases—rheumatism, acute and subacute, saturnine gout, chorea, orchitis, or mumps, and phthisis. In several of these cases, salicylate of soda had either not been well tolerated or had seemed to have little or no effect. He concludes that salophen has all the therapeutic virtues of the salicylate in acute and subacute rheumatism and in gout without its drawbacks. In the phthisical cases a single dose was followed by a fall of temperature. In all the cases salophen seemed to have a marked influence in restoring the digestive functions. In cases of chronic rheumatism it did no good. As regards dosage, the author looks upon 3 to 4 grammes (45 to 60 grains) as an average daily dose; 5 and 6 grammes (75 and 90 grains) should be given only exceptionally, and Marie is not satisfied that these large doses are more effectual than smaller ones. The 4 grammes (60 grains) should be given in six doses, either in cachets or simply suspended in water.

(15) The Direct Influence of Bicarbonate of Soda on the Gastric Secretion.

N. REICHMANN (*Therap. Monatshefte*, March, 1894) in view of the uncertain teaching as to the effects produced on the gastric mucous membrane by alkalies, investigated the matter methodically, choosing bicarbonate of soda on account of the extent to which it is generally used. The experiments were performed on human beings, the following five methods being employed. Patients drank before breakfast, during successive mornings, alternately 200 cubic centimetres of distilled water and 200 cubic centimetres of a bicarbonate solution. After 15 to 30 minutes the gastric contents were aspirated, but neither small nor large doses appeared to influence the quantity of fluid secreted. The same experiment was tried in subjects who, however, were allowed shortly after drinking to eat a breakfast. Here again the result of aspiration was negative. In the next place the alkali was administered every morning during several weeks, but no appreciable effect was produced. On the other hand, when taken after food, the acidity of the gastric contents was diminished in proportion to the amount of bicarbonate taken. Again, this investigation when extended over several weeks, produced no effect on the gastric secretion. In conclusion the author states that the examinations numbered 103, that the drug will act as an alkali even to a considerable degree, but that it in no way influences the secretory power of the stomach. Nevertheless he admits the value of a drug, which is capable of lessening acidity, and he

states that the long-continued use of weak alkalies will no doubt produce a tonic effect on a weak gastric mucous membrane.

(16) Alcoholic Applications in Phlegmonous Inflammation.

ACCORDING to Salzvedel (*Deut. militär. Zeit.*, 25) under constant application of dressings of 60 to 90 per cent. alcohol, phlegmonous inflammations of the milder sort undergo almost abortive resolution, while severer cases show unusually rapid softening, and terminate early in circumscribed abscess containing thin pus. The details of the procedure are as follows: After the skin has been washed with ether, and any wound present covered with an antiseptic mull, a moderately thick layer of absorbent cotton wool, soaked in the alcohol, is applied, and over it some waterproof material, perforated or cut in strips so as to retard but not wholly prevent evaporation. The application is renewed daily, and should be continued a few days after subsidence has begun.

PATHOLOGY.

(17) Immunity.

BUCHNER (*Münch. med. Woch.*, 1894. Nos. 37 and 38) gives a summary of his work for the past three years on immunity, and collects thus his most important conclusions: (1) Natural resistance against infection—so-called "natural immunity"—depends upon totally different causes and conditions to those on which artificial or acquired immunity depends, and though practically both may coexist in the same patient, the two sets of conditions must scientifically be considered and investigated separately. (2) Natural resistance depends, on the one hand, upon the bactericidal action of certain dissolved constituents of the organism—the so-called alexins—and, on the other hand, upon an inborn insusceptibility of the tissues and cells of the body to particular bacterial poisons. Natural resistance as a rule cannot be communicated to another animal by the blood. (3) The leucocytes possess an important function in the natural methods of defence of the organism, not as phagocytes but by reason of soluble substances which are secreted by them. Phagocytosis is only a secondary phenomenon. (4) Artificial or acquired immunity depends upon the existence of modified specific bacterial products, the so-called antitoxins found either in the blood or in the tissues of the animal or in both places. As a rule the antitoxins and the artificial immunity which they carry with them may be conveyed to other animals by the blood (and milk). (5) Antitoxins work not by direct destruction of the bacterial poisons from contact with them, but they bind—in the animal, and only through the medium of its tissues—to a diminution of the specific susceptibility of the living tissues, whereby these become insusceptible and resistant to the bacterial poison.

(18) Relation between Diphtheria and Tuberculosis.

REYLLON (*La Tuberculose*, January 30th, 1895) points out certain analogies between these two diseases, and chiefly draws attention to the fact that the families in which diphtheria finds a favourable soil are also predisposed to tuberculosis; in other words, that there exists a family temperament or disposition favourable to the reception of both these maladies. The author cites 21 families in which diphtheria had attacked one or more members at sufficiently long intervals to avoid suspicion of contagion, in illustration of the fact that diphtheria is prone to attack certain families in undue proportions. As a corollary, the author doubts the contagiousness of diphtheria, or at least believes it to be exaggerated as a cause. Diphtheria and tuberculosis coexist with special frequency in the same family. Hagenbach found *post mortem* that 10 per cent. of the diphtheritic were tuberculous, Hagenbach for 23 per cent. In the author's 21 families, 5 had already shown tuberculous manifestations. Adding other cases in which diphtheria and tuberculosis occurred in the same subject, the author finds that out of 200 cases of diphtheria admitted into hospital, there were 42 in which there was evidence of tuberculosis either in the patients themselves or in their families, which gives a percentage of 21.

(19) Death from Starvation in Children.

SEYDEL (*Wierteljahrsschrift für gerichtliche Medizin*, Dritte Folge, Band VII, S. 226) points out that the appearances found after death from starvation of young children, such as emphysema and contraction of the stomach and intestines and general wasting, are not sufficiently characteristic that a decision can be based upon them in medico-legal cases. It is also possible that for example, children might be fed immediately before death, or that the direct cause of death might be perhaps suffocation. From repeated examinations, Seydel found that in true cases of insufficient nutrition there is great atrophy of the thymus gland; he allows that atrophy of the thymus also occurs in other wasting conditions, but thinks that the condition, combined with considerable emaciation and unaccounted by organic disease of other parts, is a sure sign of wasting from inefficient and improper feeding.

(20) Sterility of Serum.

NOCARD (*Sem. Méd.*, 1895, No. 8) nothing that blood serum taken with aseptic precautions and kept free from contamination sometimes becomes modified, found that this chiefly occurs if the serum is taken after a meal. He investigated the question, and found that serum taken from an animal is almost always sterile, but that chyle is rarely so. As a rule, three or four hours after a meal a considerable number of bacteria are present in the chyle, and the numbers vary directly as the amount of food given.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(93) Chronic Pericarditis.

BRADY (*Brit. Med. J.*, May 1st, 1895) reports the case of a man, aged 68, who died of pericarditis. At the necropsy there was found slight increase in the pericardial fluid, which was opaque from contained cells and small fibrinous floccules. Both layers of the pericardium had lost their smooth glistening appearance, and presented small reddish points covered here and there with a layer of fibrinous material. The heart was hypertrophied, especially the left ventricle. No valvular lesion at the aorta and coronary arteries nor other motions. Small white granular kidneys with signs of extensive arteriosclerosis. Bacteriological examination of the pericardial fluid was negative. No micro-organisms were found by any of the various methods employed. In view of these non-bacterial cases of pericarditis uræmic; he has collected five other similar cases, and supposes that they arise from the effect of some one of the poisons circulating in the blood in the uræmic condition.

(94) Cystitis Poisoning.

SAUNDERS (*West. Med. J.*, June 6th, 1895), reports three cases of poisoning by the fruit of *Cytisus latifolius* occurring in children aged 4, 4, and 3 years respectively. The symptoms were what resembled cholera, but there were general tonic convulsions, and the temperature was raised. There was also some likeness to strychnine poisoning. The green mucus in the vomit and stools suggested poisoning by opium. In the one fatal case the mucous membrane of the alimentary canal was mostly pale. In the stomach there were a few coagulums, and in the jejunum there was some redness with desquamation of epithelium. The brain was much congested. Changes were also present in the kidneys, consisting of minute hemorrhages beneath the capsule and necrosis of the renal cells in the convoluted tubes. The nuclei of the liver cells also stained badly. No certain cystitis reaction was obtained in a chemical examination of the organs, but cystitis was found in the bladder. The contrast between the uræmic condition of the mucous membrane of the alimentary canal and the congestion of the brain and meninges was striking. The symptoms consisted in a very acute diarrhoea, with desquamation of the epithelium of the lower colon and rectum, a rise of temperature, and tonic convulsions involving the majority of the voluntary muscles. In one case the diarrhoea continued for 12 days, with abdominal distension. In all three cases there was a greatly diminished excretion of urine up to anuria. Prostration is common to all

severe diarrhoeas. The treatment generally consisted in an emetic and castor oil at the outset, and small doses of opium later; in the case in which the diarrhoea persisted for several days large rectal injections were used.

(95) Examination of the Chest.

OTIS (*Boston Med. and Surg. Jour.*, April 11th, 1895) attaches considerable importance to the value of spirometry, pneumometry (or the measure of the elastic power of the lungs), and the measurements of the circumference and diameters of the chest in natural and full inspiration. They are of special value before positive evidence of tuberculous infiltration can be obtained by auscultation and percussion. From a number of investigations he concludes that in males between 16 and 40 years the lung capacity corresponds to 22.5 to 26 cc. m. for each centimetre in height, and in women 15 cc. m. for each centimetre. If the spirometric calculation falls much below this, either the patient's method of breathing is not normal or his lungs are in fault. The former can be ascertained by the measurement of the chest in repose and in full expansion. In early phthisis the lung capacity is generally much below the average. If the general symptoms are suggestive of phthisis, and yet the vital capacity is up to or beyond the normal, this is evidence against lung disease. If phthisis is present, the test of vital capacity is also a factor of more or less importance in prognosis. The author prefers the water spirometer. The measurement of the elastic power of the lungs is made by the pneumometer or pressure spirometer. In early phthisis the inspiratory power is lessened, the expiratory remaining normal. In thoracometry a measurement is made on a level with the nipple, and another 2 inches below it. These are taken in repose, and after inflation. The shape of the chest can also be ascertained. The sum total of these tests supplements knowledge obtained by auscultation and percussion. If the vital capacity is low and expansion poor, gymnastic exercises may be of use, and lung disease thus warded off. The method of treatment and prophylaxis by lung gymnastics is, according to the author, much too neglected. Tables are appended from original observations on the measurements of the chest and lung capacity.

(96) Peripheral Neurotaxis.

PIERRIN (*Rev. de Med.*, April, 1895) records the case of a man, aged 42, who developed sensory disturbances and difficulty in walking about a month after the onset of a diphtheritic angina. Two months later he presented the typical ataxic gait and Lombard's sign. The muscles of the lower extremities were not wasted and presented no trace of paralysis. The patellar and cutaneous reflexes were absent. There were no pains in the legs but a sensation of numbness in the feet. Sensation to touch, temperature, and pain was impaired over the feet and the lower two-

thirds of the legs. When the patient was lying down marked evidences of inco-ordination could also be obtained. In the arms there was no ataxia, but in the hands sensation was impaired as in the feet, though in a lesser degree. The pupils reacted normally, and there was no ocular paralysis; the sphincters were intact and the genital functions unimpaired. Some six weeks later the inco-ordination had disappeared and the sensory disturbances had almost gone. The affection developed rapidly, the cycle being completed in 2½ months. The author thinks that the sensory nerves were alone affected. In this case the history, the absence of eye changes, and the integrity of the vesical functions formed the chief elements in the diagnosis. Contrary to what is usually observed in peripheral neuritis, there was no tenderness of muscles or nerve trunks.

SURGERY.

(97) The Operative Treatment of Congenital Dislocation of the Hip.

HOFFA (*Berliner Klinik*, June, 1895) reports the results of his operation for congenital dislocation of the hip, which consists in exposing the joint, deepening the cotyloid cavity, and pinning the head of the femur in its normal position. He describes also the different modifications in the technical details of his procedure he has adopted from time to time. This paper deals with the results of 112 operations performed on 82 patients, 30 of whom were affected with bilateral, and the remaining 52 with unilateral, dislocation. In 3 of these cases death occurred as a direct result of the operative treatment, having been due in 2 cases to prolonged anaesthesia with hæmorrhage and shock, and in the third instance to iodoform poisoning. These disasters led the author in subsequent operations to perform the operation more rapidly in order to avoid chilling of the patient, to refrain as far as possible from division of muscles, and to substitute simple sterilized gauze for iodoform dressings. In 9 cases the operation was followed by ankylosis of the affected hip. This unfortunate result is attributed in 8 of these instances to apposition in the wound. In the remaining cases of recovery in which the treatment resulted in the establishing of a freely movable joint, there was no subsequent tendency to stiffness of the hip either from adhesions or from muscular contraction. In most cases, it is stated, the mobility of the limb increased steadily after the discharge of the patients from the hospital. Return of the luxation was noted in 11 cases, in 3 the bone was displaced backwards, and in 8 forwards. In the cases of backward displacement the patients had been removed from the author's supervision before the completion of the treatment. The forward displacement he ascribes to insufficient deepening of the cotyloid cavity, and occurred in his early cases. In instances of unilateral dislocation the

operation is followed by decided lengthening of the affected limb in consequence of the restoration of the head of the femur to its normal level. The amount of persistent shortening due to deformity of the neck of the displaced bone is not very great, and may be obviated by obliquity of the pelvis and by the use on the affected side of a boot with a thicker sole. In cases of bilateral dislocation the author states that his operation results in a removal of lordosis, in a reduction to a minimum of the waddling gait, in restoration of the normal direction of the limbs, and in increased abduction mobility. It is asserted that in all cases of successful operative treatment by this method the improvement persists steadily from the period of convalescence and increases from year to year. The best possible operation in cases of congenital dislocation of the hip is one which will enable the surgeon to effect complete reduction of the displaced head of the femur, and to establish a movable joint. The author insists on the necessity of preserving the continuity of the muscles of the joint, and of restoring their healthy condition and contractile vigour. In recent modifications of his operation he refrains as far as possible from cutting the contracted muscles, and in his after-treatment he attaches great importance to electricity and massage.

(32) Iodoform Injections in Joint Disease. FERRARO (*Il Policlinico*, June 1st) reports the case of a man, aged 37, who after a long walk first noticed pain in the right knee, which was uniformly enlarged, red, and tender, and contained fluid. The joint was incised, and a considerable quantity of flaky pus let out. Two or three weeks after this, during which time the joint went on well, a small abscess formed in the upper third of the tibia; this was scraped. A similar purulent focus also appeared in the shaft of the tibia. The knee-joint became worse. The author then tried endo-articular injections of iodoform emulsion in sterilised glycerine (1-10) at intervals of twenty to twenty-five days. After each injection there was fever of maximum grade on the second or third day. The tubercle bacillus was found in the joint secretion. Slight improvement followed the injections, which were used five times, but, the patient not being satisfied, resection of the joint was finally done. It was then seen that the cavity was full of a mass of adipo-muco-fibrous connective tissue, the caseous substance being almost all gone, the osteitic foci cured or in process of cure, and the tuberculous nodules undergoing fibrous change. No bacilli were now to be found. Probably the iodoform acts by exciting a reactive inflammatory process, with formation of new connective tissue.

(33) The Surgical Treatment of Medical Intracranial Lesions.

ANGEL MONEY (*Intercolon. Quart. Journ. of Med. and Surg.*, May, 1895), in a paper

on the Surgical Treatment of Medical Cases of Profound Loss of Consciousness, suggests that the time has come when radical measures may be tried for cases of this kind, which are simply permitted to die. Intracranial hæmorrhage is regarded as a very natural accident in Bright's disease, atheroma, and hæmorrhagic pachymeningitis. When the hæmorrhage occurs in other situations than the head, death need not follow for some months and even years, and if only a few extra weeks of conscious life can be attained by any means, such means, it is held, ought to be adopted. In the author's opinion direct operation on the brain is preferable to ligature of the carotid artery. The diagnosis can thus be verified, and there is less risk of a fatal issue as the direct result of surgical interference. Inguavescent apoplexy due to cerebral hæmorrhage may have its essential features simulated by embolism and thrombosis of cerebral vessels. In cases of hæmatoma of the dura mater an exploratory incision through the dura mater might afford temporary relief to the urgent head symptoms, and clear up the nature of the case. A case is recorded of cerebral hæmorrhage into the right hemisphere as an illustration of the class of lesions in which, the author thinks, it would be the right thing to try the effect of craniotomy. In considering what would have happened had the hæmorrhagic area been exposed and drained, he holds that the patient's condition and chances could have been rendered no worse by any kind of operative interference carried out with the usual precautions of modern surgery.

(34) Treatment of Cystitis.

FREUNDENBERG (*Wien. klin. Woch.*, June 6th, 1895) has tried cantharidin in 56 cases of cystitis. The formula used was cantharidin (Merk's) 0.001 (= 1 mg.), alcohol ad solvend. 1.0; aq. destill. ad 100. A teaspoonful of this was given three or four times a day; larger doses did not succeed if this failed. Results: (1) In 5 cases no improvement; of these only 1 was afterwards cured by local treatment after trying other drugs; the other 4 resisted even operative treatment (cases of vesical tuberculosis, contracted fibrous bladder, etc.). (2) In 19 its action was slight, or even doubtful, the strangury alone being improved, or the urine clearing without the cure being complete. In 1 of these the cystitis was due to perforating silk sutures after laparotomy, and the strangury was alone improved; in another the bladder had diverticula; some remained, however, in which the drug failed without apparent cause, for example, in one case of gonorrhœal cystitis afterwards cured by sandal wood oil. (3) The remaining 32 cases were completely cured, often surprisingly quickly. In 3 cases of gonorrhœal cystitis cantharidin succeeded where sandal wood oil failed. Conclusions: (1) Cantharidin is approached only by sandal wood oil in its action in cystitis, and the latter is to be preferred if urethritis is present. (2) Its advantages are its

cheapness, tastelessness, and almost complete freedom from unpleasant symptoms, at least in the above given doses, frequent erections being noticed only once (after use for ten days), formation once, and a morbilliform eruption once. Disordered digestion or albuminuria never occurred.

MIDWIFERY AND DISEASES OF WOMEN.

(34) Vaginal Extirpation of Uterus after Labour.

CHROBAK (*Centralbl. f. Gynäk.*, No. 21, 1895) advocates this practice in cases of uncontrollable flooding where rupture is suspected, though he admits that the only two cases in which he acted on this principle ended fatally. In one case, a placenta previa labour, violent hæmorrhage set in during delivery, and a laceration involving the cervix was detected. A tampon was applied; this rapidly became soaked, and a second was firmly packed into the uterine cavity. Hæmorrhage continued, so that Chrobak decided on removing the uterus through the vagina, as that proceeding seemed to him simpler than abdominal hysterectomy. He states that the operation was not very difficult. The uterus was nearly 6 inches long. As it proved difficult to extract, a piece two fingers' breadth wide was cut, like a slice made in an orange, out of the anterior wall; then the organ was easily drawn out of the vagina. There was very little hæmorrhage during the removal of the uterus. Complete rupture of its wall was discovered; the laceration had apparently been enlarged when the second tampon was applied. The patient died. No details of the second case are given. In the one case the whole operation was done in four, and in the other in eight minutes. As far as facility of extraction is concerned, Chrobak considers his experience "encouraging."

(35) Syphilis of Vagina, Uterus, and Appendages.

NEUMANN (*Wien. med. Woch.*, No. 20, 1895) has studied this subject. Of the earlier exanthematous syphilides, none can be clearly diagnosed on the cervix or vagina above the vulva, except mucous papillary growths. Of primary syphilitic lesions only 55 were detected in 800 infected patients; in 51 the portio vaginalis, and in 4 the vagina, was attacked. Gummata are far more frequent; they are most usually seen in the introitus and lower third (anteriorly) of the vagina. A diffuse gummatous invasion of that canal has been observed. Recurrence locally is very frequent in these syphilitic lesions of the vagina. Syphilis of the tube and ovary is a rare and very indefinite complication. Only one definite case of syphilis of the body of the uterus seems to have been recorded. Metritis and endometritis often kill the foetus in syphilitic parents, but Neumann does not feel sure that these complications are in themselves specific. They

come on in many women otherwise out of health, and the debility caused by syphilis, not the infection itself, may produce the endometritis. On the other hand, syphilitic disease of the placenta is a well-known and very distinct disease. It is quite easy to understand how the fetus dies when it has to depend on such a placenta for nourishment. Neumann thinks that it is not evident why the fetus is often born dead or too weak to live many days yet free from any sign of syphilis, the placenta being also healthy. Just as mysterious is the equally frequent birth of a healthy infant when the parents show marked tertiary symptoms. The evil may, in the first class of case, lie in the fetal blood, but this point is not yet beyond the limits of hypothesis.

(32) Dilatation of the Vagina by the Tampon ("Columisation").

Neumann (*Annales de Gynéc. et d'Obstét.*, May, 1895) states that Condamin has had excellent results in the treatment of pelvic inflammation by firm plugging of the vagina. Bozemann and Tallaferro first introduced this practice. It supports prolapsed or tender structures and remedies congestion by dialysis as the plugs are always saturated in glycerine. The plugs, each as big as a walnut, when pressed after soaking, are introduced through a large speculum in the usual manner and packed very firmly. The lower part must not be plugged otherwise dysuria or retention may occur. This "columisation" of the vagina is not suitable for pyosalpinx and other severe diseases of the appendages. Condamin finds that on the other hand it is particularly suitable for posterior parametritis. It relieves the uterine congestion and promotes absorption of the parametric exudation. The patient can walk about and attend to duties after the "columisation" of the vagina. A free fluid discharge comes on about the second day. The plug may remain in place for several days. Of course the vagina must be rendered antiseptic before its application. The first plugs, which touch the cervix, should be doused with iodoform.

(33) Puncture in Pyosalpinx and Hydrosalpinx.

HOFMOHL (*Wien. klin. Woch.*, May 23rd) deprecates the too frequent operations for removal of inflamed appendages. Many patients who have undergone this operation come to him with bad after results, due to suppuration of the stump and consequent discharge of the ligature, or to adhesions between the omentum and the stump, or to intestinal obstruction from adhesion of the bowel to the stump or to the abdominal wall at the cicatrix of the operation wound. Fecal fistula is not unknown. Out of 216 operations for diseased appendages 13 died, 2 from somewhat late pulmonary complications, but 11 from causes directly connected with the operation. On the other hand, out of 100 cases of aspiration or incision through the posterior vaginal fornix

none died. In parametritis, perimetritis, and hæmatocele the results were excellent. Hofmohl therefore maintains that in confirmed diseases of the tube, or in cases where pus or blood has collected in the pelvis without any serious complications having developed, aspiration should be practised as early as possible. The appendages usually resume their normal functions and the patient is saved from mutilation.

(34) Pregnancy in apparently Imperforate Hymen.

BRAUN (*Centralbl. f. Gynäk.*, No. 23, 1895) was consulted by a newly-married woman who had found herself unfit for complete connection. He examined and found a virginal appearance of the external parts, a tight and narrow hymen, and pregnancy advanced to the fifth month. The patient had a generally contracted infundibuliform pelvis, and craniotomy was needed at the end of pregnancy. Braun notes that penetration must have been impossible in this case, where pregnancy occurred before the patient suspected it.

THERAPEUTICS.

(35) The Serum Treatment of Diphtheria.

LEICHTENSTERN AND WENDELSTADT (*Münch. med. Woch.*, June 11th, 1895) report their experience based on 123 cases, and contrast their results with those obtained in 1,353 cases before the serum period. For the purpose of comparison they divide these 1,353 cases into 11 groups containing 123 cases each. The cases of diphtheria admitted into the Cologne Hospital show very little variation in severity; in about 32 per cent. of the cases the larynx is involved. The diagnosis of diphtheria rests as hitherto upon clinical evidence. The authors maintain that they have seen improvement in the general and local condition of the patient as frequently before as since the introduction of the serum treatment. They cannot say with Kossel that every recent case of true pharyngeal diphtheria can be cured by the antitoxin used in sufficient amount, but they think that their results would have been even better if it had been possible to treat the cases earlier. The mortality among the 1,353 cases amounts to 30.9, whereas in the 123 treated with the serum it was 20.3 per cent. The authors point out that the lessened mortality was not due to slighter cases coming under treatment. The number of tracheotomies amounted to 30 per cent. in the serum period as against an average of 32 per cent. previously. Contrary to other observers, they found that the mortality among the non-tracheotomized was not materially lessened. The mortality among the tracheotomized, however, fell from 64 to 43 per cent. This they would attribute to the arrest of the extension of the membrane into the bronchi. The effect of the local curative action is seen in the diminished number of the tracheotomized and in the lessened mortality after tracheotomy.

Their experience shows that the serum is really entirely harmless. The authors also state that during the past fifteen years they have tried the various methods of treatment from time to time advocated, but that before the introduction of the serum very little change was noted in the mortality.—In *Het Weekblad van het Nederlandsch Tydschrift van Geneeskunde*, April 6th, there is a report of the results obtained with Behring's serum in the Children's Hospital, Amsterdam, from October 24th to December 24th, 1894. During that period 31 cases were treated, of which 6 died. The Loeffler bacillus was found in 20 out of the 31 cases. In 5 the diphtheria bacillus was present alone; in 10 it was combined with streptococci, in 2 with staphylococci, and in 3 with streptococci and staphylococci. There were 2 deaths, both of children under 1 year. Intubation and tracheotomy were performed in 11 cases. In 6 cases the symptoms of stenosis disappeared very soon after the injection of the serum, and in 3 in so marked a manner that tracheotomy, which seemed indicated, was dispensed with. The effect of the serum was equally remarkable in 5 cases in which no diphtheria bacilli had been found. A typical fall of temperature had been observed in very few cases, whilst in 1 case an alarming rise took place. The influence on the pulse and respiration was nil. In 5 cases the effect was decidedly unfavourable, producing collapse and cyanosis. Albumen was found in the urine in 16 cases; skin eruptions appeared in 4 cases as (1) an extensive infiltration at the place of injection, (2) urticaria, (3) a large macular eruption which appeared and disappeared several times, (4) a macular exanthem, accompanied by pain and stiffness of the large joints. Paralysis, impeding deglutition, was noted in a few cases as after-complications.

(36) Typhoid Antitoxin.

FEIPER AND BRUNER (*Wiener klin. Woch.*, May 12th, 1895), at the Congress for Internal Medicine at Munich, referred to their earlier experiments, which showed that the toxin of typhoid cultivations is contained chiefly in the bacilli themselves, for after passing a cultivation through a Chamberland filter the filtrate was less virulent than before. The bacilli are killed, without damage to the virulence of the cultivation, by warming for an hour at 55° to 60° C. Their recent experiments show that by repeatedly injecting small quantities of virulent cultivations into sheep, antitoxic substances are formed in the organism which prevent the poisonous action from showing itself. The action of this antitoxic serum depends on its power of destroying, not the bacteria, but the poison. By injecting previously or at the same time antitoxic serum, mice and guinea pigs were protected with certainty against diphtheria or tetanus the fatal dose of a virulent cultivation, and even if infected with the antitoxin one to four hours after the fatal dose was given, they could be cured.

(38) Open-air Treatment of Whooping-cough.

Ullmann, after pointing out the failure of all suggested "specifics" for whooping-cough, and the little effect which drugs of any kind have on the frequency or the severity of the paroxysms of cough or the duration of the disease, proceeds to urge (*Jahrb. f. Kinderheilkde*, Bd. xl, H. 1, S. 39) the value of open air (*freiluft*). He relies chiefly on the consideration that under ordinary circumstances the patients have fewer paroxysms during the hours in which they are out of doors. To establish this he quotes records of the paroxysms in certain cases. Thus, in one case, while indoors, the child (aged 18 months) had a paroxysm on an average every 46 minutes, while out of doors it had one every 91 minutes. In another severe case the child had nearly three times (274:1) as many paroxysms indoors as out of doors. In a mild case the difference was less (14:1). The difference in all the cases varied on different days, but it was on the whole sufficiently marked to strike and convert the parents, at first disposed to distrust the advice given. He states that a threatening paroxysm may be arrested sometimes when in the house by carrying the child to an open window, where it takes several deep inspirations, and the feeling of distress and anxiety which precedes the paroxysms passes off. Ullmann recommends that in summer and on fine days in winter the patients should be kept out of doors—not for a few hours only, but from morning to evening. He attaches much importance to their being given their meals out of doors. The paroxysm of cough and vomiting which so commonly follow a meal is thus in many instances avoided, and the serious deterioration of general nutrition liable thus to be produced is prevented. He does not look on bronchitis or even bronchopneumonia as a contraindication of the open-air cure.

(39) Intravenous Sublimato Injections.

Görl (*Münch. med. Woch.*, May 14th, 1905) gives details of 9 cases of various forms of syphilis which he has treated in this way. He uses a solution of sublimate of 1 in 1,000, and injects 1 to 2 to 5 c.cm. As experiments have shown that the sublimate is not entirely excreted in the urine on the first day, the author gave the injections every second or third day. He has never seen unpleasant symptoms. The pain that was complained of in Blaschko's cases the author would attribute to the strong solution used. If the vein is properly entered no pain is felt. The pain is caused by the escape of the solution into the connective tissue. The advantages of this method of treatment are (1) the small quantity of sublimate used; (2) the rapidity of the cure; (3) the absence of danger so far as at present known, and (4) that the treatment can be carried on without interfering with the patient's occupation. The disadvantages are (1) the impossibility of making the injections if the

veins are not accessible; and (2) the rapid appearance of relapses. The latter is the most serious objection. These injections are to be used only when the intramuscular or subcutaneous injections are objected to owing to pain, or when inoculation or administration by the mouth is impossible. They are also indicated in the tuberculous or in those peculiarly susceptible to mercury or when a rapid effect is necessary, as in cerebral syphilis.

(40) Pilocarpin as a Sudorific.

GRANDCLÉMENT (*Lyon Méd.*, May 26th, 1905) concludes from his experience of pilocarpin (1) that to produce general sweating, which he considers has been too much abandoned of late, one ought to employ the old methods as a rule, and use injections of pilocarpin only as the exception, as in some subjects the latter drug produces poisoning resembling that caused by nicotine or aconitine; and (2) to produce local sweating, the old method of wrapping the part in cotton wool and oiled silk is the best, as frictions with pilocarpin produce only an insignificant amount of sweating. In support of this latter assertion he relates a case which was treated by him with local applications of pilocarpin combined with the old cotton wool and oiled silk method. It was found that unless the latter was well applied, the sweating was practically nil in spite of the pilocarpin.

(41) Vaseline Injections in Otitis Media.

F. ALT (*Centralbl. f. ges. Therapie*, June, 1905) has at Gruber's desire systematically tested on some 250 outpatients Delstanche's method of injecting sterilised liquid vaseline (usually 1 c.cm.) through the Eustachian catheter. He finds it absolutely harmless and well borne. The following are his conclusions as to its value: (1) In chronic adhesive otitis of long standing the injections are very useful, and much preferable to simple catheterising and inflation. The hearing in nearly all cases is improved, and tinnitus lessened or even cured; sclerosis is but rarely benefited, and that slightly. (2) In chronic serous catarrh the injections cannot take the place of paracentesis, and it is doubtful if they have any advantage over the air douche. (3) In acute otitis media the vaseline treatment does not appear to be indicated.

PATHOLOGY.

(42) Pathogenic Yeast Fungus.

SANFELICE (*Centralbl. f. Bakteriologie u. Parasitenk.*, Band xvii, p. 625) gives a description of a yeast fungus, which was isolated by him from the juices of plants undergoing fermentation, and which is pathogenic. It produces, on inoculation in guinea pigs and other animals, a chronic infection with tumour formation in the lymph glands and the thoracic and abdominal viscera, while the yeast cells themselves in the tissues correspond with the different

appearances described by authors as the coccidia of malignant tumours. He gives in detail the history of an inoculation on a bitch in the neighbourhood of the mammary gland. The gland became somewhat swollen, and one month after inoculation resistant nodules were to be felt in the deeper parts, which were not bound down either to the gland tissue or to the skin. The growths increased considerably in size, and fifteen weeks after inoculation the animal was killed. During life the animal had been examined by Professor Biondi, who concluded that the growths were malignant. Microscopically in the connective tissue surrounding the glands were seen masses of cells—some with a large nucleus and fairly definite cell protoplasm, others smaller and with the nucleus situated in the periphery; the arrangement of the cells in places recalled the structure of a carcinoma. No signs of inflammation were recognisable around these newly-formed elements. Similar growths were found in the lymph glands, inguinal and mesenteric, in the kidneys and the spleen, while the lymphatic follicles of the intestine were considerably enlarged. No other organs were affected. The parasites were stained by special methods, and were to be found in the peripheral portions of the tumours.

(43) Diphtheria Bacillus and Fibrinous Rhinitis.

GERBER AND PORACK (*Deut. Arch. f. klin. Med.*, No. 54, p. 262) demonstrated by cultures and by experiments on animals the presence of virulent diphtheria bacilli in five cases of fibrinous rhinitis, which were all accompanied by definite constitutional disturbances. The membrane in the nose lasted on an average eight to fourteen days. As regards the accompanying throat affection, in two cases there was simple sore throat, in two others circumscribed blocked follicles in the tonsils without inflammation; in one case, two and a half weeks after the commencement of the nasal affection, typical throat diphtheria supervened. In addition to the diphtheria bacillus, streptococcus longus was also found regularly. In accordance with earlier observations, the authors believe that the existence of a true diphtheritic rhinitis fibrinosa has been proved. It is occasionally followed by severe general symptoms, infection of the pharynx and larynx, or post-diphtheritic paralysis. Its course is generally very chronic. True diphtheria may be conveyed by rhinitis fibrinosa, as in one of the cases investigated in which the patient and her daughter contracted diphtheria, though the mother's nose at the time only showed the pseudo-diphtheritic bacillus. The pseudo-diphtheritic bacillus may be found in true diphtheritic nasal affections fifty to eighty days after the commencement of the disease, and also in old atrophic rhinitis. The authors do not, however, regard it as proven that a definite relationship exists between the pseudo and the true diphtheritic bacillus.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(43) **Diabetes with Bronzing of the skin.** MARIE (*Sem. Méd.*, May 22nd, 1895), after reporting a case of *diabète bronzé* ("pigmentary hypertrophic cirrhosis with diabetes mellitus" of Hanot and Chauffard), gives a general description of this rare disease, of which only nine certain cases, all by French observers, and two doubtful ones have been published. (A) **Etiology:** It appears in the second half of adult life, and is more common in males than females. Cause possibly alcoholism. (B) **Onset:** Rather sudden, with all the classical signs of diabetes mellitus, together with gastric and respiratory disorders. (C) **Symptoms:** (a) Those of diabetes mellitus, the polyuria, however, being moderate, while the glycosuria amounts to 150 to 350 g. in the twenty-four hours, but diminishes or disappears towards the fatal end. (b) **Abdomen:** Distension almost constant, but ascites slight; considerable hypertrophy of liver, which is of wooden hardness and tender. There is no true icterus as a rule, but urine is high coloured without containing bile pigments. The superficial abdominal veins are enlarged; the spleen is hypertrophied; digestion is often retarded, and diarrhoea, alternating with constipation, is present usually. (c) **Emaciation and enfeeblement rapid.** (d) **Edema of legs generally present.** (e) **The cutaneous pigmentation is brown or even grey black, more or less uniform, most marked on the face, extremities, and genital organs, but is absent on the mucous membranes, and no spots are present (difference from Addison's disease).** In some cases it has been wanting. (f) **Nervous:** Loss of sexual power, absence of knee-jerk and insomnia as in diabetes. (g) **Duration:** Average 1½ months. The temperature is raised towards the end, and the edema and ascites may become considerable, and purpura may appear. (h) **Morbid Anatomy:** (a) **Macroscopic:** (1) Liver enlarged, dense, and rust-coloured, surface generally hobnailed but may be smooth, bile passages normal; (2) Intestines, mesentery, and peritoneum of a slate-black colour (in author's case also covered with milillary tubercles); (3) spleen, mesenteric and mediastinal glands enlarged, sclerosed, and of a reddish-brown rust colour; (4) pancreas sclerosed and rust-coloured, duct patent; (5) kidneys and vessels normal; (6) heart usually normal in size or even dilated with floccid reddish yellow walls, but in author's case it was atrophied; (7) lungs frequently tuberculous. (b) **Microscopic:** Liver inter- and intra-lobular cirrhosis, with masses of ochre-coloured pigment between connective tissue fibres and in hepatic cells, some of which are crowded with pigment

and disintegrate. Pancreas cirrhosed with pigment in connective tissue and parenchyma. In the lymphatic glands the pigment almost obscured their structure; kidneys pigmented to a less degree. The heart in author's case presented pigmentary degeneration of muscular fibres and sclerosed of pigmented fibrous tissue. (P) **Pathogeny:** The pigment is ferruginous; thus the liver contained, in author's case, 11.3 per thousand of iron (normal amount 0.4 per thousand), and the lymphatic glands 18.5 per thousand (normally a trace only.) This probably accounts for the colour of the peritoneum and intestine, sulphide of iron being formed by decomposition. The pigment must thus arise from hemoglobin, and is probably formed chiefly in the hepatic cell. Marie considers this disease to be an entity and not an accident supervening in the course of ordinary diabetes.

(44) **Adductor Spasm in Osteomalacia.** LITZKO (*Wiener klin. Rundsch.*, June 23rd) refers to the contracture of the adductors of the thigh which he has described as pathognomonic of osteomalacia. Various purely mechanical theories have been put forward to account for the limitation of abduction. It has been ascribed to the deformity of the neck of the femur, known as coxa vara; to the trochanter coming in contact with the ilium; to deformity of the acetabulum. It is shown, however, that the diminution of the angle formed by the neck of the femur with the shaft has but little effect in producing limitation of abduction, and also that where, owing to the deformity of the pelvis, the acetabulum approaches the horizontal, abduction is but slightly impeded. The increase in power of abduction as the osteomalacia improves has been taken as evidence that there is no adductor contracture. In a series of cases it is shown that even the limitation that remains after recovery is due to active muscular contraction, not to shortening of muscle or shrinking of capsule, nor to any of the mechanical causes mentioned above, for under an anæsthetic the range of abduction was distinctly increased. These causes may, however, share in the production of the amount of limitation of abduction which remains even after deep narcosis.

(45) **Displacements of the Liver.** J. E. GRAHAM, of Toronto, has a paper on this subject in the *Canadian Practitioner* for June. He states that displacements of the liver may occur from influences outside the liver and its attachments, such as tumours, abscesses, and the like, as well as from stretching or relaxation or undue length of the ligaments from any cause. The condition is not uncommon in women with pendulous abdomens, who have borne many children. A distinction is to be made between floating liver and merely movable liver. The author reports the case of a woman, aged 64, who had borne ten children, and presented cyanosis, dyspnoea, dilatation of the right heart, and emphysema. The liver

was displaced downwards, but could be replaced when the patient assumed the recumbent posture, and could be retained in place by the use of a bandage. In a second case, that of a man aged 35, the liver was displaced by a subphrenic abscess. There existed also pyloric obstruction and gastrocnemius. The liver lay obliquely in front of the stomach. In a third case, in a boy, the front wheel of a wagon had passed over the trunk, fracturing the seventh and eighth ribs. For a time a considerable area of dulness was found upon the left side, while the normal area of hepatic dulness could not be detected, so that the question arose whether the liver was originally displaced and an inflammatory process had taken place in the right hypochondrium, or if the liver was merely hidden under the diaphragm, and an inflammatory process had taken place about the spleen. The paper contained a tabulated statement of 30 published cases of displacement of the liver.

BURGERY.

(46) Hemiatrophy of the Tongue in Suboccipital Caries.

O. VULPIUS (*Beiträge z. klin. Chir.*, Band xiv, Heft i) reports two cases. His first case was that of a man, aged 33, supposed to have caries of the atlas, etc. The left half of the tongue was atrophied, but when protruded the tongue appeared to be bent to the right. A mastoid abscess on the left side was opened, and six weeks afterwards the patient died of hæmorrhage from the left ear. At the necropsy the hæmorrhage was found to come from the jugular vein. The symptoms during life were cleared up by the necropsy. Ulceration of the trigeminal, facial, and auditory nerves had caused the masseteric and facial paralysis and deafness on the left side; a fibro-caseous pachymeningitis had caused compression of the accessory, pneumogastric, glossopharyngeal, and hypoglossal nerves. The hypoglossal compression had brought about the paralysis and atrophy of the left half of the tongue. Hirsch has said that in cases of facial paralysis the tongue always deviates to the sound side; it is thus that Vulpius explains the apparent anomaly in this case—namely, that the tongue was protruded to the right, although the left half was paralysed and atrophied. The second case was that of a girl, aged 18, with tuberculous disease of the atlas and the axis, and atrophy of the right half of the tongue, owing doubtless to impingement of the right hypoglossal nerve. By rest and apparatus for supporting and fixing the head great improvement in the symptoms of the suboccipital caries took place, and the lingual hemiatrophy could hardly be noticed any longer. Besides these two cases Vulpius quotes others from the medical literature on the subject, and points out how important a sign the lingual hemiatrophy may be in estimating the extent of the disease at the base of the brain. In

both cases of Vulpius the lingual hemiatrophy had remained unnoticed by the patients themselves. Other causes of lingual hemiatrophy (not counting those cases in which it forms merely a part of facial hemiatrophy) are syringomyelia, syphilis, apoplexy, tabes, and general paralysis; it has occurred after mumps, scarlet fever, and saturnism, and by compression of the hypoglossal nerve from cancer, tumours of lymph glands, hydatid cysts, and carotid aneurysms. Lastly, there are traumatic cases and cases where no cause could be found; in one case the hemiatrophy was congenital.

(43) Insomnia in Surgery and its Treatment.

VAN SCHAIK (*New York Med. Journ.*, March 2nd, 1895) directs attention to the various forms of insomnia met with in surgical practice. The fear of an impending operation, though no longer so intense as in preanæsthetic days, is yet an important factor in some cases, and hence requires treatment. The author knows of no better hypnotic for this purpose than trional given in a 15-grain dose, followed up if necessary by another one within an hour. This drug is preferred on account of its comparatively rapid action, of its lack of after-effects, and of the deep sleep it induces. It has also been found very useful in cases of depreciated nervous condition due to exhausting diseases and pain, in which chloral, though a more effective sleep-producing drug, is contraindicated from its action as a heart depressant. Restlessness and jactitation occurring after an operation without serious shock—a condition probably due to relaxation of a highly-strung nervous condition—may also be relieved by trional in moderate doses. Abdominal section, in which thirst is apt to complicate the other nervous disturbances, is also very frequently followed by insomnia of a more or less severe type. In two instances of this kind trional given by the rectum has in the author's hands proved quite successful. This drug is further recommended in cases of insomnia due to certain pathological nervous conditions which may complicate surgical disorders—such, for instance, as alcoholism, arterio-sclerosis causing intracranial headache, insanity, tabes, and other diseases of the cord, and the results of the abuse of narcotics.

(44) Primary Tuberculosis of the Breast.

CATELLANI (*Il Policlinico*, June 1st, 1895) reports two cases of this disease. A girl, aged 22, had noticed a lump in her left breast for ten months. The tumour was about the size of a filbert, and was painless until quite recently, when an ulcer had formed at the base of the nipple; the skin was not adherent, and normal except at the ulcer, which was crater-like, with dry reddish edges and irregular base, upon which could be seen yellow milium nodules. In the outer half of the breast there was a rounded, irregular tumour, the size of a fist. There were two enlarged glands in the

axilla. The general health was good except for amenorrhœa, and there was no history of tubercle. The breast and axillary glands were excised, and found to contain abundant tubercles and giant cells. The pus of the abscess contained abundant tubercle bacilli. Injections into guinea-pigs gave rise to typical tuberculosis. In the author's second case the left breast had been affected for one year with a painless, hard swelling, giving rise after two months to enlargement of the axillary glands. The left breast was one and a-half times as big as the right, the skin and nipple normal. Altogether, there were three tumours in the breast, varying from the size of a pigeon's egg to that of a walnut. The general nutrition was good, and there was no tuberculous history. The patient suffered from amenorrhœa and leucorrhœa, and was a virgin. The tumours and glands were excised separately, and found to be typically tuberculous. Koch's bacillus was seen in the sections made from the axillary glands. Inoculation experiments were negative. No local relapse nor any sign of tubercle elsewhere was seen in either of these patients almost a year after operation.

(45) Gastric Ulcer treated by Scraping and Dilatation of the Pylorus.

PODRES (*Centralbl. für Chir.*, No. 15, 1895) holds that in cases of purely cicatricial affections of the pylorus, particularly when associated with extensive adhesions, better results can be obtained by Loreta's operation than by gastro-enterostomy. A case is reported of a man, aged 34, who for two years had suffered from vomiting after meals, sharp pains in the region of the pylorus, and constipation. On performing laparotomy, the author found that the pylorus and duodenum were enclosed and bound down by extensive adhesions. On incising the front wall of the stomach, at a point about 2½ inches from the pylorus, he made out (1) a circular ulcer, the base of which occupied a portion of the pylorus and a corresponding part of the smaller curvature, and (2) extensive cicatricial degeneration about the pylorus, so that only the tip of a pair of dressing forceps could be passed into the duodenal opening. This opening was gradually stretched by passing at first the forceps and afterwards one and finally two fingers. The base of the gastric ulcer was then scraped with the fingernail and a sharp spoon. The wound in the stomach was closed with Lembert's sutures. The vomiting and pain ceased after this operation, and the patient speedily recovered; he regained appetite and was able to sleep well, and when last seen, five months later, had increased in weight.

(46) Epilectomy without Niphen.

POLOMBIERI (*Gaz. degli Osped.*, June 8th, 1895) reports a case of vesical calculus in a boy aged 8, in which he removed the stone (weighing about 8 g.) through a suprapubic incision. Having opened the abdomen, he fixed the bladder to the abdominal walls by two catgut

sutures before incising the bladder. After removing the stone he sewed the bladder up with four catgut sutures. On testing its continency, a few drops were found to exude. One of the sutures fixing the bladder to the abdominal wall was left in. The abdominal incision was then closed, no drainage being used. A catheter was fixed in the bladder through the urethra, and the bladder washed out with boracic solution every three hours. The catheter was removed forty hours after the operation, and the washing discontinued after the third day, when the child could pass water in the natural way. The urine was acid the whole time.

MIDWIFERY AND DISEASES OF WOMEN.

(47) Endometritis.

WINCKEL (*Wiener med. Woch.*, No. 27, 1895) discussed this disease at the June meeting of the German Gynecological Congress. Simple uterine catarrh usually results from distinct venous congestion. It frequently arises from this cause during infancy from improper clothing, especially tight bandaging of the body. Catarrh may also arise in childhood from want of cleanliness, irritation of the vulva and entrance of worms into the vagina. Anæmia and other diseases of the blood cause catarrh in childhood. In adult life the causes of the same disease are innumerable. After bad burns, hæmorrhagic endometritis is frequent. In acute infectious diseases this disease may arise either from entrance of the specific germ into the endometrium or from irritation of that membrane due to chemical products evolved by the germ. Endometritis decidualis polyposa results from retained relics of decidua after abortion and premature labour. In endometritis exfoliativa there is never any infiltration, as has been asserted. Between the shedding of one membrane and the development of the next there may not be the least trace of any discharge. Tuberculous endometritis is rare, the tube being more commonly the seat of tuberculous disease when it attacks the female genitals. Gonorrhœal endometritis is very frequent, and Winckel contends that the gonococcus travels not only along the endometrium to the tubes, but also through the uterine wall to the peritoneum. Recent literature records no instance of true diphtheritic endometritis. The well-known septic puerperal type is chiefly set up by streptococcus pyogenes aureus. Purulent sterile endometritis is saprophytic.

(48) Brow Presentation: Internal Manipulation.

SCHUHL of Nancy (*Archives de Toccol. et de Gynéc.*, May, 1895) reports a case which shows how in brow presentation its conversion into a vertex presentation by pressure of the finger or fingers is apt to be persistently reversed directly the finger is removed. In his case the patient had a

capacious pelvis. The abnormal position of the head was rectified at the inlet, the membranes burst, but the brow came forward again. For half an hour the labor was kept against the head, but the latter did not become engaged in the pelvis. Schuchl therefore removed his hand. Five minutes later the head was found engaged in the pelvis, but the brow again presented. The mouth was open, the chin could not be reached. Within ten minutes the head was expelled, a live male child being expelled naturally. In this particular case, Schuchl observes the pelvis was capacious and the fetus's mouth was open. Poisson has already shown that this is, for mechanical reasons, an advantage in brow presentations. This case, however, shows that in general it is useless to try to "convert" a brow presentation when the head is still at the inlet.

(34) Wounds of Vagina from Falling Astride.

TAFNER and LEVI (*Sem. Méd.*, June 26th, 1895) have prepared an instructive article on this subject illustrated by drawings of dissections of the vulvar relations when the subject is erect. The urethra is rarely injured. The bulb and surrounding venous plexuses are often torn and bleed very freely. Not rarely the skin and mucosa remain intact. Then a thrombus forms which may burst or harden, or suppurate or end by becoming a cyst. Skin wounds inflicted by a sharp object on which a woman falls astride seldom run from without inwards. More often the inner side of the vulva is wounded and the lateral ramus of the ischium prevents retraction of soft parts, hence dangerous hemorrhage may occur. It is, however, generally venous. To check hemorrhage firm pressure is united on account of the extreme tenderness of the parts. Compression by antiseptic gauze is the best way to stop the bleeding. If dead, as recurrence is very common, it is best always to compress a contracted wound. The thighs must be tied together and a catheter retained or frequently passed.

(35) Ecdema and Prolapse of Cervix in Pregnancy and Labour.

GEYER (*Wochenschr. f. Geburtsh.*, No. 13, May, 1895) describes a second case of this rare condition seen in his own practice. Five have already been collected by GÉNÉROT, the discoverer of the disorder in question, and one by MICHAIL, and these eight cases complete the series. Geyler makes use of the formula "eclatant" and "eclatant" cases when general parietal or parietal parietal interventions, which also forms the title of his monograph. In Geyler's last case he first saw the patient on February 19th, 1894. She was in the seventh month of pregnancy, and complained that a body frequently protruded from the vulva and went up again. A mucous mucous discharge ran from it as long as it was down. A year previously Geyler had used the curette for endometritis. He had opportunities of examin-

ing the protruded body. It was a cylindrical structure, 2½ inches long outside the vulvar cleft, ending in a blunt extremity nearly 2 inches wide. It pitted on pressure of the finger, the depression disappearing directly the finger was removed. On careful exploration it was found to be the anterior lip of the cervix. The chief examination was made on March 24th, when labour pains were suspected. After rest, with elevation of the pelvis, the swelling disappeared. It came down again daily before labour. On the night of April 7th precipitate labour occurred, the child being delivered after four pains only, when the patient had been one hour in bed; the placenta soon followed. Geyler arrived when all was over; the uterus was perfectly normal. Ten days later the anterior lip of the cervix felt simply a little larger than the posterior. As reduction is usually spontaneous, and as this case shows that labour is but little affected, oedema of the anterior lip is hardly a dangerous complication of pregnancy. It presents, however, a formidable appearance, and therefore obstetricians should be aware of its true nature.

(36) Uterine Gonorrhoea.

WERTHEIM (*Centralbl. f. Gynäk.*, No. 26, 1895) believes that next to the urethra the uterus is the most common seat of gonorrhoea. The germ sets up true acute interstitial endometritis; in chronic disease the glandular tissue of the endometrium is greatly increased. The muscular coat is often involved, and a kind of sclerosis of the vessels occurs, whilst the connective tissue undergoes hyperplasia at the cost of the muscle cells. Gonococci are usually to be found in the inflamed mucosa, yet sometimes they are entirely absent and they rarely, if ever, can be detected in the exudations in the muscular coat. The os internum offers no protection to the entrance of gonorrhoeal poison into the uterine cavity. The cervix is less involved, and the disease is always least marked nearest the os externum. The puerperium is the most dangerous condition when gonorrhoea exists in the genital tract lower than the uterus. Menstruation, coitus, and the sound are much less liable to expose the uterine cavity to gonorrhoeal infection.

THERAPEUTICS.

(37) Serum Treatment of Diphtheria.

VAN NEE (*Dent med Week*, June 6th, 1895) has treated 52 cases with the serum of which 40 or 77 per cent. recovered. Of the tracheotomized 61 per cent., and of the non-tracheotomized 87 per cent. recovered. The author then analyses three groups of 32 consecutive cases previous to the serum treatment. In the 156 cases the total recoveries amounted to 87 per cent. In the most favourable group they were 61 per cent., and in the least favourable 50 per cent. Among the 52 cases treated with the serum, 16 slight cases, 21 out of 28 cases of medium severity, and only 3 out of

13 severe cases recovered. In 2 cases an eruption occurred. The general condition of the patients improved considerably after the injection. In 4 cases there was slight diphtheritic paralysis ending in recovery. In the 12 fatal cases death was due to bronchitis pneumonia in 6, to nephritis in 2, to cardiac paralysis in 2, and to sepsis in 2. Death due to cardiac paralysis occurred in each case long after the local process was cured. In the two cases of sepsis, the patients were admitted moribund. The author concludes that the results of the serum treatment were very good, and better than those previously obtained under other treatment. Although the favourable action of the serum is highly probable, yet it is impossible to speak positively from so small a number of cases, as the character of the epidemics apparently showed a tendency to become milder.—Egidi's (*Rif. Med.*, May 18th, 1895) cases included one adult, the rest being from 1 to 8 years old. Nine out of the 30 were cases of croup, of which 3 died; 11 were diphtheria, of which 2 died, giving a total mortality of 25 per cent. Bacteriological examination was made in every case; in 2 or 3 only was Löffler's bacillus found alone; in most of the cases there was an association of streptococci and staphylococci. Fall of temperature and improvement in the pulse and respiration was always noted after injection. Even in the most severe cases improvement of the local conditions in the throat followed injection. Urticaria was noticed twice, and once a general scarlatiniform eruption. The author prefers intubation to tracheotomy.

(38) Treatment of Dilatation of the Stomach.

A. MATTHIJS (*Rep. de Thérap.*, No. 3, 1895) discusses the treatment of this affection. When it depends upon an organic obstruction at the pylorus, a surgical operation is the only effectual remedy. Frequently, however, it is brought about by simple spasm of the valve. In such cases good results are obtained from the administration of warm drinks, which perhaps act directly upon the spasm; at any rate they allay the pain and lessen the irritation of the mucous membrane, of which spasm is the reflex consequence. With the same object alkalies may be given. When, again, dilatation is the result of stony of the muscular walls, there are several indications to fulfil. (1) The work of the organ must be curtailed by a suitable regimen, highly nutritious substances being given in a state of fine division and in small bulk. The meals, few in number, must be taken at longer intervals. Once or twice a week the contents of the stomach must be removed by the stomach-pump as far as possible after a meal. Too frequent washing out must however be avoided, and a simple emptying of the organ is often sufficient. Further, muscular action must be stimulated by such means as warm drinks, hypodermic injections of alkalies, hydropathy, electricity, and massage. (2) Gastric intestinal fermentation must be removed. To this end

washing-out of the stomach is chiefly to be relied on, the drugs usually given (naphthol, sodii salicylas, bismuthi salicylas, HCl, roscarin) being of secondary consequence. (3) Hyperacidity is to be combated by HCl; excess of this acid itself by alkalies. (4) Pain, if it does not yield to the above-mentioned treatment, will require chloroform water, cocaine, or morphine. (5) Constipation is better remedied by enemata than by purgatives. (6) The general condition should be improved by suitable measures.

(53) A New Method of Applying Electricity.

STERNUNG (*Neurol. Centralbl.*, July, 1895) describes the following method. A piece of telegraph wire is arranged so as to conduct to earth; the free end of this is joined to one end of a secondary coil, to the other end of which an ordinary wire is attached. From the free end of this wire it will be found that shocks are received distinctly stronger and more painful than in the ordinary method where two electrodes are applied to the body. If, however, the free end is connected with a well wetted electrode and placed in contact with the moistened skin no effect is felt even when the two coils of the induction apparatus are pushed completely over one another; from one person thus electrified shocks will pass to another if sufficiently near. The practical uses depend on this difference. First, diagnostically; the bare wire is used for the detection of analgesia, and hence the necessity of numerous punctures by needles, etc., with risk of sepsis is avoided. Secondly, therapeutically; the operator holding the moistened electrode in his left hand, passes his right hand over, say, the forehead of the patient, who experiences a sensation like an electric douche. In cases of headaches of all kinds, even due to cerebral tumour, and also in cases of neurasthenia, and in a variety of painful affections this method has been found to give good results.

(54) Prophylactic use of Serum in Tetanus.

VAILLARD, at the Académie des Sciences (*Sem. Méd.*, June 6th), after pointing out the inefficiency of antitoxin as a curative agent in any but the more slowly progressing forms of tetanus, and the necessity even here of combining removal of the nidus of infection, states that as a prophylactic it has a definite use. In animals it confers absolute immunity against the toxin, the immunity being temporary, and persisting, according to the dose employed for two to six weeks, and longer if the injection be repeated. After inoculation with the living virus, protection is certain and complete when the seat of infection is the subconjunctival tissue; but less so when the virus is introduced into the thickness of a muscle; this, the most severe form of inoculation, is followed, after one, two, or even three months of freedom from symptoms, by tetanus. The explanation is that the destructive action of the

phagocytes on the virus is more certain and prompt in the former than in the latter. Antitoxin should therefore be injected as a prophylactic after any wound where there is risk of infection, for example, contused wounds fouled by earth or manure, penetrating wounds where the foreign body has been in contact with earth. The prophylactic use of antitoxin will be specially valuable in tropical countries where tetanus is common after slight wounds; in the tetanus of newborn infants, and in military surgery.

(55) Chloro-Caffeine.

PICKERING (*Jour. of Phys.*, vol. xvii, No. 6) relates experiments made with the view of studying the connection between the chemical constitution and the physiological action of the stimulus employed. Xanthine increases the force and the frequency of the embryo chick's heart and the frequency of the frog's heart but does not produce any tonic contraction. Theobromine, which is di-methyl-xanthine, has a greater influence in increasing the force and frequency of the chick's heart and in large doses produces slight tonic contraction. Caffeine, which is tri-methyl-xanthine, produces marked tonic contraction. In the experiments chloro-caffeine was used, in which an atom of chlorine is introduced into the caffeine molecule without displacement of the methyl radicals. The methyl groups would tend to induce tonic contraction of the heart muscle, the chlorine an atonic condition. The introduction of the chlorine atom was found to modify considerably the physiological action of caffeine. Chloro-caffeine produces far less tonic contraction of the heart than caffeine, so that it presents, apparently, an example of "physiological antagonism" going on in the interaction of the parts of one kind of molecule and living contractile tissue—in these experiments the myo-plasm of the embryonic heart. A solution of caffeine in chlorine water acts differently, the free chlorine being very toxic to the heart. The possibility of the chloro-caffeine being decomposed in the living tissue into caffeine and chlorine was considered but no evidence of such an occurrence could be discovered. Chloro-caffeine is a powerful diuretic and also apparently a cerebral stimulant. Experiments were made also with cyano-caffeine, but this was found to act more like a cyanogen derivative than a caffeine derivative, the cyanogen molecule overpowering the three methyl groups.

PATHOLOGY.

(56) Contaminated Ice and Cholera.

WEISS (*Zeitschr. f. Hygiene und Infektionskrankheiten*, Bd. xviii, 1894, p. 492.) Since establishment of the relation between epidemics of cholera and water supply, interest has attached to the question whether cholera can be conveyed by ice which has been collected from a contaminated source. It has been many times shown that the cholera

vibrio can bear low temperature for several days, and Weiss, as the result of his investigation on this subject, is able to confirm the observations of other workers so far as concerns water. But the cholera vibrio behaves quite differently in the presence of low temperatures when it is in a suitable culture medium. In broth it remains alive for twenty-one days; in water which contains much broth it lives three days longer than in water to which only two drops of broth have been added. In pure dejecta kept in the cold, cholera vibrios die sooner than in water, whence it is to be inferred that the vibrios which are present in choleraic discharges also die out in the cold in a few days. Communication of cholera by ice is therefore not to be anticipated, and this agrees completely with the fact that no case has ever yet been observed in which the infection has been carried by ice.

(57) Infectiousness of Milk.

ERNST ("Result of Investigations made for the Trustees of the Massachusetts Society for Promoting Agriculture, Boston, 1895") investigated the effect of inoculation and feeding with milk of tuberculous cows. Care was taken to exclude any tuberculous disease of the udders themselves. Tubercle bacilli were found in the milk or cream of 12 cows out of 36. Of 88 guinea pigs inoculated subcutaneously with milk from 15 cows 12 developed tubercle. Rabbits were less easily affected. This was also the case with feeding experiments, but of 12 pigs (8 to 10 weeks old) 5, and of 21 calves 8 animals became tuberculous. The parents of all the calves were perfectly healthy. The report also contains information derived from answers to 1,100 circulars upon the subject sent to medical practitioners and veterinary surgeons. From the results of his experiments, the author expresses the opinion that no milk from tuberculous cows should be used as human food.

(58) Acute Spinal Myelitis.

TANRELLI-SALIMBENI (*Atti della R. Accad. dei Fisiocritici di Siena*, Ser. iv, vol. v) describes 3 cases of acute spinal myelitis in adults. *Post mortem* he found acute diffuse myelitis over the whole extent of the spinal cord. The anatomical appearances showed that the process was an infective one, and in two of the three cases he found elements indistinguishable from micrococci. In one case the infective nature of the case was further shown by the histological and bacteriological appearances in the spleen, liver, kidneys, and pericardium. The principal change in all cases consisted in a considerable amount of small-celled infiltration, especially around the blood vessels, which spread a greater or less distance into the neighbouring parts, and even into the lymph spaces around the nerve cells. Dependent upon these vascular lesions and the presence of microorganisms were the considerable degenerative alterations in the nervous elements seen in the cases.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(45) The Relations of Sensory Impressions and Sensory Centres to Voluntary Movements.

BASTIAN (communication to the Royal Society, April 5th, 1895) cannot accept Mott's and Sherrington's interpretation of the fact shown by them that "section of the whole series of sensory roots belonging to a limb," upper or lower, causes lasting motor paralysis in the anesthetic limb. They thought this proved that "not only the cortex, but the whole sensory path from the periphery to cortex center is in action during voluntary movement"; but this cannot be true, for in complete hemianesthesia due to lesions or functional defects in the posterior part of the internal capsule, there is no impairment of movement whatever of the anesthetic limbs, at least under visual guidance. The extent to which afferent impressions and the activity of their related centres are really needed for the production of voluntary movements must be considered in connection with the cause of this paralysis. Bastian has long contended that the so-called motor centres in the cortex are really sensory centres of kinesthetic type, which are called into activity by stimuli coming from the cortex (for volitional movements) and from afferent nerves and the lower sensory centres (reflex acts), the true motor centres existing only in the pons, bulb, and spinal cord. As examples of cortically initiated movements he takes (I) those of speech, where the auditory centre where thought of words is revived, the gross kinesthetic centre in Broca's convolution, the proper motor speech centre in the bulb and the commissural fibres of those centres are so interdependent, that a lesion in any part of this tract may cause aphasia combined with "word blindness" if the lesion be in the auditory word centre. In reading aloud a fourth centre (namely, the visual centre) receives the first impressions, which are then conveyed to the auditory word centre by commissural fibres. Thus, in case of a lesion in the visual centre, voluntary movements concerned in speech cannot be performed at the initiation of the visual, but only of the auditory, sense. Again, in (II) limb movements the visual sense performs the same office as the auditory in speech, that is, the visual and kinesthetic impressions pertaining to the movement are revived there. In (A) organic lesions, (a) destruction of kinesthetic centres causes paralysis of the corresponding limb plus loss of muscular sense and kinesthetic impressions; (b) in man existence of paralysis of limb movements following a lesion of the visual centre or of the visuo-kinesthetic commissure is not proved except for

writing movements, the destruction of the left visual word centre causing complete agraphia. (c) In the lower animals isolation of the kinesthetic centres by section of the fibres connecting them with other sensory centres causes paralysis, as after extirpation of them. Electrical irritation of the centres, however, produces the same muscular movements as before. (v) Functional defects. (a) Cerebral. Defective nutrition of the kinesthetic centres produces temporary and curable forms of paralysis, often combined with single or double hemianesthesia. In one class movements can be performed only when the eyes are open (due to kinesthetic centre being capable of being roused by a slightly stronger stimulus). (b) Spinal. Bastian believes the form of paralysis produced by Mott and Sherrington to belong to this class, that is, instead of the lowered functional activity being in the cerebral kinesthetic centres, it is probably in the motor centres themselves in the cord, so that they no longer respond to ordinary volitional stimuli from the cortex; not, as Mott and Sherrington think, that volitional power "has been absolutely abolished by the local loss of all forms of sensibility" in the paralysed limbs. This explanation agrees with other facts found in these experiments: (1) That the effects are produced only when all the sensory roots are cut may be due to overlapping of the fields of distribution of the sensory roots; (2) that the paralysis increases from the attached base to the free apex of the limb, to the delicate stimuli going to the smaller muscles of the hand being less likely to rouse the sluggish spinal centres; (3) that forcible and rapid movements, even of the fine joints at the end of the limb, take place if the animals are made to struggle, to the muscles responding to stimuli stronger under the influence of emotion; (4) that movements are produced by stimulating the corresponding kinesthetic centres electrically as easily as in a normal limb, to a profound difference between effects of volition and experimental stimulation of the cortex. At any rate, the latter shows that cutting off afferent impressions by section of the sensory roots does not entail a lowered excitability of the kinesthetic centres in the cortex, but the reverse considering the lowered activity of the spinal centres, which the absence of tonic implies. In cerebral hemianesthesia, however, there is no lowering of the activity of the spinal centres, and no cutting off of cerebellar influence, so that the action of the cortex is less interfered with. These differences may explain the presence of paralysis when posterior roots are cut and its absence in cerebral hemianesthesia.

(46) Early Diagnosis of Diabetes.

VON NOORDEN (*Centralbl. f. inn. Med.*, May 25th, 1895) draws attention to the early diagnosis of diabetes since treatment in the early stages offers considerable hopes of recovery. Treatment should be

begun before the diagnosis is made by the discovery of sugar in the urine. The author has investigated the diagnostic value of alimentary glycosuria in such cases. In 15 adipose individuals no trace of sugar could be found when food containing much carbohydrate material was administered, but when pure grape sugar was taken glycosuria was noted in 4 cases. Two of these 4 cases have since developed diabetes, and the two other cases have not been under observation long enough. If subsequent investigation confirms these observations the test with grape sugar will be of considerable diagnostic value. It should be tried in the adipose and gouty, especially when a family history of diabetes is present. The author looks upon adiposity as frequently an early symptom of diabetes.

(47) Paroxysmal Hemoglobinuria.

CHAUFFARD, at the Société Médicale des Hôpitaux (*Sem. Méd.*, June 19th), related a case of paroxysmal hemoglobinuria from cold. Ehrlich's experiment was repeated, that is, blood was examined from the two hands, one having been exposed to the air, the other tightly ligatured at the wrist and exposed to iced water fifteen minutes. In the latter the serum was a pinkish cherry colour, while in the former it was yellow. The clot did not redissolve in either case, as it should do in an attack of hemoglobinuria. This is explained by supposing that a central nervous disturbance is required in addition to exposure to cold for the production of a typical attack. The relation to the nervous system was shown by this case, for the exposure of the hand isolated by ligature to intense cold produced all the prodromal symptoms and premonitory albuminuria of a general attack. The mode of action and the path taken by the nervous reflex are uncertain, but that some nervous reflex is the starting point of the chemical process which results in an attack of hemoglobinuria seems clear.

(48) Biliary Cirrhosis in Children.

GILBERT and FOURNIER (*Rev. des Mal. de l'Enf.*, July, 1895) report 7 cases of biliary cirrhosis in children, or commencing in childhood, and presenting all the symptoms observed in the adult, but with the addition, in many cases, of hypertrophy of the spleen, so conspicuous that in those cases in which the liver is not very much enlarged—and such enlargement is in children often not great—the true nature of the disorder may be easily mistaken. They believe this enlargement of the spleen in association with biliary cirrhosis to be peculiar to cases commencing in childhood. A further peculiarity of the disease, as observed in children, is the frequency with which clubbing of the fingers may be observed. In some instances the ends of the femur and tibia were enlarged also. Evidence of the influence of the disease on the general nutrition is to be detected also in the retarded growth and the backward appearance of the sufferers.

SURGERY.

(69) Laparotomy in Tuberculous Peritonitis.

NANNOTTI AND BACIOCCHI (*Gaz. degli Osped.*, No. 57, 1895), as the result of an experimental study of this subject, conclude that laparotomy undoubtedly has a beneficial influence upon tuberculous peritonitis, even in the lower animals. In certain cases in which laparotomy succeeds it should be repeated if necessary. The involution of tuberculous nodules after laparotomy is, as a rule, rapid, but there generally remain some foci which disappear much more slowly, so that one ought to be cautious in speaking of absolute cure. The beneficial effect of laparotomy does not seem to be materially increased by washing out the peritoneal cavity with sterilised water or antiseptic solutions. In addition to the immediately beneficial effect, laparotomy may hinder the secondary localisation of tuberculosis. The operation sets up an inflammatory reaction of the peritoneum, accompanied by a noteworthy increase in its absorbing power, phagocytosis, degeneration of the cellular elements, connective tissue formation, and vascularisation of the tuberculous nodules, with successive fibrous transformation. The authors recommend comparatively early operation in man, not only for its immediately good effect, but to prevent further spreading.

(70) Radical Cure of Hernia.

FERGUSON (*Annals of Surgery*, May, 1895) says that an essential defect in many operations which are performed for the cure of hernia is removal of the sac. He advises that for the radical cure of inguinal hernia the following operation should be adopted. An incision 3 to 4 in. long is made parallel to Poupart's ligament, over the inguinal canal, to the pubic spine. All structures between the internal and external abdominal rings and above the canal are divided. The sac is then dissected out, opened for inspection, and its neck loosened from its attachments. It is then several times transfixed in a proximal direction with a stitch which has been firmly secured to the distal end, so that when the proximal end is pulled on the sac is thrown into folds. Finally, the needle which carries the thread is passed through the abdominal wall, transfixing all the structures in front of the subperitoneal tissue, and emerging 1 inch above the internal abdominal ring. Before fastening the sac it is best to raise the spermatic cord and remove any supernumerary veins, or, if this is not requisite, to make a circular incision through the fascia of the cord. The suture which folds the sac is now pulled tightly, fastened to the external oblique muscle, and the sac adjusted in proper position. Next the fascia transversalis, from the pubic spine to the internal abdominal ring, is sutured with three or four inversion sutures. The inversion suture is inserted by piercing the deep fascia parallel to Poupart's ligament in two

places from without inward with the first bite of the needle. The needle is drawn through it, and the thread is carried across to the border of the conjoined tendon, where a similar bite is taken. The approximation of the muscular aponeuroses is then done with three or four mattress sutures from below upwards, in such a manner as to bring the lower and external structures—Poupart's ligament, fibres of the external oblique, internal oblique, and transversalis muscles—over and in front of the internal and upper structures—the conjoined tendon, external oblique, and all beneath the cord. To complete the operation the cord is laid upon the external surface of the external oblique muscle and the skin sutured over it. The author recommends this method on anatomical and pathological grounds. He has used it only for one year, and hence sufficient time has not elapsed to enable him to speak of results. For the radical cure of femoral hernia the following operation is recommended: A skin incision is made parallel to Poupart's ligament, and half an inch above it. This allows the operator to reach the neck of the hernia with ease and accuracy; the scar will be out of reach of pressure or friction of the thigh, and it allows examination of the inguinal canal and rings. The sac is dissected from the surrounding structures and opened; if any omentum is found it is tied with interlocking sutures and cut away, and the raw surface of the stump covered with peritoneum before it is replaced in the abdomen. The sac is now folded upon itself, and fastened within the aperture of the crural canal. When the sac is sufficiently large to close the internal opening of the canal, suturing of the pubic fascia to Poupart's ligament, and placing the falciform process in the external opening of the canal by means of inversion sutures of strong chromic gut or silk, is sufficient. When the sac is small, the hernial opening large, and Poupart's ligament cannot with ease be approximated to the pectineal fascia, a periosteal flap may be utilised, or a flap of the pectineal fascia and muscle can be raised and stitched to form a buttress instead.

(71) Tuberculosis of the Submaxillary Gland.

AIEROLI (*Il Policlinico*, June 1st, 1895), relates the case of a man, aged 30, with negative family history, who for the last 18 months had suffered from a hard, painless, and more or less fixed swelling in the right submaxillary region. There was no history of syphilis and no lesion in the mouth. Ordinary means of treatment proving of no avail the tumour was incised; nothing came away but blood, and the wound healed by second intention. The skin over the tumour was normal. There was no enlargement of neighbouring glands. After 14 days vigorous iodomercurial treatment without improvement the tumour was excised, with good results afterwards. The growth was the size of a hen's egg, and presented the usual

appearance of tubercle in glandular structures. Bacilli (of tubercle) were found sparsely in the detritus about the tumour. The extreme rarity of submaxillary tuberculosis is perhaps due to the quality of the salivary secretions, particularly the submaxillary (containing, as it does, sulphur cyanide of potassium and other salts unfavourable to the growth of tubercle bacilli).

MIDWIFERY AND DISEASES OF WOMEN.

(72) Castration for Hysteria.

GILLES DE LA TOURETTE (*Archives de Gynec. et de Gyne.*, June, 1895) strongly opposes the practice of removing the ovaries for hysteria. The modern idea that the ovary is the seat of that neurosis is as silly and mischievous as the ancient theory that hysteria arose from the womb. Ovariotomy was odious and unscientific, but did not kill. 1872 was an evil year. Hegar and Battey both performed oophorectomy for hysterical dysmenorrhoea; Battey's case recovered. Hegar's patient dying "headed the long martyrology of hysterical patients condemned to castration and later to hysterectomy." Charcot especially condemns this unscientific and dangerous operation. He categorically denies the existence of a "genital hysteria;" he even declares that there is no such thing as hysteria, hysterio-epilepsy or epilepsy, "of menstrual origin." The catamenia are deranged as a result of the neurosis which they cannot cause. He has never seen a case where the operation could be justified. He has seen many where it had been performed, and the women remained hysterical as before. They had the extra worry caused by knowing that they had lost their ovaries which they could never get back again. Castration for hysteria in the female is as unjustifiable as it would be in the rare cases where hysteria with pain in the testes and scrotum exists in men.

(73) Ruptured Perineum: Restoration of Sphincter.

LE CONTE (*Amer. Journ. Obstet.*, June, 1895) has devised a new method to restore the sphincter ani in complete ruptures of the perineum, and to prevent the sutures being torn out by the action of that muscle, as often occurs. The two steps are the stretching of the sphincter muscle, so that it may be paralysed for a few days, and the uniting of the ends of the muscle with tendon suture. The sutures for repair of the rent in the rectum are not only introduced, but also tied first, to protect the bowel from further laceration during the next step, the stretching of the sphincter. The divided ends of that muscle are afterwards vivified. Two medium-sized catgut sutures are passed through each side of the muscle close to one raw end, and the threads are left long. The same is done close to the opposite end of the sphincter. Then the ends of the opposite threads

are tied together; this closes the sphincter. When the skin sutures are applied to the perineum, the most posterior is passed through the sphincter, so that, when tied, the muscle is held in position.

(70) Acardiac and the Twin Cord.

SCHILLER (*Zeit. f. Geburtshilfe u. Gynäk.*, vol. xxvii, No. 2, 1895) describes a case which throws some light on the disputed question about the relation of the cord of an acardiac "parasite" to the cord of the well-formed autoite. A woman gave birth to twins. One was a well-developed female child delivered after the escape of an unusual amount of liquor amnii. The pains ceased, and a swelling was detected. In about two hours they came on again. It was not till more than three hours later, when the attendants had become alarmed and puzzled, that the second twin was delivered. This twin was a shapeless, oval mass, 8½ inches long and 4 lbs. 6 ozs. in weight. It had a hairy scalp, a rudimentary mouth and blind pharynx, a vertebral column, sacrum and coccyx, and ribs. The sternum, shoulder, and pelvic bones, extremities, thoracic and abdominal viscera were absent. There was a rudimentary brain and a spinal cord. The insertion of the umbilical cord lay low down. The placenta was of fair proportions, the chorion single, the amnion double. There were two cords, and not a single umbilical cord dividing close to the bodies of the twins, as some believe to be the rule in cases like this, where the acardiac is of very low development. The autoite's cord was inserted close to the edge of placenta; at the point of insertion the parasite's umbilical vein opened into the autoite's vein, and the solitary umbilical artery of the parasite anastomosed with one of the umbilical arteries of the autoite. But after thus communicating, the two vessels of the parasite's cord ran on to the placenta, where they were found quite distinct from the vessels belonging to the autoite.

(71) Foetus Papyraceus and Anencephalous Monster with Hydrocephalus.

CURATULO (*Ann. di Obstet. e Ginec.*, May, 1895) describes an unusual abnormality in single ovum twins. In these cases double monstrosity is frequent, whilst still more frequently one twin is an acardiac, the other well developed, hydramnion being a common complication. In Curatulo's case, where the mother was 27 and in her fifth pregnancy, one twin was anencephalous and had a very short limbs. Its amniotic cavity contained a great excess of fluid. On the other hand, the second twin was a foetus papyraceus, in a very small amniotic cavity; its cord was short and slender, and was inserted into a distinctly atrophied part of the large placenta common to both twins.

(72) Retention of Urine in a Foetus.

DEVÉ (*Ann. de Gynéc. et d'Obstet.*, June, 1895) states that he found nearly seven pints of urine in the distended bladder

of an eight months foetus. Nearly 1 inch of the urethra was reduced to an impervious fibrous cord. The rectum ended in the bladder. The urine only contained 0.024 milligramme of urea to the litre. Porak relates a case of double hydronephrosis due to an incomplete valvular stricture of the membranous part of the urethra. In a case similar to Devé's, the urine was as deficient in urea. Hence the fetal kidneys probably eliminate nothing but water with chloride of sodium in the proportion which that salt holds to the blood. The true renal functions in intrauterine life are discharged by the placenta.

(73) Nephritis of Pregnancy.

GOSSMANN (*Münch. med. Woch.*, No. 26, 1895) does not find that this disease necessarily ends in chronic nephritis. He saw it recur in one patient during eight pregnancies, but she is still free from kidney symptoms when not pregnant. He finds that induction of labour by means of vaginal douches is perfectly simple, and in 2 cases this means alone proved sufficient. In one of them the child was saved and reared.

(74) Hemostasis in Vaginal Hysterectomy.

DELONX (*Lyon Méd.*, June 30th, 1895) adopts the following method of detaching the cervix, whereby the chances of hæmorrhage are reduced to a minimum. He avoids the complete circular cut into the mucous membrane. A semi-circular incision is made anteriorly and posteriorly. The ends of opposite incisions are not made to meet, so that the mucosa reflected on to the cervix in lateral fornices is not wounded. The bladder is then detached, and Douglas's pouch laid open; then the broad ligament is seized on each side between the blades of a long-handled forceps, which also grasps the mucous membrane. The uterus can then be detached. All blood vessels are already under perfect control.

THERAPEUTICS.

(75) The Serum Treatment of Malignant Growths.

RÉPIN (*Rev. le Chir.*, June, 1895) asserts that the observations of Lassar, Spronck, and Coley, amounting now to the number of 60, establish beyond doubt the remarkable fact that streptococcal toxin, when injected into any part of the body of an individual affected with a malignant growth, will excite in this growth a rapid degeneration which may extend even to necrosis, and ultimately lead in the most favourable cases to a radical cure. After a review of the cases of malignant disease treated by accidental and artificially produced erysipelas, attention is directed in the first place to the results obtained by the above mentioned observers, and afterwards to those of the author himself. These last though very imperfect are such, it is thought, as to justify further researches. The first case treated by the author was one of a large subcutaneous cystic sarcoma at the back of the

shoulder. During three weeks, injections of cultures of streptococci were made twice daily in different parts of body. At the end of this period the treatment was discontinued, although it had produced such changes in the tumour as seemed to justify further trials. At the end of the tenth day the tumour had sloughed, and was surrounded by a line of demarcation. Beyond this line, however, there were found growing sarcomatous cells. After the suspension of the injections, the tumour spread rapidly, and invaded the pleura. In 3 other cases treated in a similar manner there was a complete absence of any favourable results. In a woman suffering from secondary cancerous disease of the submaxillary glands, the injections excited lancinating pains in the tumours, but failed to produce any apparent modification. In another woman who was suffering from secondary sarcoma of the thigh, thirty intravenous injections failed to influence in any way the course of the disease. The fourth case was one of an enormous sarcoma of the thoracic wall of a man aged 40. Frequently repeated injections were made at different parts of the body and into the tumour itself, but without any result on the disease, which speedily proved fatal. Notwithstanding this frequent failure of any results on the tumours, and the decidedly bad effects of the treatment on the patients, consisting invariably in rapid emaciation and often in rigors and fever, the author is still hopeful as to the future of this method of dealing with malignant disease. The serum treatment, or, as it is called, toxitherapy, constitutes, in his opinion, a resource which is not to be despised in certain cases of tumour not amenable to operation. In such cases as, for instance, those of large lympho-sarcomata, injections of streptococcal toxin will, he thinks, produce at least temporary amelioration and retard growth, and if carried out with energy and perseverance, afford some chance of a radical cure.

(76) Mercurial Eruptions.

O. ROSENTHAL (*Berl. Klin. Woch.*, 1895, Nos. 23 and 24) first mentions folliculitis as occurring from the external use of mercury. The lesion consists in hard red nodules separated by normal or slightly reddened skin. These nodules may suppurate owing to secondary infection. An erythema and also eczema may result from the local action of mercury. Mercurial eczema may be papular, vesicular, or pustular; it may also be a moist eczema. In severe cases there may be a marked exfoliative dermatitis, of which the author relates a case in a patient, aged 21. The mercurial erythema may resemble the rash of measles or scarlet fever. Where it results from the local action of mercury it starts from the site of the injection. Sometimes even minute hæmorrhages may occur into the skin. An exudative form of erythema multiforme has been seen. The most serious mercurial eruption is that resembling pemphigus, of which the author relates a case.

Mercurial eruptions have a polymorphic character. The mucous membranes may be affected in the same way as the skin. Mercury administered by the mouth or by subcutaneous injection, etc., may give rise to these eruptions, but not so often as inunction does. The author mentions that under the use of inunction mercurial sores, mercurial eruptions, stomatitis, salivation, etc., have rather decreased in frequency than otherwise. Other symptoms of mercurial intoxication are rarely present along with the eruption. Besides idiosyncrasy, dose, the kind of preparation and the manner it is used may predispose to mercurial intoxication. According to the severity of the eruption, general symptoms such as depression, headache, fever, etc., may exist.

(21) Treatment of Snakebite by Calcium Chloride.

PHISALIX and BERTRAND, at the Académie des Sciences (*Sém. Méd.*, June 19th) report the results of experiments with chloride of calcium in cases of snakebite. Its therapeutic action is not, as thought by Calverley, due to formation of some substance neutralising the poison, nor to its entering the circulation and there destroying the poison as it would in a test tube, but depends simply on its local effect; it destroys the poison locally, and causes the tissues to slough, and so prevents absorption of the toxic material. Hence they conclude that the injections of calcium chloride must be made deeply at the actual spot where the fangs entered, and that they are useless if made in any other part.

(22) Ferratin.

MARFORI (*Archiv. Italiane de Biologie*, Tome xxii, Fasc. i., p. 62) gives the results of some new researches on the absorption of ferratin and its biological action. He says that the different conditions in which the mucous membrane of the intestine happens to be largely affects the quantity of ferratin that can be absorbed. In order that absorption may take place, before all things it is necessary that the preparation should not be decomposed in the gastro-intestinal canal, but the sulphuretted hydrogen, which is sometimes present in the intestine in large quantities, may attack the ferratin slowly, and bring about its decomposition. Researches on the absorption of this substance may, therefore, give very different quantitative results according to the greater or lesser intensity of the putrefactive processes going on in the intestine. The large amount of absorption (13.7 to 41.68 per cent.) that occurs after administration of saline purgatives Marfori attributes in part to the aseptic condition of the intestine, and in part to the fact that saline purgatives cause a desquamation of the upper layers of the intestinal epithelium, and therefore expose a thinner layer of young cells through which absorption more readily takes place. When the gastro-intestinal canal is in its normal condition the absorption of ferratin is much less, according to Schmiedeberg, but since the

latter's experiments render it impossible to distinguish between the iron of the ferratin and the iron introduced in the food, Marfori proceeded as follows: He administered to the animal a saline purgative, and fed it solely upon milk; the lower part of the intestine was also cleared by saline enemata. About a week later ferratin was given in repeated doses. The amount absorbed varied between 11 and 30 per cent. of the amount administered. With reference to the question whether ill-effects might not arise from long continued administration of the drug, Marfori found that it was impossible to poison animals by injecting large doses into the blood; nevertheless a man would need to take about 2½ lbs. of ferratin in the course of a month to produce a similar result, assuming as a basis for calculation experiments on dogs. Since he would actually, however, only receive about one-twentieth of that amount, there is no danger in continued administration of the drug, a statement confirmed by clinical experience.

(23) Trional in Internal Diseases.

SEITZER (*Wien. Klin. Woch.*, June 6th, 1895) reports the results obtained in Dräsche's clinic from the use of this drug. It was tried in a great number of cases (25 of which are given in detail), and a dose of 1 to 2 g. given in the early morning after several sleepless nights. Conclusions: (1) Trional is not only a hypnotic for different forms of psychoses, but acts equally well in lung (especially phthisis) and heart cases. (2) Sleep is induced quickly, and continues as a rule during the following night. (3) Some patients remained stupid with sleep even the whole of the next day, but as a rule the sleep resembled that of a normal person. (4) No bad effects on the circulation or respiration were observed in any case. (5) In isolated cases retching, and even vomiting, occurred on waking; this seemed to be due to idiosyncrasy. (6) The results were also excellent in insomnia due to intercostal neuralgia, rachialgia, sciatica, lightning pains of tabs, and even the pain of cancer. (7) The effects approached those of morphine more nearly than of any other hypnotic.

PATHOLOGY.

(24) Cholera Spirillum in Egg Medium.

DÖRIZ (*Zeitschr. für Hygien.*, June, 1895) records the results of experiments with the cholera spirillum in egg medium. Hüppe recommended this medium, thinking that grown thus the spirillum generated H₂S, and was anaerobic, and that the conditions of growth were thus more like those in the human intestine. It is shown, however, by one series of experiments that in fresh eggs, sterilised superficially with 1 y.l. perchloric, inoculation of cholera spirillum with due precautions produces a culture either pure or with admixture of foreign organisms, in the former case without, in the latter case with formation of H₂S. Occasion-

ally the foreign organisms cannot be demonstrated when H₂S is formed, probably owing to the small number present or to the cloudiness of the microscopic preparations in these cases. In a further series of eggs in which the outer layer of white is sterilised to a certain depth by exposure to boiling water, or to formalin, it is shown that by this means the formation of H₂S and also the presence of foreign organisms is diminished. This accords with the discovery of Abel and Draer that micro-organisms penetrate eggs if these are allowed to become dirty and especially if exposed to damp; and also disproves Hammerl's view that some cholera spirilla formed abundant H₂S while others formed little or none, for spirilla from the same source as his were used in these experiments. It is concluded that cholera spirillum in egg medium does not form H₂S recognisable by ordinary methods, and further that egg is a most unsuitable medium for pure culture of bacteria, as it is impossible to know beforehand whether the egg is sterile.

(25) So called "Gynaecomastia."

H. STIEHA (*Beilage z. Mün. Char.*, Band xiv, Heft i) gives the results of his histological examination of this condition of the male breast. He comes to the conclusion that the name "gynaecomastia" is only justified in regard to the outward appearance of the mamma in these cases. The name must not be taken to imply that the male breast in such cases has any real histological resemblance to the secreting female breast. According to Stieha, the condition depends chiefly on a hyperplasia of the connective tissue of the normal male breast. The connective tissue encroaches on the neighbouring fat; the fatty tissue and the glandular tissue, however, also both take a part in the hyperplasia. In the tubular ducts short processes or pouches can be made out, but this does not justify anyone in saying that the gland in these cases is scirrhous as in the secreting female mamma.

(26) Antiseptic Treatment of the Navel in the Newly-born.

SCHLIEP (*Therap. Monatshefte*, June, 1895) advocates antiseptic treatment of the stump of the umbilical cord after childbirth, instead of the usual dirty treatment commonly adopted. He mentions Schroder, who insisted on strict asepsis during and after treatment of the cord by means of antiseptic baths and treatment of the stump with dermatol, which hastened the process of mummification. By this means Schroder showed that many sources of infection were avoided, especially contamination by dirty bath water. Schliep advocates this treatment, but substitutes for dermatol a 2 per cent. solution of silver nitrate, applied twice daily by means of a brush. He states that the day after birth the stump begins to become dry and on the second day it has shrunk to a fifth of its normal size, and on the fourth day the treatment is complete.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(97) Angina Pectoris, Gouty Arthritis, and Diabetes.

FURSTIN, after relating in detail three cases, appends (*Berl. klin. Woch.*, June 24th, 1895) some remarks on the connection between these diseases. In two cases in which diabetes and gout occurred in fat individuals there were also anginal attacks. In one case gout preceded diabetes, but in the other the reverse was noted. Most often diabetes follows upon gout. Attacks of gout may alternate with the diabetic manifestations. Diabetes appears to be a more favourable disease in the gouty. In both cases the angina pectoris was the most troublesome complaint. The anginal manifestations occurred in the first case ten years after the first attack of gout, whereas in the other case the angina appeared at the same time as the diabetes, or even before it. Both cases were in the author's opinion genuine examples of angina pectoris. It is difficult to determine in these cases whether the angina was dependent on the diabetes or on the gout. In both diseases the anginal attacks may be of a functional character. In both his cases the author thinks that the angina depended on disease in the circulatory apparatus, as changes in the heart were noted in both cases, and probably coronary in one of them. A sharp distinction cannot be drawn between angina caused by anatomical changes and that due to functional causes. The author has observed cases in which such anginal attacks have existed during many years. The prognosis is, however, serious even if no change can be made out in the circulatory organs.

(98) Painful Temporary Paralysis in Children.

BRUNON (*Presse Méd.*, June 20th, 1895) discusses painful temporary paralysis occurring in young children. Out of 22 cases 2 had paralysis of the lower extremities, all others having the arm only involved. Out of 14 all but 1 were under 5 years old. In all there was an absolutely sudden onset, sometimes following the slightest traumatism; often no cause was observed. The paralysis is complete from the onset; amelioration is gradual. All passive movements are retained, all active movements are abolished, the arm hanging inert by the side. The child screams when the slightest examination is attempted. No anatomical lesion is found except occasional cracking of the joints. Recovery takes place in from 24 hours to a week. Most authors take the view that there are in such cases anatomical lesions such as subluxation, stretching or twisting of ligaments. Brunon believes with Chassaignac that in the cases in ques-

tion any idea of fracture, dislocation, or tearing of ligaments may be dismissed, as no deformity, oedymosis, or interrupted movement of joints can be found. A differential diagnosis is needed between this and the form of paralysis due to partial dislocation of the head of the radius, a pathognomonic sign of the latter being the impossibility of supination. In 17 cases of this nature 2 only held the arm hanging straight. In the 22 cases under consideration all hung limply by the side and could be freely flexed, pronated, or supinated. The initial lesion may be an injury to ligaments but examination fails to localise the injury. Pain is general from shoulder to finger tips. The condition appears to be due to a reflex inhibitory action, of which other examples are numerous and which affords a rational explanation of the paralysis. Mechanical, emotional, or psychological stimuli are known to produce such conditions. An intellectual factor, the memory of the initial pain, explains the persistent crying of the child, the fear of being touched. There is no pain when the child is not handled. Much depends on the influence of suggestion made by those in charge of the child. In one case in which Brunon was able to make a diagnosis before seeing the patient, he was able to manipulate the arm freely from behind a curtain, while on his attempting to do so openly the child at once began to scream. An analogous case is cited of a child who was not allowed to see his crushed finger for three weeks until the new nail began to grow. At the sight of it he cried as if in pain, and kept the finger extended, not attempting to use the hand for two days. The spontaneous cure of these cases as memory fades seems to corroborate the view advanced.

(99) Vascular Obstruction in Influenza.

CATHOMAS, of Eichhorst's clinic, refers (*Münch. med. Woch.*, July 2nd, 1895) to the circulatory lesions in influenza. As regards the venous system, thrombosis due to phlebitis has been noted. Four cases are quoted in which arterial embolism occurred. They were all fatal. The popliteal, femoral, brachial, and Sylvian arteries were respectively involved. Arterio-thrombosis has been known to occur in seven cases, excluding several others in which the Sylvian artery was involved. The author then relates the following case, occurring in a patient aged 64, in hospital for extensive eczema, and who developed influenza. The respiratory and circulatory organs appeared healthy. During the attack of influenza the patient was seized with difficulty of breathing, and later he had severe pain in the right arm. There was no pulse in the right radial artery, the axillary artery being obviously obstructed. The patient ultimately died. An adherent clot was found in the axillary artery. A clot was also found in the aorta where the innominate is given off. The heart was enlarged, but no clots were present in it. The case was one of arterio-throm-

bosis. In a second case referred to, a man, aged 40, was seized during convalescence from influenza with severe pain in both legs after an attack of coughing. Gangrene followed, and the patient subsequently died. Although there was no necropsy, the lesion was no doubt caused by an arterio-thrombosis. The author concludes that vascular obstruction may occur in influenza as in other infective diseases; that it may be due to embolism of arteries or veins; that arterio-thrombosis is a rare complication of influenza, and may begin suddenly like embolism, and that the differential diagnosis between embolism and thrombosis may be difficult.

(100) Subacute Suppurative Polyarthritis.

H. NEUMANN (*Deut. med. Woch.*, June 13th, 1895) records the following case. A boy, aged 9, developed, after diphtheria and measles, an otitis media. This was followed by a simple periphagus and purpuric patches over the left side of the body. Nephritis also supervened. Later there was painful swelling in the muscles of the left foot, left upper arm, left buttock, and left thigh, which ended at times in suppuration. The joints were unaffected except a passing inflammation in the left hip and knee-joints. There was profuse sweating. A streptococcus almost in pure culture was found in the pus. After three months' illness the patient made a complete recovery. Such cases are very rare, and they mostly terminate fatally. The starting-point of the infection was the throat. It was curious how the left side of the body was almost alone involved.

SURGERY.

(101) Recent Advances in Cerebral Surgery.

VON BERNHARDT (*Centralblatt für Chirurgie*, No. 27, 1895), at a recent Congress of the German Surgical Society held at Berlin, brought under notice certain advances that have been recently made in the department of cerebral surgery. In cases of tumour of the brain surgery has of late done very little beyond facilitating a correct diagnosis, and rendering operative interference less dangerous. In Jacksonian epilepsy surgical treatment is usually followed by relapse, and can effect a certain cure only in those cases in which the convulsions are due to the compression of a circumscribed cortical motor centre by a tumour, as for instance, a cyst of traumatic origin. On the other hand, very decided progress has been made in the operative treatment of different forms of intracranial suppuration of otitic origin, such as cerebral abscess, epidural suppuration, infective thrombosis of the lateral sinus, and leptomeningitis. The most dangerous forms of chronic aural suppuration, which is usually excited by a collection of cholesteatoma in the interior of the ear, are indicated by intercurrent acute and subacute attacks, with fetid discharge, and by the presence of polypoid granulations on the tympanic cavity and the

auditory meatus. The extension of the inflammation through the thin and carious tegmen tympani sets up pachymeningitis, which in its turn gives rise to an extradural or epitympanic abscess, or to an intradural cerebral abscess. The cerebral abscess, when small and in an early stage of development, is situated at the surface of the brain, but as it enlarges it sinks into the substance of the affected lobe. As the diagnosis between a superficial and epitympanic abscess on the one hand and a cerebral abscess on the other is attended with much difficulty, von Bergmann holds that it is necessary in performing an operation to expose to view both the extradural abscess and the part of the temporal lobe most likely to be involved in the extension of the suppurative process. An operation is described by which the upper and anterior surfaces of the petrosal bone are exposed through a quadrangular opening made in the squamous portion of the temporal bone, just above the line of the zygoma, and between a line in front drawn directly upwards to the sagittal suture from the tragus, and a parallel line behind carried upwards from the posterior border of the mastoid process. By this wound the mastoid antrum and cells may be opened if necessary, and the sigmoid fossa be reached. In conclusion Bergmann alludes to the successful results of the surgical treatment of infective thrombosis of the lateral sinus. Exposure and incision of the sinus, with ligation of the internal jugular vein, proved successful in 6 out of 13 cases treated by Jansen of Berlin. These cases, added to those of Macewen and other surgeons, show that the operative treatment resulted in recovery in 27 out of 45 patients. Thrombosis of the lateral sinus, it is pointed out, is often associated with extradural abscess on the roof of the tympanic cavity, and in most cases of cerebellar abscess forms a communication between this collection of pus and the suppurative in the middle ear. In exposing the outer surface of the mastoid process and the bone lying behind this, search should be made for the mastoid emissary vein. Not only is the orifice a good guide to the sinus, but in addition the state of the vessel may help the diagnosis. If it contains pus suppurative in and about the lateral sinus is indicated; if it be blocked by a thrombus this will be a sure sign of thrombosis extending to the cavernous sinus. Von Bergmann, attributing much of the recent progress in cerebral surgery to improvements in technical details and in instruments, makes use, in opening the skull, of a circular saw worked by electricity, with which he divides the outer table, whilst the inner table is divided by the careful application of a chisel.

(92) Dislocation of the Ulnar Nerve at the Elbow.

At the recent meeting of the American Surgical Association at New York (*Med. News*, June 15th), Henry R. Wharton, of Philadelphia, reported an instance of this injury which came under his own ob-

servation, together with thirteen others collected from medical literature. The condition is a comparatively rare one occurring independently of fractures or dislocations of the bones of the elbow, and may result from direct violence or from muscular effort or violent flexion of the arm at the elbow, causing laceration of the fascia that holds the nerve in its groove at the back of the inner condyle of the humerus. In two cases of dislocation of the ulnar nerve in dead subjects, the internal condyle of the humerus was found small, and the groove for the nerve shallow, and the fascia binding down the nerve very poorly developed; an unusual forward position of the internal lateral ligament was also noted. The most satisfactory method of securing the nerve consists in exposing it, and, a bed having been made for the nerve by dividing the fibrous structures behind the inner condyle of the humerus, fixing it in its usual position by two kangaroo tendon loops passed through the inner margin of the triceps tendon and somewhat loosely around the nerve, several sutures being used to unite the divided margin of the fascial expansion of the triceps tendon superficial to the nerve. In all cases in which the nerve has been exposed and sutured in its normal position the result has been satisfactory. In no recorded case has neuritis developed as a result of operative treatment.

(93) Gonorrhoeal Cystitis Cured by Influenza.

GOLDBERG (*Centralbl. f. inn. Med.*, June 20th, 1895) observes that influenza has occasionally been known to produce a cystitis. He reports a case in which a man, aged 22, was suddenly and completely cured of a chronic gonorrhoeal cystitis by an attack of influenza. The patient was first seen by the author six months after the onset of the gonorrhoea. The urine then contained pus, a small quantity of albumen, but no casts or other formed renal elements. The bladder was tender on palpation. The cystoscope showed the bladder walls to be of a dark-greyish colour with prominent muscular fasciculi. Washing out the bladder only produced some slight improvement, the urine still remaining turbid. In an attack of influenza the urine rapidly became clear, and ceased to contain either pus or albumen. The subjective symptoms also disappeared. There could be no doubt of the causal connection between the influenza and the cure of the cystitis, which had already lasted 1½ year. Possibly the toxins of influenza had so impaired the vitality of the micro-organisms setting up the cystitis, as to render their further development impossible.

(94) The Operative Treatment of Spinal Caries.

CALOT (*Revue d'Orthopédie*, July, 1895) holds that in the present state of science it is unjustifiable to operate in cases of paralysis due to Pott's disease of the spine. Most of these cases, he asserts, will recover if treated by prolonged rest. Of 20 cases treated by the

author in the course of the past four years by rest and immobilisation, 19 are either quite cured or on the way to complete cure, 1 only having succumbed in consequence of the rupture of a large psoas abscess into the bladder. Operative treatment in Pott's disease is contraindicated by the seat and extent of the lesions; by the nature of the tuberculous process; and above all by the risks attending surgical interference. It is stated that in 50 per cent. of the recorded cases thus treated death has been due directly to the operation, and there is reason to believe that this mortality really amounts to between 60 and 80 per cent. The author concludes that the operative treatment which is so fatal or useless in a large majority of cases does not afford in the few successful cases better results than those obtained by a strictly orthopaedic treatment. A serious operation which might be regarded as justifiable in inevitably fatal diseases such as tuberculous meningitis, hydrocephalus, and gastric and intestinal cancer, ought not to be practised in the treatment of an affection which needs only time and patience to ensure recovery.

MIDWIFERY AND DISEASES OF WOMEN.

(95) Intrauterine Infection with the Typhoid Bacillus.

FERUND AND LEVY (*Berl. klin. Woch.*, June 14th, 1895) relate the following case: A woman, aged 24, fell ill with enteric fever in the fifth month of her third pregnancy. In the fourth week of the disease abortion occurred. This had no ill-effect on the course of the disease, and the patient made a good recovery after a relapse. The foetus died as soon as the cord was divided. The bacteriological examination was commenced twenty minutes after birth. Tubes were inoculated from the spleen and the placental blood, and in three days' time colonies were developed. The micro-organism was proved bacteriologically to be the typhoid bacillus. It yielded all the characteristic distinctions from the *B. coli communis*. The case shows that the typhoid bacillus can pass over from the mother to the foetus. Every precaution was taken to render the genital passages free of micro-organisms. The number of typhoid bacilli present was small, and perhaps this will account for the negative results obtained in some cases. Nothing abnormal was found in the foetus except an enlarged spleen. Careful examination of the placenta revealed no lesion. Thus no cause could be found in the foetus or placenta for the interruption of pregnancy. Abortion took place at a time when the most severe pyrexia was over. There was no evidence of recent endometritis, as has been urged by some authorities, although some thickening of the decidua indicated the presence of an endometritis before conception. It is most probable that some lesion of the placenta is the direct cause of the passing over of the bacilli from the

mother to the foetus, although none could be found here. The typhoid bacillus, after once passing over to the foetus, caused a septicemic disease. It was a blood infection, as is occasionally seen in the adult without intestinal lesions.

(96) Artificial Abortion.

GARRIGUES (*Amer. Gynec. and Obstet. Journ.*, June, 1895) believes that the conditions which justify artificial abortion apart from acute diseases are especially serious pulmonary tuberculosis, severe valvular heart disease, aortic aneurysm, carcinoma not amenable to radical treatment, chronic nephritis, severe affections of the nerve centres, and present or threatened insanity. Abortion offers two dangers—hemorrhage and septicemia. The evacuation of the uterus should be conducted, under anæsthetics, with every precaution. The cervix is dilated by means of conical hard rubber and expanding steel dilators until there is room enough at least for a curette, but if possible for a finger besides. The spongy endometrium should be removed thoroughly, as well as the fœtus and membranes. Garrigues scrapes as long as anything comes out. Before scraping the uterus is washed out with creolin, and afterwards a quart of a 1 per cent. solution of that drug is passed through the uterus by irrigation. Drainage is not needed during the first two months; the vagina need simply be plugged for a day. Later the uterus should be packed with iodoform gauze, gradually withdrawn daily so as to give the uterus a chance of contracting well before the last of the packing is removed from four to six days after the operation. After the end of the fourth month the measures used for induction of premature labour are indicated, especially dilatation of the cervix, introduction of a bougie, and packing of the cervical canal with iodoform gauze. No artificial abortion should be performed without a consultation report, signed by the consultants and kept by the operator.

(97) Treatment of Soft Sores in Females.

VON HENRY (*Monats. f. Geburt. u. Gynäk.*, June, 1895) has found that the treatment of soft chancre involves certain difficulties in women, especially if the disease be treated as in males, the patients taking no rest. Iodoform is so disagreeable that the patients often neglect to apply it according to prescription. Even when it or any similar therapeutic powder is dusted on the chancre, urine lodging between the labia after micturition and, above all, free vaginal discharges rapidly decompose the chemical agent, neutralising it the good which it can do and increasing any offensive property which it may possess. The best treatment is immediate cauterisation with phenol. The genitals must be well cleansed with sublimate first. The "sore" will then appear to be made up of numerous minute ulcers, but some separate ulcers are often to be found far off. Hence, the search for the full extent of the disease

must be conducted in a good light. Then each ulcer is touched with a concentrated solution of phenol (acid. carbol. liq. fact., P. G., almost the same as B. P.; see Squire's *Companion*, fifteenth edition). A small, thin piece of wood, made rough at the end, is the best instrument for the purpose. The edges of each sore must be well touched up. Dry wadding is placed over the eschars. Hip-baths and weak antiseptic injections and lotions are then prescribed. About five days after the first application the parts must be examined. As a rule the sores will be found healing. Of course any ulcer still active must be touched with the carbolic solution. If not too late, this treatment prevents the suppuration of inguinal glands without requiring enforced rest.

(98) Fracture of Humerus at Birth: Temporary Paralysis.

LOVIOU (*Annales de Gynec. et d'Obstet.*, June, 1895) relates a labour where the child's humerus was broken during delivery of the shoulders. A plaster splint was immediately applied. A few days later much callus had developed, and the arm soon became paralysed. After a few more days the callus diminished, and the member resumed its functions. Loviou attributes the paralysis to compression of the musculospiral nerve by the callus. Budin, in a discussion on this case, expressed a suspicion that the loss of power was due to pressure from the plaster-of-paris bandage. Charpentier stated that the paralysed muscles become atrophied as a rule; hence this case had an unusually favourable termination.

(99) The gases in Women's Milk.

KÜTZ (*Zeitschrift f. Biologie*, Vol. xxxii, part 2, 1895) has analysed human milk, and in so doing has taken every precaution to prevent the entrance of air from without before making the analysis. Hoppe-Seyler in 1839 made out the proportions of the most abundant gases as follows: oxygen 0.16 per cent., carbonic acid 1.88 per cent., and nitrogen 1.38 per cent. More recent authorities give conflicting evidence. Selschenow and Pilger found carbonic acid in much larger proportion (8 or 7 per cent.). As the result of careful analysis of five samples from three women, Dr. Kütz has arrived at very uniform proportions, in fact, roughly speaking, the gases stand at: oxygen 1.5 per cent., carbonic acid 2.5 per cent., and nitrogen 3.5 per cent. In all five samples the gases kept the same figures as above indicated, with but slight variation in decimals.

THERAPEUTICS.

(100) Uric Acid and its Salts.

MARSHALL (*Ther. med. Week.*, May 2nd, 1895) discusses the solubility of uric acid in gouty deposits and in concretions. The solubility depends on (1) the amount to be dissolved, (2) the reaction of the medium, (3) the presence

of other bodies. This last point has hitherto received but little attention. Non-poisonous bodies capable of dissolving uric acid in the resort are also expected to dissolve it in the body, whether in the case of the blood or of the urine. The author has shown that even in the reagent glass these bodies lose their solvent action when urine is present. Uricidin does not dissolve uric acid, and yet it gives to uric acid dissolving properties. Lysidin is an extraordinary solvent for uric acid, but it loses these properties if urine is present. Thus bodies exist in the urine which by their presence alone annul the dissolving powers of lysidin, etc. It would appear that the extensive use of these agents is not only useless but may even be harmful. The author has searched for the bodies which hinder this solvent action. Neither the urinary pigment nor urea has any such action. The earthy phosphates were precipitated and filtered off. The clear fluid was then evaporated to dryness, and the residue ignited. Then it was found that the residue when dissolved had the same hindering action on the solvent powers of lysidin, etc., as the urine itself. The most important among these bodies in the residue is sodium chloride. A few granules of common salt exercise a similar hindering action. Lysidin and piperazin when not chemically pure have far less solvent action on uric acid, and impure uric acid is also much less easily dissolved. If lysidin or piperazin be added to blood serum, the resulting fluid dissolves uric acid nearly as readily as an aqueous solution of these agents. If saline solution or even a granule of common salt is added, the solvent action is lost. In the blood the salts amount to only 0.85 per cent., whereas 16 to 17 g. of sodium chloride is excreted daily. Hence the difference between blood and urine. Thus uric acid is dissolved in the urine in a complicated and as yet ill-understood fashion. Certain mineral waters have the power of dissolving out uric acid within the urinary apparatus or in the urine, but the mode of action is not understood. The important point is not to study the properties of uric acid apart from its surroundings; the characters of the media in which the uric acid is dissolved must be investigated.

(101) Organotherapeutics.

COMBE (*Res. Med. de la Suisse Rom.*, May 20th, 1895), divides the glands with an internal secretion (that is, into the blood) into two groups. The first includes those whose active principles neutralise or render inert or even useful the toxic elements circulating in the organism ("antitoxic glands," including the liver, pancreas, and thyroid for certain, and probably the thymus, pituitary body, suprarenal capsules, and perhaps even the kidneys). The second includes the glands secreting a substance useful or perhaps necessary for the normal functions of the organism ("vivifying glands," the spleen, testicle, and bone marrow). (1) Antitoxic glands. (A) The

Pancreas: This is an extero-internal gland, external as regards the secretion into the intestine and internal as regards the substances discharged directly into the blood. The active principle of this internal secretion is a glycolytic ferment, whose function is to render inert or useful the circulating glycogen. Combe had treated one case of diabetes of eight years' duration with sandwiches of pancreas, and the sugar disappeared from the urine completely, but the case was afterwards lost sight of. (v) The Thyroid (1). Thyroid and Myxodema: This gland plays the same part with the toxic products of digestion of albumins as the pancreas with those of hydrocarbons. The author treated two cases of congenital myxodema, aged 2 and 4 years respectively, while previously reported cases have been 15, 20, or even 30 years old; both mothers had had a severe attack of influenza during gestation, and both children were born at ten months, without a thyroid. One was myxodematous at birth, while in the other myxodema developed at eight months (? time when thymus atrophied). The symptoms were a myxodematous facies together with macroglossia, a short neck with pseudolipomata, prominent abdomen, and limbs large, deformed, and pachydermatous. The idiocy was absolute, and they had no idea of taking nourishment (*Pflanzen-menschen* of Eschsch.). The bodily development was much retarded, the one 2 years old being only 68 cm. long, the other 4 years old only 69 cm. No teeth were present in either. With 3 g. of thyroid, at first given *per anum*, later *per os* (four days of treatment alternating with a like period without), all the symptoms disappeared. After 2 months one child was rather backward for its age, but very intelligent. The child, aged 4 years, after thirteen months of treatment, had grown 20 cm., had all its teeth, and could walk alone; the one aged 2 years had grown 11 cm., had all its teeth, and could walk if led by the hand. (2) Thyroid and Uric Acid Diathesis. Combe has treated gout in the acute stage and other chronic cases with thyroid with very good results, the excretion of urea and uric acid being markedly increased. II. Vivifying Glands: Of 70 reported cases of infantile pseudo-leukemic anemia, 68 died. Of the author's 8 cases, 6 died before the new treatment came in, the other 2 were treated with bone marrow. Of these, 1 was quite cured, the other nearly. He therefore thinks bone marrow worth trying in other blood diseases (leukemia, chlorosis, etc.).

(102) Argentamine in Gonorrhoea.

ALBERTAZZI (*Gazz. degli Osped.*, July 16th, 1895) has been using argentamine, which is a phosphate of silver dissolved in ethylenediamine, in the treatment of gonorrhoea. In 1 in 4,000 to 1 in 2,000 solutions it makes a good urethral injection, and, as it does not coagulate the albumen in contact with the urethral mucosa, it is able to reach the gonococci hidden in the intercellular spaces

of the epithelial stratum. The author has had only one negative result in 50 cases, and in that case the patient was unwilling to forego bicycling, sexual intercourse, or alcohol during the treatment. Solutions of 1 in 4,000 sterilise pure cultures of gonococcus after five to seven minutes' contact. Injections of 1 in 1,000 are borne without appreciable pain. The secretion increases after the first few injections, but then diminishes progressively and rapidly. Usually after five or six days an improvement in the character of the discharge takes place. The period of treatment varies from seven to fifteen days. These injections may be used at any period of the disease, even in the early acute stages.

PATHOLOGY.

(103) The Influence of Fever and Leucocytosis upon the Course of Infective Diseases.

LOEWY AND RICHTER (*Deut. med. Woch.*, 1895, No. 15) investigated the effect of an increase of temperature produced in animals by puncture of the brain (Sachs-Aronsohn's method) upon the course of chicken-cholera, pneumonia, and diphtheria. The animals' temperatures were in this way raised for several days up to or even above 42° C. They found that the animals under these circumstances withstood two to three times the usually fatal dose of the various bacteria mentioned, but that with 100 times the fatal dose the warmed animals died sooner than their controls. The best results were obtained with the pneumococcus, which can be definitely attenuated outside the animal body by growing at 42° C. For the investigation of the effect of leucocytosis pilocarpin was first of all used, but later, on account of the disturbing poisonous effects of this drug, spermin was used. Intravenous injection prevented the fatal effect of three to four times the usually fatal dose of pneumococcus when the micro-organism was injected later than the spermin, but cure did not occur if the spermin was injected twenty-four hours after the pneumococcus; death was under these circumstances only postponed. The authors conclude that the organism has in leucocytosis and in fever protective mechanisms against infection.

(104) The Cholera Bacillus in New Milk.

The question of the bactericide properties of new milk affirmed by Weigmann and Hesse has been submitted by Basenau to a new series of investigations in the laboratory of the University of Amsterdam. His results (*Weekblad van het Nederlandsch Tijdschrift voor Geneeskunde*, May 18th) point to an opposite conclusion. Hesse had experimented on agar-agar only; Basenau made his tests according to the method of Koch, using the most favourable medium for the cultivation of the cholera bacillus. After thirty-one hours the micro-organism had multiplied from twelve to thirty-five times; after thirty-two hours they had multiplied five

times at chamber temperature; and twenty times at 24° C. The sanitary importance of these experiments becomes evident when it is remembered that Hesse recommends new milk as a prophylactic and curative in times of cholera epidemic.

(105) Death in Burns.

SILBERMANN (*Centralbl. f. inn. Med.*, May 18th, 1895) first refers to the various theories of interference with cutaneous perspiration, of the entrance of fibrin ferment into the blood current, of the absorption of muscular-like toxins, etc. Reflex vascular paralysis, with secondary cardiac paralysis, is believed by some to be the cause of death. The most commonly accepted view would attribute death to the severe damage done to the red blood cells. These changes consist in swelling, division, fragmentation, dissolving out of pigment, and other profound morphological alterations. Vascular obstruction and its results thus ensue. A limitation of the functions of the red cells is caused by the heat. Proof has been given by the author and others that the damage done to the blood discs leads to their adhesion to blood plates and to the formation of numerous thromboses. The author has shown that the red cells in those burnt have a much diminished resistance. Experimentally he has proved that the congestion in organs is not uniformly distributed; that hemorrhages occur in the lungs, kidneys, etc., and very often there is necrosis and fatty degeneration of cells. These parenchymatous changes are due to circulatory disturbances—stasis, thrombosis, thrombo-embolism. They were most common in the lungs, kidneys, liver, and rare in the brain. The dyspnoea, cyanosis, anuria, vomiting, etc., and especially the rapid fall in blood pressure, may be explained by the obstruction of vessels. Pulmonary lesions are frequently found in death from burns. The nephritis sometimes observed is also due to circulatory disturbances.

(106) Rapid Staining.

CULLEN (*Centr. f. allg. Path. u. path. Anat.*, 1895, Bd. vi, No. 11, p. 448) describes a rapid method for staining fresh tissues after hardening with formalin. Sections can be stained in the post-mortem room within fifteen minutes of removal of the tissue from the body. The fresh material is frozen, and sections are cut and placed in 50 per cent. watery solution of formalin for five minutes, thence into 50 per cent. alcohol (three minutes), absolute alcohol (one minute), and washed in water; they may then be stained and mounted in the usual way. Another method by which better results are obtained takes two hours and a quart. r. In it the fresh material is soaked in a 10 per cent. watery solution of formalin for two hours, and then frozen, cut, and placed in 50 per cent. alcohol. The later procedure is as in the previous method. The pieces of tissue in the second method must not be greater than 2 millimetres in thickness.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(187) Glioma of the Left Frontal Lobe.

OMER (*Il Policlinico*, June 15th, 1895) reports the case of a woman, aged 35, who first began to suffer from left frontal headache, nausea, and vomiting in 1887. The pain lasted some hours and kept her in bed. In 1889 she suffered from convulsive attacks coming on chiefly at night, setting in with sudden unconsciousness and without any aura. The convulsions were general in type, the head and eyes generally turned to the right. In 1890 a relative improvement took place, but in 1891 the symptoms returned more severely, and she then complained of deficient sight; the memory and attention were also weakened. In the early months of 1892 she had right facial paralysis with hemiparesis of the right side, chiefly affecting the arm, the muscles of which were in a state of hypertonicity. The headache was more continuous and more diffuse. Almost complete anosmia and amaurosis. There was atrophy of the optic disc. Hearing and taste normal. Voice and phonation unaltered, but amnesic aphasia and paraphasia were present. There was no history of syphilis, cancer, or tubercle. The patient was operated on in September, 1893, and a large glioma found in the region of the second left frontal convolution. The growth was removed at a second operation eight days after the first. For some time the patient seemed relieved by the removal, but had a good deal of trouble from an extensive cerebral hernia. She left the hospital in March, 1894, and died in November of the same year with abscess in the site of the operation.

(188) Influenzal Encephalitis.

NAUWERCK (*Deut. med. Woch.*, June 20th, 1895), observes that recent epidemics of influenza have shown that an acute non-suppurative encephalitis may be among the manifestations of influenza. He records two cases in which the brain was examined for the influenza bacillus (Pfeiffer): (1) A girl, aged 14, was seized a few days after an attack of influenza with cerebral symptoms, and died at the end of a week. In the longitudinal sinus there was an adherent clot. A large number of well-defined foci of softening were present in the brain, and in the neighbourhood of these foci the pial veins were filled with firm clot. The ventricles contained a small quantity of fluid. The bacteriological examination was negative. (2) A girl, aged 19, was seized during an epidemic of influenza with headache and vomiting. She rapidly became unconscious, and died in a few days. The ventricles contained a large quantity of slightly turbid fluid. In the right cere-

bellar hemisphere there was an apoplectic focus of the size of a walnut. The brain substance about it was beset with minute hemorrhages. The lesion also extended into the left hemisphere. The cavities of the ear and nose were healthy. Tubes were inoculated especially from the fluid in the ventricles, and Pfeiffer's bacillus was discovered. The same microorganism was also found in some centrifugalised cerebrospinal fluid, as well as in sections from the diseased focus above named. According to present knowledge this influential encephalitis might be caused by: (1) the absorption of toxins from the pulmonary lesions; (2) a mixed infection; and (3) the local action of the influenza bacillus. There were no streptococci, staphylococci, or pneumococci present, whereas the influenza bacillus was found in the lesion. The author thinks, however, that the above-named cocci may at times play an important part in producing the encephalitis. Examination of the fluid obtained by Quincke's puncture may give important information. Clinicians have thought that this encephalitis is due to capillary embolic lesions. The blood in these cases is mostly free from the bacilli. Thus the author shows by this case that the brain may be rapidly and fatally infected with the influenza bacillus. The disease in this case was unaccompanied by fever. The involvement of the cerebellum in this case explained the occipital headache, stumbling gait, etc. The effusion into the ventricles was inflammatory in character.

(189) Athetoid Attitude in Friedreich's Disease.

LONGE and LAGRANGE (*Annales de Méd.*, March 7th, 1895) report cases of Friedreich's disease in two sisters aged respectively 15 and 16. In both sisters the titubating gait and absence of knee-jerks are characteristic of the disease, but the sphincters, pupils, general and special sensation are unaffected; the nystagmus, moreover, is not at all marked. Their first symptoms were noticed at the age of 6 or 7, before which time they are said to have been well formed and to have had normal intelligence: they were not backward in learning to walk. The first symptom was apparently a choreiform inco-ordination, which was mistaken for true chorea minor. At the age of 8 disturbance in their gait was remarked, and their intelligence suffered later on, that of the eldest sister being now the more feeble. They have three brothers, younger than themselves, who are quite healthy. The chief point of interest in the two sisters is the "athetoid" attitude which they assume when they walk. When they walk their heads are bent forwards, and there is dorso-lumbar lordosis; their forearms are pronated and their wrists flexed, so that the back of the hand faces the ground. The attitude is rendered more striking by emotion. There is no true athetosis; the attitude is an "intention attitude" (only occur-

ring on voluntary movements, and is not so marked as to suggest that it is a phenomenon independent of the Friedreich's disease.

(190) Scleroderma.

FRIEDRICH (*Munch. med. Woch.*, May 7th, 1895) relates a case of extensive scleroderma in a girl aged 21. The diagnosis was made certain by the sclerosis, atrophy, and pigmentation of the skin and by the absence of sensory disturbances. A case related by Kaposi and Singer, in which a partial atrophy of the thyroid gland was present and the smallness of the same gland in his patient led the author to try the thyroid treatment. No beneficial action was noted, and the treatment had to be discontinued owing to headache, sleeplessness. Improvement was obtained by massage. The case was complicated by cutaneous hemorrhages, a very uncommon event in scleroderma. That the disease is a tropho-neurosis is supported by the disturbance in secretion and the muscular atrophy (such as facial hemiatrophy) sometimes seen. Scleroderma affects women more than men and is uncommon under 20 years of age. Sensation to temperature and touch was unaffected in this case, but there was slight hyperæsthesia to the electric current. As regards treatment, massage properly applied along with numerous baths and lubrication of the skin has given the author the best results in these cases. The improvement has fallen short of cure. The palliative action of electrical treatment is at times considerable.

SURGERY.

(191) Splenectomy for Splenic Hydatid.

HAHN (*Deut. med. Woch.*, July 11th, 1895) relates the following case. A woman, aged 35, noticed shortly after her confinement a swelling in the abdomen, which steadily increased in size. On admission the abdomen was distended, and a fluctuating and very freely movable tumour occupied the left side of it. The lower border of the tumour gave the impression of being the edge of the spleen. When the tumour was turned out of the abdomen by pressure on the loin, it appeared to be either a cystic sarcoma, a blood cyst, or a hydatid cyst involving the spleen. It was thought best for several reasons to remove it entirely, so the pedicle containing large vessel was ligatured in several parts and divided. Subsequent examination proved the tumour to be a hydatid. An examination of the blood (Kroenig) showed an increase in white cells at the time of the operation, a considerable diminution four days later, almost the normal relation in four weeks' time, and again a diminution four months after the operation. The patient made a good recovery. There was no enlargement of the thyroid or lymphatic glands while the patient was under observation. The frequency of splenic hydatid among all cases of hydatid disease varies from 0.7 to 3.4 per cent. 373

according to different observers. The author then discusses the best way of dealing with the disease, and short details are given of 7 cases treated by splenectomy; 5 of these recovered, and here either only a few or no adhesions were present. If there are extensive adhesions it is best to stitch the cyst to the abdominal wall and to incise it, and this may be done in one or two sittings. The author says that tapping either with or without aspiration must be avoided owing to the high mortality. In the author's case the thinness of the cyst wall might have led to rupture if it had been secured to the abdominal wall. In cases where the cyst wall is thin, or where there is atrophy of the spleen, great mobility of the tumour, and a long pedicle, splenectomy is by far the least dangerous procedure. However dangerous the removal of the spleen in diseased conditions (especially leukaemia) is, the operation of splenectomy for dislocation after injury, or for cyst formation as well as experimental pathology, show that the absence of a healthy spleen or of one atrophied by pressure is without any real disadvantage to the individual.

(112) Immediate Suture of the Gall Ducts and Gall Bladder after Extraction of Stones.

J. W. ELLIOTT, of Boston, read a paper on this subject at the recent meeting of the American Surgical Association at New York (*Med. News*, June 15th). He contended that the operations of cholecystotomy and cholecystenterostomy have become too much the routine practice for the relief of gall stones, and that incision of the ducts or the gall bladder, followed by immediate suture, is the proper operation in the majority of cases, especially in recent cases. He reported five such operations: one on the hepatic duct, one on the common duct, and three on the gall bladder. All were successful. The following conclusions were presented: (1) Every operation should be conducted with the idea of restoring the functions of the ducts, and any irreparable injury to them is a serious calamity. (2) Immediate closure of the gall bladder is safe if the ducts are clear and its walls healthy. (3) Incision and suture of the cystic duct are preferable to prolonged manipulation. (4) Incision and suture of the hepatic and common ducts constitute the operation to be chosen for impacted stones. (5) The mortality of this operation is less than 18 per cent. (6) If the condition of the patient is critical a preliminary cholecystotomy is advisable. (7) Cholecystenterostomy should be reserved for irreducible stenosis of the common duct.

(113) Nephropexy.

VULLIET (*Rev. Méd.*, No. 6, June, 1895) describes an operation undertaken by himself and his colleague Pouliet for fixing a floating kidney. The usual method of fixation by suture is unsatisfactory, owing to the friability of the kidney tissue. The operation reported substitutes a living tendon, which

firmly fixes the kidney in a position. The experiment was first tried on a large dog and proved satisfactory. A patient suffering from an extreme displacement and unable to walk or gain her living was chosen for the operation. An ordinary extraperitoneal incision was made to reach the kidney. A second incision, 8 centimetres in length and having its centre opposite the first lumbar spine, was made parallel with, and 2 centimetres external to, the dorsal spines. The teguments and dorsal aponeurosis were incised and the tendinous slips of the *dorsalis longus* found. The tendon which is inserted into the first lumbar was chosen, this being of about the proportions of a stout bootlace, and usually about 22 to 24 centimetres in length. This was raised by two fingers inserted beneath, and by traction stripped up to its insertion, near the shoulder, shreds of muscular tissue being left attached to its free end. A strong stylet was then passed through the muscles between the twelfth dorsal and first lumbar vertebrae into the abdominal cavity; the tendon threaded on this and drawn through. The kidney was then drawn out through the first incision and a stylet passed from below up beneath the capsule along the posterior border. The tendon was threaded through this and drawn downwards, reappearing at the lower part and leaving a free end 4 or 5 centimetres in length. This was passed outwards through the muscles of the abdominal walls and fixed with metal sutures in the wound, the tendon having described in its course the figure 8. The operation was extraperitoneal; there was hardly any hæmorrhage; no temperature, and hardly any pain. The wounds healed by first intention in eight days, and the patient was shortly afterwards discharged completely cured.

MIDWIFERY AND DISEASES OF WOMEN.

(114) Removal of Cancerous Ovary and Uterus with Resection of Bladder and Intestine.

KÜMMELL (*Deutsche med. Woch.*, July 4th, 1895) describes a piece of bold surgery which met with success. A woman, aged 49, was operated upon for ovarian and uterine tumour in the middle of May, 1894. A large myoma and a cancerous right ovary were discovered. The myoma was infected with cancer from the ovary, as was the bladder. The separation of the cancerous ovary from deep pelvic adhesions proved very difficult. Two inches of small intestine adhered to the ovary; as the serous and muscular coats only appeared infected with cancer they were dissected off, and the mucosa being tucked into the lumen, the defect in the outer coats was closed by two continuous sutures, as in circular resection of gut. Nearly one-third of the upper part of the bladder was resected, the wounded edges being closed with two rows of continuous catgut sutures. The pedicle of

the uterine myoma was treated extraperitoneally. A catheter was not retained. The patient recovered from this very severe operation much more quickly than was expected. The catheter was not required. At first there was very frequent micturition; at the end of a fortnight urine was passed quite naturally, and could be retained for long. Five months after operation the patient was in excellent health and had gained weight very perceptibly.

(115) Symphysiotomy in 1892-94.

ROBERT P. HARRIS (*Amer. Gynec. and Obstet. Journ.*, June, 1895), publishes statistics of interest in relation to symphysiotomy. In 1892, 85 cases were reported in thirteen countries, with the loss of 10 women and 24 children. Thirty-seven were French, 6 women and 3 children being lost; 12 German, with loss of 2 women and 4 children; 11 symphysiotomies were performed in Italy, where none of the mothers were lost and only 1 child died. In the United States and Austria there were 7 cases, with the loss of 2 children, and none of the women in each of those countries. In no other land were over 4 attempted. In 1893 the results in fifteen countries were as follows:

Countries.	Cases.	Women Died.	Children Lost.
Germany ...	37	1	8
United States ...	31	5	7
Austria ...	30	7	4
France ...	24	4	5
Russia ...	19	1	3
Italy ...	5	—	2
Belgium ...	2	—	—
Canada ...	2	—	—
Switzerland ...	1	—	—
Sweden ...	1	—	—
Roumania ...	1	—	—
England ...	1	—	—
Holland ...	1	—	—
Brazil ...	1	—	—
India ..	1	—	—
	148	18	29

(116) Pregnancy and Exophthalmic Goitre. SIGNIER (*Répertoire Universel d'Obstet. et de Gynec.*, June 25th, 1895) describes a case where exophthalmic goitre began with a pregnancy, the symptoms ameliorating after delivery. He believes that the pregnancy was really the cause of the enlargement of the thyroid gland. Possibly the diminution in its size after parturition depended on some temporary condition in connection with the puerperium. Even so simple a cause as the necessary rest may explain the favourable change which, after all, may not prove permanent.

(117) Involution of the Uterus after Labour.

BROWNE (*Virchow's Archiv.*, vol. cxli, Pt. 1, July, 1895) has prepared an important monograph on this subject, the result of experiments at the Boerhaave Laboratory, Leyden. He finds that the first cause of diminution in volume of the muscle cells is a discharge of glycogen from the hypertrophied muscular fibres; at the same

time the oedematous intermuscular connective tissue parts with much of its water through absorption. The glycogen is probably removed by the lymphatics after chemical decomposition. For the first few hours after delivery the above changes alone constitute involution. The muscular coats of the arteries, much compressed by the contractions of the uterus during labour, share in the loss of glycogen. At the end of the first day true fatty degeneration can be detected in the muscle cells. After a few days this well-known process alone finishes the involution of the uterus, no more glycogen being excreted.

(117) **Treatment of Myoma by Operation.** VON ERLACH (*Wiener klin. Woch.*, July 1st, 1895) has had very successful results in hysterectomy for myoma. Out of 69 operations, only 2 were lost, 1 dying of embolism and 1 of acute yellow atrophy of the liver. Five total extirpations by abdominal section and 4 by the vaginal operation all recovered. He greatly prefers the latter proceeding whenever practicable. The patient is left in a more favourable condition than when there is an abdominal caesarean; besides, with further experience this operation can no doubt be yet simplified. When the abdomen is opened total removal of the uterus is the ideal operation. When it offers special difficulties, or if the operator is not experienced, supravaginal amputation with retroperitoneal treatment of the stump is advisable. The extraperitoneal method should now be discarded or only practised in very exceptional cases.

(118) **Actinomycosis of Internal Organs and Peritoneum.**

CHOUX (*Arch. Gén. de Méd.*, June, 1895) believes in surgical interference, although the rare cases of actinomycosis of the Fallopian tubes and ovaries seem very unsuited, according to the well-known original clinical reports, for operation. Though Netter and Cart advocate therapeutic treatment by iodide of potassium, so successful in animals, Choux thinks that in abdominal actinomycosis the salt may be given for a short time, but, if its slow action is found to be outstripped by generalisation of the parasitic disease, laparotomy is called for.

(119) **Abnormal Termination of the Ureter in the Female.**

WÜLFER (*Prager med. Woch.*, No. 24, 1895) has written a valuable article on this condition. Five instances are recorded of the ureter opening into the urethra. In one of these the bladder was absent, yet the patient, aged 47, did not suffer from incontinence of urine; nor was this complication present in two other cases where the bladder existed, but retention and hydronephrosis were observed in another of the series. Lastly, incontinence of urine was observed in one case, but the patient was aged 14, an age when that affection is frequent without abnormali-

ties. The ureters were made to open into the bladder by a plastic operation. Six cases of congenital uretero-vaginal fistula are known, though in only 3 was the ureter absolutely patent. An operation to open the canal into the bladder was undertaken in all 3, but in 1 the desired communication could not be effected. In 10 cases the ureter opened into the vestibule; in 2 of these 10 the bladder was absent. When only one ureter opens in this manner the patient suffers from incontinence of urine and yet can pass a quantity from the bladder daily.

(120) **Abortion: Decidua Vera Intact.** GOTTSCHALK (*Centralbl. f. Gynäk.*, No. 25, 1895), showed at the May meeting of the Berlin Obstetrical Society a second month's ovum spontaneously delivered with the decidua vera intact. The abortion followed a prolonged railway journey. The membranes assumed the form of the uterine cavity, including the cervix. It could plainly be seen, however, on examining the decidua vera, that the membrane in question ceased inferiorly at the level of the internal os. Keilmann was in error when he made out that the vera lined the canal of the cervix. The vera in Gottschalk's case certainly assumed the form of the cervix, but that was owing to a hæmorrhage in the foetal membranes inferiorly, which caused them to bulge down as far as the os externum. The blood on clotting made a perfect cast of the cervical canal. The decidua vera, though shed entire, showed diffuse hæmorrhages all over its substance.

THERAPEUTICS.

(121) **The Treatment of Diabetes Mellitus.** ROBIN (*Bull. de l'Acad. de Méd.*, No. 23, 1895) describes in detail the medical treatment—"alternating treatment"—which he prescribes in diabetes. He believes that in this disease there is an increased activity of the chemical changes of general nutrition, and of the hepatic cells in particular, which is the result of increased activity of the nervous system. Hence he recommends drugs which diminish the activity of these general changes by acting primarily on the nervous system. The treatment is divided into three stages: (1) For four days a powder, containing about 15 grains of antipyrin and 8 grains of sodium bicarbonate, is given twice a day. In addition cod-liver oil is taken twice a day with the meals, and Seignette salt as a morning purgative. (2) At the end of four or five days the antipyrin is discontinued, and sulphate of quinine prescribed—about 8 grains in a cachet at the midday meal. This is taken for six days, then discontinued for four days, and afterwards taken again for six days. Before the morning and evening meals a cachet is recommended containing arseniate of soda, carbonate of lithium, and cod-liver oil. (3) After fifteen days these drugs are discontinued, and the author prescribes, for ten days, a pill containing opium, belladonna, and

valerian. The cod-liver oil is discontinued, and the patient is allowed to drink a weak solution of bicarbonate of soda (1 in 120). In the case of nervous women, or if there should be intolerance of the opium and belladonna pills, 15 grains of potassium bromide are given two or three times a day for eight days. In addition to the medical treatment the diet is regulated. On account of the loss of inorganic salts in diabetes (demineralisation) the author recommends the food to be well salted; to supply potassium salts he advises green vegetables, especially cabbage and endive, and also a weak solution of potassium tartrate to dilute the wine taken at meals; and to counteract the loss of phosphates of magnesium and calcium he prescribes glycerophosphates of lime and magnesia. He also recommends bouillon on account of the inorganic salts which it contains. If sugar is still present in the urine after the third stage of the medical treatment above mentioned the course is recommenced. After a second course, whether sugar has disappeared or not, the drugs are discontinued for one month. Robin has treated, by this alternating method, 100 cases of diabetes, in each of which the daily quantity of sugar excreted was 100 grammes or more. In 24 of these recovery has occurred; in 25 recovery is still doubtful; in 33 there has been considerable and permanent improvement; in 18 the results have been negative.

(122) **The Serum Treatment of Diphtheria.** EIGDI (*Suppl. al Policlin.*, May 25th 1895) reports the results of serum treatment in 20 cases of diphtheria. Nineteen out of the 20 were aged from 1 to 8 years; 1 was 28 years old. Nine had laryngeal diphtheria; in 11 the fauces were affected; 5 of these had nasal diphtheria also. Of the laryngeal cases 3 died, of the faucial 2, giving altogether a mortality of 25 per cent. This mortality would probably have been reduced but for the difficulty in procuring the serum in the earlier cases and in its tardy application. Bacteriological examination was made in every case. In 3 only was Loeffler's bacillus found alone; in the other cases it was always associated with other micro-organisms. In 4 of the cases Loeffler's bacillus was not found at all, but only streptococci and staphylococci. The author believes the serum treatment to be quite innocuous and prefers injecting the serum in one single dose into the veins. There was considerable variation in the power of the different serums used. After injection the author noticed almost constantly a lowering of the temperature, improvement in the pulse and respiration, and diminution in the albuminuria. A local improvement in the throat occurred even in the severe cases which died. The membrane softened and became detached, and was more easily washed off the parts. The author used no other treatment except simple washing of the throat with boiled or boracic water. Urticaria followed after injection.

tion in 2 cases, and once a milinary eruption over the whole body, coupled with high fever. Post-diphtheritic paralysis occurred once only. In the 9 laryngeal cases intubation was performed 5 times (with 3 deaths). Serum treatment by its local effects makes intubation easier, so that the author decidedly prefers this operation to tracheotomy.—Ricci (*Ital.*, April 29th) reports 10 cases of membranous croup treated with serum. Bacteriological examination was not made, but clinically the cases were diphtheritic. Cure rapidly followed treatment in all the cases except one in which the diphtheritic symptoms had set in after an attack of measles. Intubation was performed and Behring serum No. 2 injected; but high fever and great agitation set in, and the patient (aged 20 months) died in a convulsion eighteen hours after the injection. Intubation was performed in 6 out of the 10 cases and tracheotomy once. The cases are very briefly reported; no mention is made as to any urticaria or other results of injection. "Speedy cure" followed injection in all the 9 cases, so presumably no noticeable ill effects followed the use of the serum.—Morax (*Sém. Méd.*, May 8th, 1895) gives the statistics compiled by the health bureau of Canton Vaud. Eighty-five cases were submitted to this treatment with a mortality of 15.4 per cent. (15 per cent. in the cases treated in hospital, or only 10.5 per cent. if 1 case be deducted which was moribund when injected). In 1894, among 404 cases notified as diphtheria, the mortality was 37 per cent.; in 1893, 64 per cent.; while in hospital cases the mortality was 47 per cent. in 1893 and 33 per cent. in 1894.

123) Leguminous Alimentation in Diseases of Digestion and Nutrition.

BOVET (*Presse Méd.*, May 11th, 1895) refers to the apparent connection between richness in albumen, or the nitrogenous elements of plants, and organic phosphorus, these two seeming to run parallel. In the leguminosae they are found in greatest proportion. One consequence of the association of phosphates with albumen (vegetable), and the "diffusibility" of phosphoric acid, is that food of this character (leguminous) is very readily dissolved and digested in the alimentary canal, even in the absence of the usual ferments. The presence of a relatively large amount of potash salts in this food is also noted. In the laboratory of Professor Hayem a dog was fed for thirteen days on an exclusive diet of "legumine," a soup free from salt. The result was first a marked decrease in its weight, amounting to one tenth. An analysis of the gastric juice at the beginning and end of the experiment showed a marked increase in two most important values, namely, hydrochloric acid and chlorine. This may be interpreted as increased digestive power. A similar experiment on a patient, aged 42, suffering from chronic gastritis, slight dilatation, and loss of motor power of the stomach, weakness and emaciation, showed re-

sults altogether comparable to the above. At the beginning the gastric juice, although highly acid, was free from hydrochloric acid. At the end of two months the total acidity was not increased, while hydrochloric acid was present in almost normal amount. Digestion (previously slow and painful) no longer inconvenienced the patient. Neurasthenia was lessened, and she slept eight hours daily without awaking, something she had not done for a long time previously. In this case a certain addition of leguminous aliment was made to the otherwise unaltered ordinary diet. The author therefore considers leguminous food suitable and valuable as aliment in similar cases, and also in diabetes and obesity.

PATHOLOGY.

(124) The Epidemiological Conditions of Cholera.

METCHNIKOFF (*Ann. de l'Institut Pasteur*, 1894, p. 520), for the purpose of throwing light on the epidemiological conditions of cholera, so far as they do not directly depend for their explanation on the properties on the comma bacillus, investigated the conditions of Versailles, which he speaks of as immune from cholera, and St. Cloud, which is not immune to the same degree. In the water supply of both places cholera vibrios, or at any rate vibrios indistinguishable from those of cholera and capable of inducing diarrhoea in man, were found by Sanarelli. According to Metchnikoff, the cholera vibrio can grow freely in water, and be found in it undiminished in virulence several months after the end of an epidemic. But since the vibrio behaves in the same way in the water of places immune from cholera, local immunity against cholera cannot depend upon the fact that cholera vibrios cannot live in such immune places. Nor can the immunity depend upon the fact that by repeated small doses of the water the inhabitants have become immune, since the blood serum of persons living in immune places does not confer immunity upon guinea-pigs. From choleraic dejecta that had been preserved for several months colonies were obtained identical with those of the cholera vibrio, but differing in the respects that they grow only at temperatures beneath 30°C., gave no indol reaction, and were not pathogenic for animals. These organisms were sown on gelatine plates, but refused to grow. On leaving the plates exposed to the air a small number of other microbes fell upon them. The greater number of these had no apparent influence upon the vibrios, but by some sarcinae, and particularly by some yeasts, the growth of the vibrios was markedly affected, so that if the author wished to revivify a vibrio that would no longer grow he inoculated along with it one of several micro-organisms and obtained his object. Many micro-organisms act in the opposite way. Metchnikoff isolated from the contents of the stomach a sarcina,

a torula, and a non-liquefying bacillus, all of which favour the growth of the vibrio, while in the guinea pig's intestine he found others that hinder the growth. It follows, therefore, that the cholera vibrio is considerably modified by the micro-organisms which surround it. He concludes that immunity or susceptibility of man and other animals in the case of cholera largely depends upon the other microbes in the intestinal canal. By means of this fact the fundamental truth that Koch's comma bacillus is the specific cause of cholera can easily be reconciled with the information given by epidemiology.

(125) Immunisation against the Surgical Lesions due to the Bacterium *Coli* Commune.

SALVATI AND GARTANO (*Rif. Med.*, May 20th and 21st, 1895) have succeeded in preparing an antitoxic serum, injection of which into guinea-pigs and rabbits served to protect them against the lesions caused by the bacterium *coli* commune. A toxin prepared from a culture of the bacterium *coli* was injected hypodermically and intraperitoneally into guinea-pigs and rabbits. After each injection the animals showed fever, with depression of the general health; reaction most marked at the first injection; after a time they ceased to react, and were then proof against injections of bacterium *coli* cultures which sufficed to kill control animals. If the injections of toxin were continued after the period at which the animals ceased to react, they died from progressive marasmus, with atrophy of the internal organs. The authors also experimented with success on the effects of injecting contemporaneously the toxin and antitoxic serum. Although the animals had high fever, refused food, and lost weight, none died.

(126) Examination of Sputum for Tubercle Bacilli.

SPENGLER (*Deutsch. med. Woch.*, 1895, No. 15) describes a new method for the preparation of sputum which it is desired to investigate for the presence of tubercle bacilli. Equal volumes of sputum and of warm water rendered feebly alkaline with caustic soda are well mixed with 0.1 to 1.0 per cent. of trypsin and placed in the incubator. Putrefaction is prevented by the addition, two or three hours later, of a small quantity of crystalline carbolic acid. As soon as a deposit has formed the supernatant fluid is poured off, the deposit washed with fresh alkaline water, and again placed in the incubator. This process is repeated several times, and finally the sediment is collected upon a filter paper and dried somewhat. Portions are then stained in the usual way. As a rule in twelve to twenty-four hours so little sediment remains that only a few microscopic slides are needed. If the digestion of the sputum be not carried on for too long a time, the tubercle bacilli undergo no modification in their staining properties.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(121) Lumbar Puncture.

STADLMANN (*Berl. klin. Woch.*, July 25th, 1896) observes that although this procedure is generally easy, it may not be so in the case of restless and semi-conscious patients. In infectious meningitis the fluid drawn off should be clear, with tubercle bacilli in it, in suppurative meningitis turbid or purulent with pyogenic micro-organisms in it, and in cerebral abscess clear and without micro-organisms. Tubercle bacilli have not been found at times by some observers, although Lichtheim has never missed them. Clear fluid without micro-organisms may also exist in tumor cerebri, simple meningitis, epineuritis, and even suppurative meningitis. The difficulty of distinguishing at times between cerebral abscess and meningitis is well known. If pus is drawn off by lumbar puncture suppurative meningitis must be present. Sometimes the fluid has been turbid only, but this is thought by Lichtheim to be exceptional. The author then records a case of suppurative meningitis secondary to fracture of the base, where the fluid was turbid and blood stained. Too much importance must not be attached to blood-stained fluid. A case of fatal meningitis secondary to ear disease is also recorded. Here clear fluid was drawn off during life, and no tubercle bacilli or other micro-organisms could be found in it by cultivation or otherwise. The author thinks it doubtful whether a communication exists (at least in the pathological condition) between the subarachnoid space and the cavities of the ventricles. He suggests that the drawing off the fluid may lead to an extension of the infection to the cord. He would account for the patients unexplained pain after aspiration as well as the limited amount of fluid at times obtained by the closure of the communication between the ventricles and the subarachnoid space. The author emphasizes the importance of the positive and the unreliability of the negative evidence obtained by lumbar puncture.

(122) The Etiology of Articular Rheumatism.

CHVOSTEK (*Wien. klin. Wochenschrift*, June 27th, 1896) criticizes a communication by Singer (*ibid.*, June 23th, 1896), who found in the urine of 17 cases of articular rheumatism staphylococcus albus ten times, staphylococcus aureus once streptococcus three times, staphylococcus albus with streptococcus twice, and bacillus coli once. Their constant presence, the number of colonies, and the fact that the number of colonies became less or vanished as the clinical symptoms improved led him to look

upon these cocci as the exciting cause of the disease, and to conclude that articular rheumatism has no single exciting cause. Chvostek found, however, that the urine gave negative results in 9 out of 13 cases examined by him. In one diplococcus urem was found, in one (when urine was not drawn off by the catheter) staphylococcus albus, and in one a large coccus, probably from the urethra. The cause of these conflicting results was probably the methods employed, as Chvostek found cocci in 10 out of 18 healthy urines when it was not drawn off by the catheter. Kraus proved (*ibid.*, June 27th) that in various infective diseases bacteria may be present in the urine, which have no etiological relation to the disease, but yet disappear with it. Thus Singer was not justified in looking upon these bacteria as the exciting cause of rheumatism. Chvostek further examined the blood, urine, and synovial fluid in 12 cases of acute rheumatism simultaneously, and in a large number of cases the synovial fluid, together with some other organ—for example, the tonsils. In every case the results as regards the synovial fluid were negative unless the joint affection was due to sepsis or gonorrhea. That many observers have obtained positive results in cases of articular rheumatism is to be explained by: (1) cases of sepsis with metastatic joint changes not having been excluded; (2) many of these examinations being made post-mortem. The author found that in animals an immigration of bacteria into the joints took place very soon after death, and that they were often those normally present in the animal (intestinal, etc.). As regards the question whether bacteria in the blood can reach the joint during life experiments showed: (1) that the walls of blood vessels not evidently altered anatomically are permeable to bacteria; (2) the anatomical structure of the synovia and its vessels is an obstacle, and bacteria enter the joints considerably later than the kidneys through the renal vessels; (3) the exit of bacteria depends on (a) their kind—thus staphylococcus passes most readily, then streptococcus, and bacterium coli hardly at all; this is probably due to the virulence of the micro-organism for the animal, and also to certain tissues being more liable to certain bacilli than others. (b) Their virulence—thus virulent cultures of staphylococcus are found in the joint sooner than attenuated ones. In this connection the action of toxins must be considered. (c) Other factors chiefly nervous, thus cutting the nerves of vessels hastens the exit of bacteria. Conclusions: (1) The cases of articular rheumatism examined were not caused by direct bacterial invasion of the joint, but either by toxins produced directly by micro-organisms or by chemico-toxic substances (for example, intestinal); (2) that these substances act in a given case on the joints depends on many factors, such as the structure and exposed position of joints; (3) probably any micro-organism may excite the dis-

ease; (4) they may enter the body anywhere, but probably most frequently by the intestines or tonsils.

(123) Antioscopy of the Larynx.

KIRSTEIS, of Gerhardt's clinic (*Berl. klin. Woch.*, June 3rd, 1896), draws attention to the fact that by throwing back the head the angle between the axes of the oral cavity and trachea can be much widened out. When using Rosenheim's antioscope he found that by depressing the tongue he could see into the larynx. The following directions are given. The pharynx and posterior surface of the larynx are painted with 20 per cent. cocaine, and the patient having loosened his clothes, lies on a couch with the head overhanging, or sits in a chair with the head thrown well back. The antioscope is then introduced. This consists roughly of a tongue depressor carrying an electric lamp at the end. The antioscope is introduced with the left hand, and pushed forward without touching the posterior pharyngeal wall to a level with Santorini's cartilage, when the tongue is pressed strongly downwards, the teeth being used as a fulcrum. Tender teeth may give rise to difficulties. The electric lamp is not used. The parts of the larynx, especially the posterior part, can be seen with the greatest clarity. The trachea, esophagus, etc., can be used under the closest inspection. Tumours of the vocal cords or subglottic region can be more easily removed than by the ordinary intralaryngeal method. The mucous membrane of the trachea can be seen, and the author says that catheterisation of the bronchi would present no great difficulty. With his instrument the epiglottis is invisible, and the anterior commissure of the cords cannot be well seen. The author does not think that this new method will supersede the old one, but that it will enlarge our means of diagnosis and treatment.

SURGERY.

(124) Castration for Prostatic Hypertrophy.

KRENNER (*Berl. klin. Wochenschrift*, August, 1896), in a lecture on the operative treatment of enlarged prostate, reports 8 cases of this affection in which he performed double castration. The operation was followed by considerable relief in these cases, but one patient, aged 77, died from exhaustion after an interval of four weeks. In a review of his own cases, and those published by other surgeons, he states that in a large majority of instances of senile enlargement of the prostate Wharton's operation is certainly followed by a more or less rapid shrinking of the prostatic tissue. This result of double castration in most cases enables the patient to dispense with the use of the catheter, and to discharge urine spontaneously. The bladder trouble also, as much relieved, and the general condition is improved. In the selection of suitable cases attention should be paid to the condition of the vascular structure of the bladder.

If the detrusor muscle be paralysed to such an extent that the bladder cannot be completely emptied even by the use of a catheter, it would be useless to expect a restoration of normal function as a result of removal of the obstruction to the flow of urine. In two of the cases here recorded, however, good results in this respect were obtained in spite of considerable weakness of the detrusor. In many cases the diminished size of the prostate after double castration permits of the more ready introduction of a catheter, and thus wards off the dangers of retention. In the author's opinion, the treatment of hypertrophy by double castration compares favourably with other operative measures in being simpler in performance and less dangerous. It can be performed without subjecting the patient to the risk of general anaesthesia, and necessitates but a very short stay in bed, which with regard to old and enfeebled subjects is a very important point. The operation, it is stated, should be recommended only to those whose sufferings have attained a high degree, and can no longer be relieved by mere symptomatic treatment. The author met with no objection to the operation from any of his patients, all of whom were well satisfied with its results. The recorded instances of success are so numerous and striking that the author has been led to the conclusion that the surgeon is certainly justified in suitable cases of enlarged prostate in advising and performing this operation. Although a more extended series of observations is needed before a clear and absolute judgment can be formed on this new method, there can be no doubt, the author holds, that this procedure is a valuable addition to the operative means of dealing with advanced and grave forms of prostatic hypertrophy. The observations with regard to the influence of unilateral castration on the growth of the prostate are very contradictory, and further information is needed before any definite conclusion can be reached on this question.

(131) Excision of an Oesophageal Pouch.

S. J. MIXTER, of Boston, read a paper on this subject at the recent meeting of the American Surgical Association at New York (*Med. News*, June 15th). A woman, aged 50, had always had some difficulty in swallowing, which during four years had become aggravated. Oesophageal bougies were passed, previous to her admission to the hospital, but without marked improvement. Attempts were made to pass oesophageal bougies and probangs but without success, all being stopped about 8½ inches from the incisor teeth. Some regurgitation of food attended three attempts. It was found, however, that a bougie of any size that could be made to pass the obstruction by hugging the right side of the oesophagus went on without difficulty into the stomach without being grasped as by a stricture. After three weeks of treatment the woman was able to swallow slightly better; but after some time

she returned, having worn an oesophageal tube most of the time, and having been able to swallow only soft solids and liquids. The operation consisted of an incision 3 inches long, parallel to and in front of the sterno-mastoid. The omohyoid was divided, and the oesophagus reached in the usual manner. The bulb of a probang previously introduced could easily be felt, and on dissection the pouch in which it was situated was easily isolated. An incision was made into the sac, whence the finger could be passed without difficulty up into the pharynx, and, after hooking it over a sharp edge of mucous membrane, down into the oesophagus. The largest bougie (about ½ inch in diameter) could easily be passed into the stomach after the tip had been guided by the finger past the fold. The pouch, about the size of an egg, lay to the left and behind the oesophagus. Enough of the sac was removed to make the oesophagus a straight tube from the "spur" up, and the edges were united with interrupted catgut stitches. The external wound was closed with the exception of a small opening for drainage by means of a gauze wick. Recovery was perfect, and the patient had had no return of the trouble, being able to swallow any kind of food. The case is an example of the true oesophageal pouch, there being no constriction in the tube, and the obstruction to the passage of food being only the thin crescentic edge of the spur between the pouch and the oesophagus, which pressing against the opposite side of the oesophagus, acted as a valve.

(132) Intestinal Hemorrhage after Herniotomy.

FIKL (*Wiener klin. Wochenschrift*, June 27th, 1895) reports a case in which sixteen days after herniotomy for strangulated left inguinal hernia melæna occurred. The knuckle of the small intestine at the operation was of a deep red colour, and the constriction tight, but the peritoneum was still smooth and glossy, and the fluid in the sac clear. On the third day after operation scybala were removed from the rectum with a spoon, and on the following two days copious normal evacuations resulted from enemata and calomel. The treatment of the hæmorrhage was ice to the abdomen and ergotin internally, with the result that the stools were natural four days later. The cause was probably necrosis of a small piece of mucous membrane at the seat of constriction, which had existed three days before the operation. There were no gastric symptoms. Albert (*ibid.*, No. 22) regards such cases as very rare, but Fikl thinks they may be commoner than is generally supposed.

(133) Rose's Operation for Trigeminal Neuralgia.

ESKRIDGE AND ROGERS (*American Journal of the Medical Sciences*, July, 1895) report a case of neuralgia of the right trigeminal nerve of eight years' duration treated with success by excision of the three divisions at the Gasserian ganglion and partial destruction of the gland itself. The patient was a man, aged 45

years, on whom an operation was performed by Rogers in 1892 for partial excision of the right inferior dental nerve. This operation gave complete relief for a time, but four months later the suffering became so intense that the patient threatened to commit suicide. In May, 1893, Rogers again operated, and on this occasion the Gasserian ganglion was exposed by Rose's method. The operation proved to be a very difficult one. The manual labour of the first part was very trying, as there was considerable and continuous oozing of blood, and in dealing with the ganglion the operator had to trust to the tactile sensation of his fingers, as he was unable to see the deep-seated parts of the wound. The substance of the ganglion, it is stated, was completely dismembered by a sharp hook and other instruments. Although no antiseptics were used on the wound or on the dressings the recovery, though retarded, was very satisfactory. In August, 1894—about fifteen months after the operation—the patient had had no return of the pain. Eskridge, who examined the patient in September, 1893, found that he had gained several pounds in weight since the operation and was quite well. The first division of the trigeminal nerve, he found, had not been completely divided. Taste was absent in the right anterior portion of the tongue, whilst smell was present and equal on the two sides.

MIDWIFERY AND DISEASES OF WOMEN.

(134) The Protection of the Internal Organs in Gonorrhœa.

AUVARD (*Arch. de Toccol. et de Gynéc.*, June, 1895) strongly objects to the use of the curette in the course of acute gonorrhœa. Theoretically the practice seems justifiable, but experience has proved that it is one of the surest ways cause extension of the disease to the tubes and ovaries. After the use of the curette, a minute piece of infected glandular tissue may be left behind. The entire surface of the uterine cavity may be disinfected by and after the scraping, yet then the mucosa, which acts as a rampart against microbic infection, has been destroyed. The probable entrance of specific pus from the vagina, an accident difficult to avoid, sets up uterine gonorrhœa of a type worse than the first attack. The parametrium, under these circumstances, is very liable to be invaded through the open and damaged lymphatics. In order to prevent inflammation of the tubes and ovaries complete rest must be enforced. The great danger in gonorrhœal salpingitis is sterility, and as in married women the fact of infection is a source of great misery, the patient's mental annoyance is much aggravated by the subsequent complications which render her barren. In the early stage of gonorrhœa, the more timid our surgery the better for the patient. The uterine cavity is best left alone. The vagina and cervix should be swabbed with a 1 per

cent. solution of nitrate of silver once or twice a week, and a 1 in 1,000 solution of sublimate employed as an injection twice daily. In the early stage of inflammation of the appendages Auvar recommends ice. It should be broken in small pieces, mixed with a little salt, placed in an india-rubber bag, and applied to the tender hypogastrium or iliac fossa. A double layer of flannel should be laid on the skin to protect it from the ice. When the pain is less and the other symptoms mild, blisters will be sufficient. The patient must not get up till a day or two after all pain has passed off. Glycerine plugs must then be applied about three times weekly. By such methods, used in time, sterility and the need for removal of the tubes and ovaries may be averted.

(132) Cure of Uterine Disease by Vibrations.

BOURCAUT (*Ann. de Gynéc. et d'Obstét.*, June, 1895) would revolutionise uterine therapeutics by extending Brandt and Kelgren's principle of using manual vibrations to ensure absorption of inflammatory exudations. In the case of the uterus instruments are required. Lischbeck has already invented a good apparatus for producing vibrations by electric means. In the case of the uterus the vibrations must be rapid, very regular, and penetrating. The vibrations can be perfectly transmitted through the abdominal walls. Bourcart, acting on the knowledge of these facts, has contrived a portable dynamo, to which he fits on a vibrator, which he places with his right hand against the parietes. The uterus is pushed towards the parietes by the left forefinger passed into the vagina. In the same way the Fallopian tubes and ovaries may be pressed in the direction of the vibrator. Bourcart declares that subinvolution is particularly benefited by the vibration treatment. In metrorrhagia from fibroids it is equally useful; the tumour may even diminish in size under a course of this treatment. He treats endometritis by vibrations transmitted by means of a specially constructed stem, but he admits that further study of this new variety of uterine therapeutics is required.

(133) Vesicular Mole followed by Malignant Changes.

MARCHELAND (*Monatsh. f. Geburtshilfe u. Gynäk.*, June, 1895), tabulates 15 cases of deciduoma malignum, and no fewer than 12 of malignant growths following the development of vesicular mole. It appears that a case was noted as long ago as 1786, but the first ever recognised in our days was described in 1883 by Gattenplan, and 10 out of the 13 have been reported since the beginning of 1880. Eleven died less than two years after the vesicular mole was removed; in 1 there was no after-history beyond the sixth or seventh week when the uterus contained deposits. In the remaining case, the uterus was removed through the vagina. Three months later the patient was doing well. Marchand

gives reasons based on histological research why vesicular molar pregnancy should particularly predispose patients to malignant disease of this type. He is not at all certain as to the precise homology of malignant deciduoma as a tumour; it differs from cancer in many ways, though it is of epithelial origin. It may be taken as proved that this newly-discovered disease is well established, and seems to be growing more frequent.

(137) Spontaneous Rupture of the Non-Gravid Uterus.

MAINANT (*Wiener med. Presse*, June 9th, 1895) remarks that this accident is believed by many to be mythical. He has, however, observed two cases. In the first there was hematometra with extreme retroflexion; rupture occurred, abdominal section was performed, and the patient recovered. In the second case pyometra existed. The uterine walls gave way. The abdominal cavity was opened. This time the operation was also successful.

(138) Lactation Statistics.

WIDOW (*Centralblatt f. Gynäk.*, No. 20, 1895) has collected the following statistics at the Freiburg Maternity. Out of 525 women in childbirth only half could suckle thoroughly during the first two weeks. In 99 no milk at all was secreted. Imperfect nipples were noted in 49 cases, fissures in 46, and insufficient secretion of milk in 44. Only 33 suckled freely without any of the above-named unfavourable complications. Widow classifies breasts under three groups, the percentage in his series being: good breasts, 56 per cent.; medium, 21 per cent.; and bad, 11 per cent. The development of the nipple bore a direct relation to the value of the breast as a secretory organ.

THERAPEUTICS.

(139) Guaiacol as a Local Anesthetic.

LUCAS-CHAMPIONNIÈRE (*Bull. de l'Acad. de Méd.*, July 30th) reports the results of a trial of a new method of local anesthesia, which André, a pharmacist, of Paris, first successfully applied in his own person in the form of an ointment containing guaiacol for the relief of a very painful burn. Encouraged by this, he tried the same drug in the form of a hypodermic injection, using a sterilised solution of guaiacol in oil of sweet almonds; he afterwards, however, found olive oil a better diluent, being purer and more readily sterilised. Solutions of 1 in 10 and 1 in 20 are used, a syringe of the former strength containing 10, and of the latter 5, centigrammes of guaiacol. The method was first tried for the extraction of teeth, perfect analgesia being produced, while the sensation of contact and movement was left. Lucas-Championnière has himself tried the method for minor operations (removal of cysts of the scalp, etc.), with complete success. The injection was fol-

lowed by no unpleasant effect, except a small oedema of the gums after the earlier trials, probably due to a faulty technique and possibly also to some defect in the preparation of the solution. As a local anesthetic guaiacol is as powerful as cocaine, and it has the advantage over the latter that ten times larger doses can be given without ill consequence. The full effect does not manifest itself till five minutes after the injection, and in most cases it will be well to wait seven or eight minutes before proceeding to operate. It is probable that a smaller dose than 10 centigrammes will be found sufficient, and experiments to determine this point are in progress. In discussing the communication, Fernald bore witness to the value of the method, but he added that some caution was required in its employment. He had himself used it, not subcutaneously, but as an external application, in doses of 1 cubic centimetre, and by this means had been able to relieve persistent pain, notably the intercostal neuralgia of phthisical patients. In some of these cases, while the pain had ceased, the application had been followed by subnormal temperature and other symptoms of collapse, but without fatal result. Fernald said that the action of guaiacol was at present being studied by himself, Gilbert, Doyon, and others; it had been found to have a decided anesthetic and antipyretic effect when applied locally. The mechanism was a very marked vasoconstrictor action; this explained the local sphacelus noted by Lucas-Championnière, and should be borne in mind in the practical application of the method which he had described.

(140) Intravenous Injections of Mercuric Chloride in Syphilis.

WALTER L. FYLE of Washington, in a reprint from the *Philadelphia Medical News*, describes and discusses the use of intravenous injections of mercuric chloride introduced by Bacelli (*Gazz. Med. di Roma*, 1893, xix). The following is the composition of the fluid injected: B hydr. chlorid. 1 g., sodii chlorid. 3 g., aque 1,000 g. A small quantity of alcohol may be added to facilitate solution. The mixture should be well stirred and filtered until perfectly clear. It is advisable, but not necessary, to sterilise it, both to be perfectly aseptic and to facilitate solution. A ligature is applied above the elbow, and any one of the superficial veins in the neighbourhood may be selected as the point for injection. The point selected and the surrounding area are thoroughly scrubbed and disinfected with a 1 in 1000 solution of mercuric chloride or a 2 per cent. solution of carbolic acid. The needle, previously sterilised, is plunged directly toward the centre, at the point selected, and a few drops of blood allowed to come out, assuring entrance into the vein; the barrel is carefully applied, applying any entrance of air. Loosen the ligature and make the injection, at first using only 1 g. of the solution, and progressively increasing to 4 g. at a

dose. Repeated injections can be made in the same vein. The median cephalic vein and the median basilic are the best for the purpose. The advantages of the method are: (1) There is absolute certainty of absorption. (2) There is no pain to speak of. (3) There is no disturbance of the digestive tract during treatment. Slight salivation and diarrhoea, temporary only, are the only local disturbances reported. (4) There is more rapid absorption and therapeutic effect than by any other method. (5) Less of the mercurial salt is required. (6) Absolute exactitude of dosage can be obtained. (7) Not a single accident has been recorded. (8) The method is perfectly reliable. All cases reported have shown some improvement, and never any retrogression. (9) Abscesses do not form. (10) There are no cutaneous irritations or eruptions, such as follow friction or innervations. (11) The nervous symptoms sometimes associated with the hypodermic method are never observed with the intravenous injections. (12) It is successful often when all other methods fail. (13) There is no history of recurrence after a cure. (14) Mercuric chloride has a preservative action on the red blood corpuscles, and hence must be valuable intravenously in such a disease as syphilis, in which there is a strong tendency toward destruction of the red blood corpuscles and subsequent anaemia. The disadvantages are: (1) The needle may not reach the vein; but this can be remedied by applying the needle first and awaiting the appearance of a few drops of blood. (2) Some of the blood may extravasate into the subcutaneous tissue, adjacent to the point of injection; but this has rarely occurred, and the blood is soon absorbed. (3) There is likely to be a slight stomatitis at first. (4) There is the appearance of albumen in the urine after the injections, which, however, often follows hypodermic administration. (5) There is, as in all intravenous injections, a subsequent polyuria and increase of urea, but neither has any special disadvantage. (6) During the injection, through a reflex action on the circulatory centre, fainting may supervene, but is of no vital import. (7) Jaundice has been slight salivation immediately after the injection of small doses. This is liable to happen in any administration of mercury. In the opinion of the author the advantages so far overbalance the objections that, viewing the present status of treatment, we can but accept this as the most successful. He would not, however, advocate it in cases easily amenable to ordinary treatment or in the early stages of syphilis, but considers it of especial value in obstinate cases, resisting other treatment, or in advanced cases of organic syphilis, or when immediate relief is urgently called for by reason of pain, encroachment on a vital part, or rapid destruction of tissue. Investigation may prove it to be most valuable immediately after the diagnosis is made, eliminating or destroying the syphilitic

virus before it has produced any decided effect on the general system. At present there is no evidence to warrant this statement; but, as the method is virtually devoid of dangerous or untoward results, it should be given some trial in the beginning of the disease.

(141) *Ichthyol in the Treatment of Phthisis.* SCARPA (*Rif. Med.*, March 6th, 1895) communicated to the Medical Society of Turin the results obtained by him in the treatment of 150 cases of pulmonary phthisis with sulpho-ichthyolate of ammonium. Of the 150 cases so treated, 23 died, but these were already in a desperate condition when the treatment was commenced; 17 are at present cured to all appearance, having no subjective symptoms, and objectively only such signs as may be called the inevitable relics of the disease; 50 are much relieved, and in a fair way to recovery; 32 show an improvement less marked but still evident; 28 show as yet no appreciable change. Contrary to what is observed with guaiacol and creasote, the improvement begins with the special symptoms—for example, cough, expectoration, pain; improvement in the general symptoms, appetite, strength, fever, and sweating, comes later, after two or three weeks. The author uses a 30 per cent. solution in water, glycerine, or alcohol, of which he administers 20 to 200 drops daily in water.

(142) Internal Use of Cocaine in Whooping-cough.

WELLS AND CARRÉ (*Sem. Méd.*, June 19th) have treated some 300 cases of whooping-cough by the internal administration of hydrochlorate of cocaine in doses varying from 4 milligrammes in infants of 8 months to 2 centigrammes in children of 5 or 6 years. These doses were given three times in the 24 hours. The treatment had a very favourable effect on the symptoms and course of the disease. Vomiting was checked, appetite returned, the attacks of cough diminished both in frequency and in intensity, sleep was less disturbed, and the duration of illness was markedly lessened, the disease being cured, as a rule, in three weeks, sometimes in a fortnight. Cocaine is generally well borne by children. The only disagreeable effect occasionally noted is looseness of the bowels, which, as constipation is a frequent accompaniment of whooping-cough, the authors think an advantage rather than otherwise.

PATHOLOGY.

(143) Phlorhizine and Glycosuria.

COOLEN (*Arch. Pharmacodynamie*, vol. 1, fasc. iv) records the results of a large number of experiments with reference to the action of phlorhizine (phloridzine) in producing glycosuria. His experiments confirm the results of v. Mering and others, and show that phlorhizine produces in dogs an intense and prolonged glycosuria, which may be

fatal; but it does not produce a permanent diabetes, since the glycosuria disappears after the administration of phlorhizine has been discontinued. Cooleen finds that the results are more marked when the drug is injected hypodermically than when it is given internally; also suspension of phlorhizine in olive oil or in mucilage of gum arabic is more active than when it is dissolved in water or in a weak solution of carbonate of soda. In addition to glycosuria, phlorhizine gives rise to loss of weight, polyuria, azoturia, increased specific gravity of the urine, and other minor changes. The author confirms the statements of previous experimenters with reference to the difficulty of producing phlorhizine glycosuria in rabbits. He finds, however, that even in rabbits the hypodermic injection of large doses of phlorhizine (6 grains daily) produces glycosuria. He concludes that the liver has no action in preventing phlorhizine diabetes, because he finds that the minimal dose of the drug which produces glycosuria after intravenous injection gives the same result when injected into the portal venous system. It has been frequently stated that in phlorhizine diabetes there is no increase of the sugar in the blood, and therefore this glycosuria has been looked upon as renal in origin. But Cooleen finds that in rabbits phlorhizine causes an increase in the amount of sugar in the blood and this is greater still after extirpation of the kidneys. Hence the author thinks we are not justified in generally regarding phlorhizine glycosuria as renal in origin. He believes it is due to hyperglycemia, as are other forms of glycosuria.

(144) Osteomyelitis produced by *Bacterium Coli Commune*.

AKERMAN, as the result of an inquiry into the etiology of osteomyelitis (*Arch. de Méd. Experimentale*, May, 1895), draws the following conclusions: *Bacterium coli* injected into the veins of a young rabbit produces inflammatory lesions of the osseous system. These lesions resemble in many of their characters those produced by the organisms of suppuration. In the first stage the lesions produced by the *B. coli commune* present themselves as infiltrations of embryonic cells in the soft parts of the bone, and, when the later stage is reached, these form softening foci and circumscribed abscesses beneath the periosteum and in the interior of the bone. These lesions are most frequent in the neighbourhood of the epiphysis and are almost always multiple. They are mostly seen at the inferior extremity of the femur and the upper part of the tibia, but they may be found in any of the long bones. Besides these acute lesions, others of a more chronic character may be seen, where a portion of bone undergoes a slow necrosis, and sequestrum is formed. The author believes that future observations will show many cases of osteomyelitis to be due to infection by the *B. coli commune*.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

1146 Gastric Peristalsis.

BRUNSON (*Arch. Gen. Med.*, July, 1895) reports a case in Hahn's clinic in which there was vomiting and wasting, and a small tumour could be felt in the region of the pylorus. The ingestion of food caused visible peristalsis. Following peristalsis may arise spontaneously, continuously or be provoked by various agents. The spontaneous form is much the rarer. Pinching the abdominal wall, the local application of ice, the shivering caused by cough or by sudden movement of the body, and also the electric current, may produce the visible peristalsis. As to possible causes, it may occur during exertion, and both fluids and solids may produce it. The reaction of the muscle is not instantaneous. The waves succeed each other from left to right; excepting a wave from right to left may follow the other one. It is very rare to have antiperistaltic movements. During nausea the peristalsis is increased, but in vomiting it is retarded by the contraction of the abdominal muscles. Sometimes the patient feels nothing, but at other times ill-defined discomfort may be complained of. The cause of the peristalsis is a some obstruction of the pylorus, the stomach muscle being intact. The obstruction may be caused by a gross lesion at the pylorus, or even by spasm. Rapid development of the obstruction is necessary for the production of visible peristalsis. This peristalsis has been rarely noted in the hysterical when the intestine may also share in it. The obstruction might even exist in the stomach walls as in annular constriction, or in the duodenum. Cases with visible peristalsis due to severe non-malignant stenosis should be attacked by pylorotomy or gastrojejunostomy.

1147 The Uric Acid Diathesis.

BRUNSON (*Contrib. J. Am. Med.*, July, 1895) discusses in a preliminary communication the diagnosis and treatment of this diathesis. The conditions leading to the formation of uric acid calculi are the same as those which produce a precipitation of uric acid—namely, insufficient water, too great acidity, too much uric acid, or a combination of these factors. The question really is as to how much uric acid exists in the urinary passages in a state suited to the formation of calculi. The author proposes a new method for ascertaining the amount of uric acid passed undissolved. In the uric acid diathesis crystals are found in clear urine, and these usually increase steadily. The same process is noted if the urine is concentrated. The author gets the patient to pass urine into special filters.

Some 4 to 10 filters may be used in the day. Thus the amount of uric acid passed in an undissolved state can be ascertained. The error of the method lies in the loss of some 50 c.cm. of urine in the filters, and in the gain of as much uric acid as deposits between urination and filtration. The amount of uric acid separating out on standing is also ascertained, as well as the amount still in solution (by the silver method). By this procedure the amount of stone-forming uric acid can be estimated. The author tests the value of treatment by finding out the effect of any given agent upon the three separate quantities of uric acid obtained in the above-named way. He has thus investigated the value of urea and carbonate of ammonium. Urea forms a very soluble compound with uric acid, and carbonate of ammonium is excreted as urea. He finds both these agents valuable in the prevention of calculus formation.

1148 Diabetic Coma.

HIRSCHFELD (*Deut. med. Woch.*, June 27th, 1895) says that the increase in the excretion of acetone is due to too little carbohydrate food. In 7 cases of diabetes with acetone the disease ran its course rapidly, the longest duration being twenty, and the shortest twelve, months. The glycosuria was very considerable in all the cases, and the acetone increased as time went on. Acetone excretion above 1 gramme is an unfavourable sign. In other milder cases of diabetes dying of other causes than coma the acetone excretion was small. The age of 5 out of the 7 cases above named was over 40 years. Considerable over-exertion and failure in nutrition are existing causes. In several cases the author registered a loss of weight during ten days before the onset of the coma. After a strict nitrogenous diet coma has been known to appear. The author believes inanition to be the most important cause of coma. The beneficial effect of over-nutrition also speaks in favour of the disadvantages of insufficient food. More importance is now attached to abundant nourishment in diabetes than was formerly the case. Occasionally coma has followed the use of anaesthetics. Ether should be preferred. Perhaps the harmful effect of chloroform is due to its action on the heart and vessels. The diagnosis of coma is mostly easy. The patient may begin with gastric disturbances; headache and a feeling of drowsiness follow. Abortive forms of coma are very frequent. One or more symptoms may be marked, but they disappear. Sometimes abdominal symptoms have been very conspicuous, even intestinal obstruction being simulated. Intestinal intubation has been advanced as a cause of coma, yet careful attention to the bowels did not ward it off. In three diabetic cases arising from surgical disease a suddenly increased acetone excretion preceded the getting worse. The cases may be arranged in two groups. (1) Young persons with considerable glycosuria and marked and increasing acetoneuria, in whom the course is rapid; and

(2) old people with mild diabetes, who, in consequence of gangrene or severe septic disease develop coma. To prevent muscular exertion must be required. The estimation of acetone is important; the general condition of the patient and the state of the pulse and breathing after exertion should be noted. The condition of nutrition must be attended to. Overfeeding should at times be had recourse to. Small quantities of carbohydrates, not too much as usual, and abundant fat and some alcohol are recommended. With coma requiring more carbohydrates should be given. Glycerine may be tried, as it increases the excretion of acetone. Infusion of alkalies has only a passing effect.

1149 Hematoma of the Leg and Ankle.
A. F. FLECK (*Pres. Med.*, May 10th, 1895) dwells upon the danger of thrombosis and embolism in cases of extensive bruises of the lower limb. He insists upon the necessity for absolute rest until the part has resumed its normal condition. Two cases which he relates illustrate the accident referred to. In the first a lady was thrown out of a carriage, and sustained extensive bruises and ecchymoses in the left leg and elsewhere. She was progressing well until the ninth day, when there was a slight access of pain and swelling. The next day the patient was suddenly seized with a feeling of suffocation, and fell back pale, with pulse almost imperceptible and respiration hurried. She recovered in a few minutes, but in the course of convalescence and in spite of the precautions taken, two other attacks occurred. The second case was more serious, and was the result of a similar accident. Seventeen days after the accident, when the patient was seemingly on the high road to recovery, she attempted to sit up in bed, suddenly cried "J'touffe," and died.

SURGERY.

1150 Indirect Operative Treatment of Prostatic Hypertrophy.

WHITE (*Annals of Surg.*, July, 1895) deals at length with the causation and treatment of hypertrophy of the prostate. Consideration of a theory of causation which the author states has given much help to an understanding both of the results of double castration and of some of the clinical features of prostatic growths is followed by a summary of 111 cases treated by castration, and a review of the objections that have thus far been urged against the operation, and of its relative merits and future prospects. In conclusion experimental and other evidence is adduced with regard to the value of unilateral castration, and of ligature of the whole or of part of the cord. The function of the testis, like that of the ovary, is a twofold—the reproduction of the species, and the development and preservation of the sexual characteristics of the individual. The need of the existence of the latter function ceases when full adult life is reached, but it is pre-

sible, the author holds, that the activity of the testis and ovary in this respect does not disappear coincidentally, and that hypertrophy of closely allied organs such as these is the result of this misdirected energy. The theoretical objections urged against double castration have been fully negatived by clinical experience, which shows that rapid atrophy of the enlarged prostate follows the operation in a very large proportion of cases—about 87 per cent.—and that disappearance or considerable diminution of long-standing cystitis occurs in about half the number of patients thus treated. Moreover, amelioration of the most troublesome symptoms is produced in 88 per cent. of the cases; and a return to local conditions not very far removed from those that are normal may be expected in a considerable number—46.4 per cent. Of the 111 cases tabulated by the author 18 were fatal. But of these, it is held, there are 13 that may fairly be excluded in an attempt to ascertain the legitimate mortality in patients operated on under surgically favourable conditions, that is to say, before the actual onset of uræmia, or before the kidneys have become disorganised through backward pressure and consequent infection. Even of the desperate cases which make up this series of deaths, in many—75 per cent.—shrinkage of the prostate and improvement of the symptoms followed the operation. Comparison with other operative procedures seems to the author to justify the conclusion that apart from sentimental objections castration offers a better prospect of permanent success than any other method of treatment. The value of this operation is further enhanced by its smaller mortality as compared with that of prostatectomy, by the absence of any risk of permanent fistula, perineal or suprapubic, by the ease and quickness with which it can be performed, and by the possibility of avoiding anaesthetics, which in these cases are in themselves dangerous. The evidence as to the efficacy of unilateral castration is at present contradictory. In two cases, at least, this operation has resulted in a very marked improvement of symptoms. The author's experiments on dogs have shown, in nearly every case in which the vas deferens was tied or divided on both sides, that without much change in the testicles commencing atrophy and considerable loss of weight in the prostate resulted. The absence of corresponding testicular changes, however, rendered these results somewhat anomalous. Ligation of the vascular constituents of the cord or of the whole cord will produce atrophy of the prostate, but only after it has caused disorganisation of the testis.

(132) Division of the Vas Deferens for Prostatic Hypertrophy.

ISWANDI (*Centralbl. für Chir.*, No. 28, 1895) reports a case of enlarged prostate, with serious and intractable urinary trouble in a patient, aged 71, which was successfully treated by

double ligation and division of the vas deferens on both sides. The incontinence ceased after the operation, the urine became quite clear, and the enlarged prostate diminished so much in size that it could no longer be felt on rectal examination. The epididymis on each side became smaller and harder after the operation, and the volume of each testis was reduced by one half, the condition of these parts resembling that consequent on chronic gonorrhœal epididymitis.

(133) Paræsthesia of the External Cutaneous Nerve of the Thigh.

THIS condition is described by Lucas-Championnière (*Journ. de Méd.*, July 25th, 1895). The subjects of it, who may otherwise be in good health, complain of abnormal sensations, pain of a more or less stabbing or burning character in the upper and outer part of the thigh and tensor vagina femoris. Either side may be affected, and in one case the condition was bilateral. There may be merely a feeling of twitching or cramp in the part. These symptoms are always most marked when the patient walks, and may even disappear completely when he is at rest, especially if in a recumbent posture. The pain and discomfort may be so great that anything touching the limb may be unbearable. The writer quotes two cases of officers in the German army who could not wear their swords on account of the pain. On examination there may be a certain degree of anaesthesia, and even some loss of sensation of heat, and in a case under the care of the author there was pain on pressure over the nerve at its point of exit from the pelvis. There are no trophic lesions and no alteration to electrical reaction. With one exception, all the cases have occurred in the male sex. The onset seems to be insidious, and the duration varies from a few months to years. In one case there was a history of traumatism, but otherwise the etiology is very obscure. The writer points out the importance of diagnosis from hysteria and tabes dorsalis. Counter-irritation and massage have been of benefit as treatment.

(134) Laparotomy for Acute Suppurative Peritonitis in Infancy.

MIRABELLA (*Rif. Med.*, July 1st, 1895) reports two cases of acute suppurative peritonitis in children of 2½ years and 3 years respectively, in which he performed laparotomy with successful results. In neither case could any known cause for the peritonitis be found. The usual medicinal means—opium, ice, leeches, etc.—were first tried, and as these proved of no avail, laparotomy was performed. The incision was a pretty free one, extending from the umbilicus to the pubes; sero-pus came out in large quantity. The peritoneal cavity was washed out with sterilised water, and the wound then closed. In the first case the fever fell at once, the wound healed by first intention, and the child was able to leave his bed on the tenth day after the

operation, and is now (two years after the operation) perfectly well. In the second case the post-operative course was interfered with by slight reaccumulation of pus necessitating counter drainage; but eventually the child recovered, and is now (twenty-three months after operation) in good health.

MIDWIFERY AND DISEASES OF WOMEN.

(135) Hernia after Ovariectomy.

WINTER (*Centralbl. f. Gynäk.*, No. 29, 1895) read an important communication on this subject at the June meeting of the German Gynaecological Congress. Hernia after ovariectomy and other operations on pelvic organs is very frequent. Protection against this troublesome and dangerous complication is all the more necessary because operations for the cure of the hernia are very unsatisfactory. Winter has known 8 out of 9 such procedures to fail, though the sac was dissected away and the parietal layers were united separately. The cause of hernia after abdominal section is failure of union of the aponeurotic layer. Hence Winter always unites the edges of this layer separately with a continuous catgut suture after closing the peritoneal incision in the same manner. The skin and subcutaneous tissue are united with interrupted silk sutures, and, lastly, the skin wound is closed accurately by means of a running catgut suture. Collodion is applied along the wound. Failure of union is due not so much to early infection of the wound as to supuration of the suture tracks. An important discussion followed the reading of Winter's paper. Dührssen maintained that simple interrupted silkworm-gut sutures passed through all the layers of the wound were quite sufficient. He hardly ever saw hernia after their employment. Martin was of the same opinion, but he used a separate catgut suture for the skin.

(136) Decidua Maligna in America.

WHITRIDGE WILLIAMS (*Amer. Gynec. and Obstet. Journ.*, June, 1895) describes what seems to be the first case observed in the United States; none, it must be remembered, have as yet been reported in any English speaking country. The patient was a negress who had been pregnant several times. She was delivered on April 15th, 1894, at term of a dead child, after a normal but lingering labour; much blood was lost in the third stage. The placenta was soft and boggy, but there was no loss of blood after its expulsion. There was high temperature and great prostration during the puerperium, and a painful nodule developed in the right labium majus. It grew rapidly, broke down, became sloughy, and caused death from septicæmia on July 12th, less than three months after labour. Sloughing hæmatoma was diagnosed. The recto-vaginal septum was ulcerated and perforated. Two submucous growths, one over an inch wide, filled the uterine cavity. In

each lung were forty to fifty metastases, varying from a pea to a walnut in size. The kidneys, left ovary, liver, and spleen were similarly affected. The uterine and secondary growths all bore the microscopic characters of deciduoma malignum.

(153) Auxiliary Breasts.

Goldmann (*Archiv f. Gynäk.*, Vol. xlix, Pt. 2, 1895) records a case in which two accessory mammary glands without nipples were present. One lay in the hollow of the right axilla. At its greatest development it was of the size of a goose's egg. The second was placed on the thorax a little under four inches below the apex of the axilla and somewhat anterior to the middle axillary line. It was larger than the right supplementary breast. At the end of the third week after delivery it underwent complete involution; the patient did not on this occasion suckle her child. The patient was 32, the accessory mammae had always developed during her pregnancies. When suckling she found that any cause, particularly suitable diet, which increased the flow of milk in the normal mammae caused the abnormal growths to become large and tense. The aspirating syringe was passed into one of the axillary breasts and true milk extracted, as proved by analysis.

(154) Removal of Inflamed Appendages or Hysterectomy.

SCHAUTA (*Centr. f. Gynäk.*, No. 29, 1895) in opening a discussion on the relative merits of removal of the appendages and hysterectomy at the Vienna meeting of the German Gynecological Association declared himself in favour of the rather extreme measure of removing the uterus as well as the appendages. Amputation of the tube and ovary on one side was very unsatisfactory, and even after double operations hemorrhage, leucorrhœa, adhesions to the stump, and fixation of the uterus caused much trouble and pain. In gonorrheal disease both appendages should be removed, even if the tube and ovary on one side seemed healthy, when the surgeon determined on attempting an operation of this class. But Schauta says that under the above circumstances the uterus should be removed as well. If it be not fixed and therefore can be drawn down to the vulva, the vaginal operation should be preferred; otherwise the uterus must be amputated through an abdominal wound. Fritsch and Landau supported Schauta. Voss maintained that the best results which followed amputation of the appendages were due to fresh gonorrheal infection.

(155) Uterus Bidelphæ: Abortion: Uterus Bicornis with Pyometra.

HANSEN (*Centr. f. Gynäk.*, No. 29, 1895) describes a case in which two complete uteri existed; they were entirely separate, the lowest part of each cervix touching its fellow externally. A trace of a septum was detected along the anterior wall of the vagina. The patient

was 32, and had borne eight children to term, two other pregnancies ending in abortion. She consulted her doctor on account of metrorrhagia of six months' duration; myoma was diagnosed. On examination the above abnormalities were discovered. The bleeding was due to a recent abortion. In the second case the patient was aged 30, married three years, and sterile. She had been subject for seventeen years to dysmenorrhœa, the pain had recently increased, and purulent discharge came away. The uterus was pushed to the left by an elastic swelling as big as a fist. On pressure on the swelling pus escaped from the uterus, though the os externum could not be found by search with a fine sound. There was, in fact, a uterus bicornis unicollis, the common canal of the cervix had become closed, a pyometra had developed, and the canal opening again spontaneously, the pus escaped. The swelling was incised, the remaining pus evacuated, the uterine canal washed out; a sound could now be easily passed along the canal of the cervix. A tampon was applied. The pains ceased.

(156) Fœtal Tumour Impeding Labour.

HEFFECK (*Centr. f. Gynäk.*, No. 25, 1895), recently exhibited a fœtus with a large cystic kidney. Labour was much complicated by the size of the tumour, and the child could not be delivered till its abdomen was opened and the tumour diminished in size.

THERAPEUTICS.

(157) Serumtherapy.

SCHAEFER (*Arch. gén. de Méd.*, August, 1895) discusses the present position of the serum treatment after referring to the researches upon which it has been built up. (1) *Tuberculosis*.—Richtel and Héricourt were the first to treat the disease with serum obtained from refractory animals, but up to the present moment no very good results have been obtained. (2) *Rabies*.—Serum treatment does not appear to have a great future, as immunisation by intensive vaccination gives greater success. (3) *Pneumonia*.—After referring to the investigations the author observes that the serum treatment deserves to be considered. The reason that it has not been more generally adopted is probably on account of the difficulty of obtaining the serum from immunised rabbits. (4) *Enteric Fever*.—Here the clinical application of laboratory facts has not given any very good results. This may be partly due to the length of time between the penetration of the poison and the treatment, and partly possibly owing to mixed infections. (5) *Typhus*.—The injection of serum from patients who had suffered from typhus was adopted with good results by Lograin in an epidemic in Algeria. (6) *Cholera*.—The cholera peritonitis of animals is very different from cholera in man. Behring recently announced that he had obtained a curative serum, but the results have not yet been published

(7) *Syphilis*.—The serum from the dog and lamb have been employed, and sometimes with good results. (8) *Streptococcus Infection*.—Animals have been vaccinated against this infection. The serum so obtained has been used in periperal fever with good effect. It has also been employed in erysipelas and angina. (9) *Cancer*.—The results as yet obtained are insufficient to carry conviction. (10) *Tetanus*.—Well-marked tetanus is very difficult to cure in animals, and thus it is not to be wondered at that the results obtained in man are not conclusive. The serum, however, provides a valuable prophylactic agent against tetanus. (11) *Diphtheria*.—It is in this disease that the serum treatment has registered its greatest triumphs. Where mixed infections exist the results have naturally not been so favourable. The slight accidents caused by the treatment are to be disregarded in view of its remarkable efficacy. The author then refers to the successful application of the serum treatment to snakebites. The general results thus far obtained by the serum-therapy promise a successful future for this new method of treatment.

(158) The Serum Treatment of Cancer.

PANNE DOMENOUR (*Presse Méd.*, June 1st, 1895), with reference to the recent results of Emmerich and Scholl (*see ERRATUM*, May 11th, 1895) and others, considers that (1) Serotherapy is logically applicable only to microbic affections, or those which by their symptoms may be supposed to be such; (2) cancer does not belong to this group in any of its characters, for (a) the fact of its more frequent occurrence in one neighbourhood or house only proves that the exciting cause is more frequent there, and not that cancer is contagious; (b) a parasite is not necessary for the transplanting of a living cell, cancerous or not; (c) the pseudo-coccidia have not been proved to be parasites; (3) the facts interpreted to prove the curative action of serum injections (whether erysipelas toxin or the juice of a sarcoma) have the same value as those known before of the modifying action of chemical substances (for example, oil of phosphorus, picric acid, pyktonin, etc.). The latter, when injected, cause a local aseptic necrosis which attracts leucocytes, so that the part is absorbed and the tumour undergoes temporary diminution in size. The former act by their contained toxins exerting a negative chemiotactic action, which in some cases may be of such extent as to lead to the same result. There is thus never any real cure of the whole disease.

(159) The Cholera Antitoxin.

RANROM (*Dent. med. Week.*, 1895, No. 29) reports his investigations into this subject. He shows that the dissolved cholera poison, free from micro-organisms, causes a fall of temperature in the same way as a virulent cholera culture. He separates this poison from a boiling culture. Similar results are obtained, whether it is injected into

the abdominal cavity or subcutaneously, but the action is more rapid in the former case. The minimum fatal dose took effect more quickly with the poison than with living cholera vibrios. This fluid, freed from bacilli, cannot be preserved for long, and the author has been unable to maintain its virulence by artificial means. The poison is little altered by heat. The addition of calcium chloride, etc., does not impair its activity. When concentrated it becomes extremely virulent. A solid substance can be obtained from this fluid, which acts in the same way as the fluid. The author finds 0.07 g. of this solid to be the minimum fatal dose for a guinea-pig weighing 200 g. In fatal cases a fall of temperature is noted. The solid substance administered to guinea-pigs by the stomach is harmless. The author has immunized various animals against cholera, and has obtained an antitoxin from the blood. Guinea-pigs, when injected with a mixture of the cholera poison and this antitoxin, did not die; they could thus stand twice or thrice the minimum fatal dose. Control experiments were also made with the serum obtained from non-immunized animals. He found the curative serum efficient, even when injected at a different place to the poison. He also found the serum efficient against the poisonous culture fluid as well as against the infection produced by living cholera vibrios. If the serum were injected forty-eight hours before the cholera bouillon it had also a life-saving effect.

(143) Treatment of Pneumonia by Digitalis.

MARGELI-ÅKERHOLM (*Cent. all. f. inn. Med.*, August 10th, 1895). First refers to the results obtained by various physicians with this treatment, and especially to those of Petresco. The mortality in Petresco's 1172 cases varied from 1.2 to 2.6 per cent., but the patients were healthy young soldiers. In 475 cases treated in Masand's Poliklinik the average mortality was 11 per cent., and here the patients were mostly poorly housed and advanced in life. In the author's 64 cases treated by digitalis, 11 died. Of 40 cases under 50 years of age, not one died of pure pneumonia, the 2 deaths occurring in cases of phthisis complicated by pneumonia. Of the 9 remaining fatal cases, 7 were hopeless from the outset, and 2 were over 70 years of age. The object of the digitalis treatment is the regulation of the circulation through the lungs, no diuretic effect being expected. The author would also attribute the good results to the increase of leucocytes which is produced. His investigations show that both in animals and man digitalis produces a leucocytosis. The author used digitalis in large doses. He thinks it the chief therapeutic agent in the treatment of acute pneumonia. He is of opinion that hyalocyanate measures should, when possible, be combined with it, as in this way the leucocytes are also decreased in number.

PATHOLOGY.

(142) Immunization against Cholera.

SCHNEIDERMAN (*Myslov. I. Indochai*, 1895 p. 145), taking advantage of an epidemic of cholera at Largin, near Marburg, in the autumn of 1894 investigated the blood serum of patients convalescent from the disease with regard to its immunizing properties. The blood taken from the median vein was kept for twenty-four hours in an ice cupboard, and the serum injected intraperitoneally into guinea-pigs. Twenty-four hours later the animals were injected also intraperitoneally with a fatal dose of cholera vibrios. These were of different origin but in part were obtained from the Largin epidemic. It was found that in the blood of such convalescent patients certain substances are present which have a specific immunising property against the laboratory cholera of guinea-pigs. The amount and efficacy of these substances are not constant, but show variations bearing some ratio to the severity of the disease.

(144) Microbic Origin of Rickets.

MIRCOIT (*Gaz. Med. di Torino*, No. 11, 1895) pleads for the microbic origin of rickets, believing that the disease is caused by the effect of ordinary pyogenic organisms upon the osseous and nervous system. Clinically he finds support for this theory in the fact that rickets develops independently of racial condition; frequently begins with eczema, boils, or intestinal catarrh; occasionally occurs epidemically; and is accompanied by fever, polyarthritic and bone pains, hydrocephalus, marasmus, and paresis of lower extremities. Pyogenic organisms have been found in the bones and central nervous system of rickety children. Experimental injection of pyogens into the bones and epiphyseal cartilages of young rabbits produced common osteomyelitis, but in other cases an osteomyelitis without trace of suppuration, with hypertrophy of the ends of the bones, hypertrophy of cartilages analogous to that of rickets, and marasmus.

(145) Death in Acute Pneumonia.

BOLLINGER (*Munch. med. Woch.*, August 6th, 1895) mentions that death in acute pneumonia is usually attributed to (1) inefficiency of the lungs owing to extensive consolidation; (2) severity of the infection, as in septic forms of pneumonia; (3) complications, such as meningitis, pericarditis, etc.; (4) heart failure, which may be due to inherent weakness in the heart, or be brought about by the pneumonic infection. Individual resistance is also an important factor. The author draws attention to two facts noted after death from acute pneumonia: (1) the general anemia of all organs, and (2) the absence of so-called collateral hyperemia in parts of the lungs unaffected by the pneumonic process. The author would attribute this to the extensive exudation, which rots the blood of

its most important elements. The results of this exudation are practically similar to those produced by the recurrent internal hemorrhage noted in some of the infections. The leucocytosis seen in acute pneumonia is a regenerative process to compensate for the loss to the blood occasioned by the exudation. Thus the author thinks that the critical collapse manifestations in croup pneumonia, and the fatal cardiac insufficiency are due to the oligemia which leads to an inadequate nutrition of the cardiac muscle. Finally, he draws attention to the harm done by blood letting. Blood should be administered by all possible methods; perhaps even the infusion of saline solution should be adapted to compensate for the oligemia.

(146) A Pathogenic Bacterial Parasite of Fishes.

SIEBER (*Gazeta Lekarska*, 1895, Nos. 13, 14, 16, and 17) discusses the question of poisoning caused in man by eating certain fish. It is known that several fish secrete poisonous materials for the purpose of self defence, and these the author calls "physiological." But poisoning by fish that produce no such physiological poisons is by no means uncommon, especially in Russia. Sieber investigated the cause of a fish epidemic in Nencki's laboratory at St. Petersburg. In an aquarium in the Palace, where fish destined for the table had been kept during the past ten years, there occurred on a certain occasion so high a mortality that thirty fish died in two days. The bacterial investigation of the cause of this mortality was entrusted by Nencki to Sieber. From the muscle and organs of the dead and sick fish, from the surface of the aquarium and from the exit tubes, as also from the water in the aquarium, was found an anaerobic bacillus called by Sieber *B. piscicidus agilis*, which is intensely poisonous for cold blooded animals. It is a short, actively motile, spore-bearing, gas-forming bacillus, which can be cultivated on ordinary culture media, and which grows well at 12°, or 37.5° C. It keeps its virulence for a month in ordinary spring water. It is very virulent for frogs, guinea-pigs, mice, rabbits, and dogs, but birds are immune. From all animals, cold as well as warm blooded, the bacillus was reared in pure culture after death from a solution. By filtration through a Chamberland filter a fluid was obtained which gave an intense red colour with ferric perchloride. The symptoms produced in the animal by injection of the toxin are rapidly and shortness of breathing with general discomfort; larger doses lead to apathy and paralysis. The investigator separated from the cultures certain alkaloids, such as e-doverin, etc., and also another present only in small quantities but intensely poisonous. It must be added that Sieber found the same bacillus in the excretions of two cholera patients and in many fish bought in the St. Petersburg market during the cholera epidemic.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(107) The Physical Signs of Abdominal Disease.

The first of a series of articles compiled from Hayem's lectures by Lion (*Arch. Gén. de Méd.*, August) on certain forms of abdominal disease, is devoted to the consideration of the effects of compression, or, as he terms it, "corset disease." Judging from Hayem, this is a more complicated condition than would at first appear, for, according as the natural conformation of the thorax varies, so constriction by the corset differs in its effects. The author describes three chief deformities. The first is suprahepatic constriction, and is found in women with a naturally large thorax, and of low stature. There is diminution of the antero-posterior diameter, and the lower ribs are displaced outwards. In this form there is downward displacement of the liver, and, in a general way, all the abdominal organs, including the pyloric end of the stomach; the stomach, therefore, assumes an almost vertical position, and the transverse colon becomes V-shaped. In the second variety there is hepatic constriction, the thorax is long, and tapers; there is not much external deformity, but merely a tendency to bending outwards of the lower ribs at their angles. In this variety there is diminution of abdominal capacity, the liver increases in vertical extent, and presses the pylorus and duodenum against the vertebral column. There is thus no displacement, but compression; the result is dilatation of the stomach towards the pyloric end, with, perhaps, hour-glass constriction as well. The third variety is considered by the author as the most important and the least recognised. It is the subhepatic. The compression takes place at the level of the last ribs and the lower margin of the liver. In many cases a certain amount of shortness of the sternum induces this deformity. The result is a displacement upwards of the liver, with consequent tension of the diaphragm. This produces a certain immobility of the diaphragm and the lower thorax, so that palpitation and dyspnoea may be present on movement, and even slight exercise may cause general discomfort. The transverse colon is also displaced, and so with deficient diaphragmatic action constipation is caused, especially as the dyspnoea, etc., induce the patient to lead an inactive life.

(108) Infective Jaundice.

BANTI (*Deut. med. Woch.*, August 1st, 1896) relates a case of so-called simple jaundice, in which, in his opinion, the infective character of the disease was established. The patient, aged 22, pre-

sented the ordinary symptoms of slight jaundice, which lasted about a fortnight. The liver was enlarged, as also the spleen. The stools were always coloured with bile pigment, so that there was no obstruction of the ducts. The temperature seems to have been raised, and there was frequent nose-bleeding. The treatment was by naphthol and salol. While the disease was at its height 3 c.cm. of blood were withdrawn from the spleen with a sterilised syringe, and under the usual precautions. The author obtained from this blood a capsulated micro-organism in pure culture. It did not stain by Gram's method. It was pathogenic to white mice, and when injected into dogs, guinea-pigs, and rabbits it displayed marked pyogenic properties. It was most closely allied to two forms of proteus and to the bacillus of rhinoscleroma. The author does not think that the presence of the micro-organism in the spleen could have been due to a secondary infection. Many of the symptoms presented by the patient were in favour of an infective process, and the micro-organism present was closely allied to pathogenic forms found in man. The fact that it did not produce jaundice in animals does not, in the author's opinion, invalidate his conclusions. Some micro-organisms have a hæmatolytic action. It does not follow that every case of simple jaundice is due to this micro-organism. The author would divide jaundice into the toxic and infective varieties; the latter may own many causes. It remains to be shown how often the *B. icterogenes capsulatus* causes jaundice.

(109) The Prognosis of Albuminuria in Typhoid.

Lecoq has investigated this point (*Journ. de Méd.*, June 26th, 1896), and shows that albuminuria, though an almost constant condition in typhoid, is also one the significance of which varies. It may appear at the end of the first week or early in the second, and does not in any way affect the course of the disease, being merely the albuminuria of pyrexia. When, however, it appears later, at the end of the third week, it is an indication that grave changes are taking place in the kidney, and that toxic products will in future be eliminated with difficulty, and that uræmia may at any time declare itself. In such cases, even if the attack of typhoid be apparently slight, a guarded prognosis must be given. Although recovery may take place after kidney complications arise, such is not usually the case, the mortality being 60 per cent. Moreover, the quantity of albumen passed is no indication as to what the result may be, for in some cases there is a fatal termination although the quantity has been small. Of more importance is the amount of urine; when this is small the prognosis is grave.

(110) Diagnosis of Epidemic Cerebro-spinal Meningitis.

BOUVERIE (*Centr. Bl. f. Bakt. u. Immunitätskde.*, April 10th) points out that

not infrequently a severe nasal catarrh is present at the commencement of an attack of epidemic cerebro-spinal meningitis; also Weigert has found purulent inflammation of the upper part of the nasal cavities on post-mortem examination of some cases. The author has examined bacteriologically the nasal secretion in a series of cases of this disease, and has found Weigert's *diplococcus intracellulæris meningitidis* by microscopical examination of cover-glass preparation or by cultivations in all recent cases. Details are given of the 18 cases examined. The nasal secretion of fifty persons who were not suffering from the disease was also examined bacteriologically, but the *diplococcus intracellulæris meningitidis* was found in two cases only, and in both of these there was the possibility of exposure to the infection. For the detection of the *diplococcus* cover-glass preparations of the nasal mucus are simply stained with a watery solution of gentian violet for a few seconds. The author regards as characteristic the occurrence of three or four diplococci enclosed in a leucocyte, and also the presence in the specimen of many cells containing these diplococci. The appearance with respect to the intracellular position is very similar to that of the gonococcus. The fact that the organism, which is regarded as an exciter of the disease, was found in the nasal secretion in all recent cases which Salzer examined led him to conclude that infection is by the diplococci being inhaled; are then taken up by leucocytes, afterwards find their way by the pharynx into the brain and meninges. He believes the detection of the *diplococcus* in the nasal secretion to be of great importance in the diagnosis. The probability of detection is greater the earlier the examination is made. The author regards the nasal secretion as infectious.

BURGERY.

(111) Apparent Double Penis.

At the Congress of Gynaecology, Obstetrics, and Pediatrics recently held at Bordeaux (*Sem. Méd.*, August 1st), Lannelongue reported the following case: Some years ago a woman brought to him a male infant, aged 3 months, which passed water both through an umbilical appendix resembling a penis and by the natural organ which was in its proper place. The jet which came from the umbilical canal described a curve more than 30 centimetres in diameter. On examination, it was found that the apparent abdominal penis was an umbilical hernia caused by the persistence of the urachus. A urinary fistula had been produced on the separation of the umbilical cord. The child having died of bronchopneumonia, Lannelongue made a post-mortem examination. The bladder was injected, and it was then seen that that viscus was prolonged by a channel as large as the forefinger, namely, the urachus, up to the umbilicus. This

channel extended into the external appendix, where it opened by an oblique orifice resembling the meatus urinarius. The contractions of the bladder in micturition caused a stream in both directions, umbilical and urethral, hence the double jet of urine seen from time to time; this, however, was exceptional, as the musculo-elastic ring of the umbilicus fulfilled the function of a sphincter and prevented the escape of urine through that orifice. Lannelongue says that this case once more shows the necessity of tying the umbilical cord only after having satisfied oneself that there is no hernia at the proximal end.

(172) Treatment of Hypospadias.

LAURENT (Extract from the *Bull. de l'Acad. Royale de Méd. de Belgique*, 1895) reports a case in which an extensive cleft along the under surface of the penis was, after failure of other methods, successfully closed by the following operation: Two parallel incisions, each about 2½ inches in length, were made in the left groin, reaching from the lower part of the abdomen to the upper part of the thigh; the intervening portion of skin having been detached from the subjacent fascia, a bridge-shaped flap attached above and below was thus formed; under this bridge of skin the penis was then passed, its inferior surface being directed forwards, and the cut edges of the patent urethra were fixed by sutures to the raw posterior surface of the skin; the operation was completed fourteen days later by division of the flap of skin above and below the part which had contracted firm adhesion to the under surface of the penis.

(173) Gastric Digestion after Gastro-enterostomy.

DEBOVE AND SOUPAULT (*Bull. de l'Acad. de Méd.*, August 6th, 1895) have studied the process of gastric digestion in a man, aged 37, on whom Terrier had done gastro-enterostomy for pyloric cancer. The patient was greatly relieved by the operation; his gastric symptoms disappeared, and he gained 38½ lbs. in three months. Examination by means of test meals showed that there was still gastric stagnation, that peptic digestion was almost inhibited by the absence of H. Cl., and that shortly after each meal bile and pancreatic juice flowed back into the stomach without causing any inconvenience. The case was further interesting from the fact that the physical and chemical signs led originally to the diagnosis of cicatrizing ulcer, in spite of which malignant disease was found at the operation.

(174) Saline Infusion in Cases of Suppression of Urine after Surgical Operation.

McBRIDEN (*Annals of Surgery*, August, 1895) has reported to the New York Surgical Society a case of suppression of urine after operation for the removal of a large calculus from the right kidney, in which the patient, a man,

aged 50, recovered after the injection into a vein of the arm of a quart of salt solution. The operation on the kidney was attended with but moderate bleeding, no ligature and no packing having been required for its control. In the course of the next twenty-four hours nausea began, and was soon followed by vomiting, headache, and symptoms of uramic poisoning. There was no voluntary discharge of urine, and only 4 drachms were obtained by catheter during the first twenty-four hours after the operation. The saline infusion was followed in the course of a few hours by the discharge of 34 ounces of urine, and the patient steadily recovered. In the discussion on this report reference was made to a case of total suppression of urine after an operation for gangrenous hernia, in which striking improvement had followed similar treatment. It was also pointed out that Dickinson had in the *BRITISH MEDICAL JOURNAL* called attention to the fact that patients could be aroused from diabetic coma in a few minutes by saline infusion.

MIDWIFERY AND DISEASES OF WOMEN.

(175) Extrauterine Gestation diagnosed at Six Months, Operated on near Term.

PINARD (*Bull. de l'Acad. de Méd.*, August 6th, 1895) records the following, which he describes as an ideal case. The patient was aged 36, had had no illness, and had been regular from the age of 14 till July, 1894. During August of that year she had nausea and vomiting; on the 22nd and 23rd she lost a fluid, which was just pink. The symptoms continued during September, on the 22nd and 23rd of which month there was a similar loss. In October she was kept in bed for two days by abdominal pain, which reappeared in November, and was then associated with pain in micturition and defecation. From that time, till February 26th, 1895, when she came under Pinard's care, she was attended by several doctors, each of whom adopted a different diagnosis and treatment. One of them, thinking she had a fibroid, made her take in all about an ounce of savin powder, which did not, however, produce any ill effect. When admitted she looked ill and pinched. The left thigh and leg were painful and cedematous. The abdomen looked like that of the sixth month of pregnancy. The abdominal wall was tense, smooth, and without linear albicantes. Palpation revealed a cystic immobile tumour, extending 2 inches above the umbilicus and apparently fixed by deep adhesions. The foetal parts could only be made out with difficulty by deep palpation, but the heart sounds were easily heard to the right of and below the umbilicus. By the right side of this tumour one could feel a small one, the size of a tangerine orange, which hardened and softened under examination. When contracted the groove between it and the large tumour became evident. Vaginal examination showed that the cervix, which was slightly deflected forwards

and to the right, and softened as in uterine gestation, was continuous with the small tumour. Cephalic ballotement was obtained in the large tumour. No sound was passed into the uterus for fear of setting up reflex action; the diagnosis of extrauterine gestation at about 6½ months with a living child was established without requiring to be clinched by proving the uterus empty. The patient was kept absolutely at rest in bed, and the oedema of the left leg cured by position. On April 30th the fundus of the tumour was 35 cm. above the symphysis and the uterus 11½ cm.; the cervix was soft as that of a primipara at term. Operation, May 2nd: Uterus found empty, cavity 14½ cm. long. Median incision in abdominal wall; cyst walls exposed: seen to be very slight and filled with enormous vessels, some greater than the little finger. On seizing the wall one of the vessels burst, and the hemorrhage was only rendered greater on attempting to secure it, so great was the friability of the walls. The cyst was therefore rapidly opened and the child extracted by the foot. Hemorrhage was restrained first by pressure of the hands, then by pressure forceps and ligatures. The walls of the cyst were sown to the margins of the abdominal wound, the edge of the placenta being included in the suture. A wound was thus formed 10 cm. in diameter, with the placenta for its base; it was filled with iodoform and salicylic gauze. The operation lasted an hour, and the child, a boy weighing 5½ lbs., after a brief period of respiratory difficulty, was perfectly vigorous. There was at first a slight facial asymmetry, and a depression on the left upper jaw caused by the point of the left shoulder, against which it had been pressed in the cyst; these soon disappeared, and on the ninetieth day the boy weighed 12 lbs. The maternal wound was not dressed till May 15th, when it was washed with biniodide, 1 in 4,000. The placenta came away piecemeal between May 25th and June 2nd. The wound healed up, and the patient got up on the forty-third day, having suckled her infant from the first day after its birth. Pinard comments on the rare occurrence of ectopic gestation in a primipara with no history of affection of the abdominal or genital organs. The symptomatology was, except for the absence of an expelled decidua, characteristic, the presence of two tumours having the characters described being pathognomonic. The foetal members, contrary to what is stated in books, are harder to feel in ectopic than in uterine gestation. With regard to treatment, Pinard modifies Werth's dictum as follows: "Every diagnosed extrauterine pregnancy calls for surgical interference." In the first half of pregnancy, or when a foetus has been dead two months, the cyst should, as Werth suggests, be treated as a malignant growth. When the foetus has been dead but a short time, Pinard prefers the remote risk of suppuration to the certain one of hemorrhage; if any untoward sym-

ptoma come on he at once removes the fistula. If the fetus is alive and six months old, he delays operation till it is viable, which in extrauterine formation is not till the nine month, the risk to the mother from hemorrhage being in nowise increased by waiting after the placenta is once fully formed. The cardinal point in the operation is not to touch the placenta or to extirpate the sac. The possibility of septicaemia from retention is slight, while the hemorrhage in immediate extraction is enormous and often uncontrollable. He sums up the point in these words, "The removal of the cyst is, perhaps, more surgical, but certainly less prudent." He has not had one bad accident in 16 cases in which the placenta was treated as in this one. Daily irrigation with 1 in 4,000 bichloride produces no toxic effect. With regard to the child, deformities are frequent in extrauterine fetuses, and are comparable to those in the children of primiparae with little amniotic fluid and resistant uterine walls. The child is also likely, as in Caesarean section, to suffer from a special kind of shock causing a temporary difficulty in respiration. The mother and child were shown to the Académie.

(176) Eclampsia of Pregnancy with Amaurosis.

RABCEWSEY (*Przeglad Chirurgiczny*, vol. II, part 3, 1895) has come across an instance of convulsions during pregnancy in which every fit was regularly preceded by a transitory amaurosis as well as by edema of the face, which was also of short duration. Two sets of convulsions occurred during one pregnancy, the first about the end of the seventh month, four attacks taking place within 24 hours, the second in the course of the eighth month when two fits were observed. After the last convulsion a healthy child was delivered. The mother recovered perfectly. The two prominent symptoms above mentioned developed before each of the six fits which took place at two epochs of pregnancy. Olshausen has been able to collect only three cases of eclampsia in which the fit was preceded, as in Rabcewsky's patient, by an aura.

(177) Calculus in the Fallopian Tube.

CLELL (*Ann. Hopkins Hosp. Rep.*, vol. IV, 1895, p. 26) describes and figures an S-shaped calculus concretion, nearly one inch long, in a diseased tube. It was composed almost entirely of phosphate of lime. On pressure it was soft and yielding. The patient had been an invalid for many years, and suffered chiefly from some gastric disorder. She had also acquired the morphine habit subsequently to an attack of rheumatism several years before operation. The pelvic trouble is reported as very acute, only beginning about ten days before the parts were removed, the patient catching cold. The temperature at the time of operation was 104°, and the patient was in a state of extreme collapse. An exploratory laparotomy was

performed, and the right tube and ovary were removed. The patient grew rapidly worse during the brief operation, and died seven hours later. No necropsy is reported. There was hydrosalpinx, the tube being also inflamed and the ovary involved.

(178) Vulvo-Vaginal Leucoplakia and Cancer.

At the Congress of Gynecology, Obstetrics, and Pediatrics, recently held at Bordeaux (*Sem. Méd.*, August 21st), E. Monod said that vulvo-vaginal leucoplakia, though much more rare than leucoplakia of the mouth, is practically identical with that affection. Like it, it shows a marked tendency to undergo epitheliomatous transformation, and it is one of the causes of primary cancer of the vulva and vagina. When the condition exists the indication is to remove by way of prevention the affected parts when the limited number of white patches allows that to be done without too great mutilation. Where the lesions are confluent the case should be kept under careful observation, so that surgical intervention may be made at the slightest suspicious appearance. Epithelioma of the vulva and vagina, when it can be definitely recognised, should be completely removed at the earliest possible moment, but the chances of recurrence, either local or in the glands, is very great.

THERAPEUTICS.

(179) The Thyroid Treatment of Psoriasis.

At the French Congress of Internal Medicine recently held at Bordeaux (*Sem. Méd.*, August 17th) G. Thibierge stated that he had tried the thyroid treatment in 11 cases of psoriasis. The substance was given for varying periods from a fortnight to two months in daily doses of from 2 to 8, and exceptionally 12, 16, and 20 g. of fresh uncooked thyroid, and in total doses of 72 to 288 g. The general effects were the same as those seen in cases of myxedema treated in the same way, namely, headache, pains in the limbs, gastric disturbance, tachycardia, asthenia, and loss of flesh. The loss of weight in the majority of the patients exceeded 6 kilos, in less than 6 weeks, and it was not checked by the excessive appetite which the patient showed after an initial period of anorexia. Nevertheless, the doses being equal, these general disturbances were less marked than in the myxedema cases; the author concludes from this that in the latter the effects apparently due to the treatment are in part also due to the disease. The therapeutic effects of the treatment on psoriasis were nil in 3 cases, including the one in which the largest doses were given and thyroidism was most marked. In the other 8 the effect was good, but did not extend to complete cure, local treatment being always required to get rid of the lesions. Therefore, in Thibierge's opinion, the thyroid treatment is not a specific for psoriasis, nor should it be employed as a matter of

routine. It should be reserved for refractory cases in which all the ordinary methods of treatment have been tried in vain, and the effect should be very carefully watched.

(180) Antipyrin in Diseases of Children.

At the French Congress of Internal Medicine recently held at Bordeaux (*Sem. Méd.*, August 17th) Comby stated that antipyrin can be given to children as an antipyretic, an antispasmodic, an analgesic, and to check diarrhoea. The drug is well borne by children of all ages, and it can be given in large doses. Only once in hundreds of cases has Comby seen a slight fugitive erythema caused by the administration of antipyrin. It has never in his experience caused disorder of the stomach or intestine, vomiting, or any ill effect on the kidney. In children suffering from febrile or spasmodic (chorea) diseases, antipyrin should not be given in fractional but in large doses to produce its full effect. According to the age of the patient 25 or 50 centigrammes, or 1 g., should be given at a time; this dose may be repeated two, three, five, and even six times a day. The same doses may be continued for weeks without ill effect. In chorea antipyrin as a rule diminishes the violence and disorderliness of the movements and shortens the duration of the disease. In whooping cough antipyrin has failed in the author's hands. In painful affections and in infantile hyperaesthesia it is unreliable, but Comby admits that his experience on this point is not sufficient to base a final conclusion upon. In fevers antipyrin causes a notable reduction of temperature; it is one of the surest of antipyretics, and may be used without fear. When antipyrin in a sufficient dose does not lower the temperature it is a prognostic sign of ill omen. In the simple diarrhoea of nurslings antipyrin is neither so powerful nor so sure in its effect as in febrile or spasmodic affections.

(181) Action of Antipyretics on the Blood.

At the French Congress of Internal Medicine, recently held at Bordeaux (*Sem. Méd.*, August 17th), Hénocque presented a communication on this subject. He began by pointing out that one of the antipyretics most in use, namely, antipyrin, has a powerful haemostatic action. This property he claims to have discovered in 1884, in the course of some experiments with the drug. The haemostatic action is local and its mechanism is vaso-constriction and retraction of the tissues, with formation of a minute clot which is extremely retractile and aseptic. Antipyrin has also a favourable effect on coagulation. The action of antipyretics on the blood when administered in toxic doses may be summed up as a transformation of oxyhaemoglobin into methaemoglobin. A phase of anaemia or diminution of oxyhaemoglobin precedes the accumulation of methaemoglobin. In this period there is at the same time production and elimination of methaemoglobin; if elimination is

hindered, or transformation is too rapid, phenomena of cyanosis may be produced which must be distinguished from those of the period of intoxication. These various phenomena may be studied haematoscopically, and the influence of antipyretics on the activity of reduction of oxyhemoglobin, that is to say the energy with which changes take place between the blood and the tissues will be recognised, and the influence of antipyretics on the activity of elementary oxydations will be determined.

(182) *Antipyretic Effects of Gualacol externally Applied.*

At the French Congress of Internal Medicine recently held at Bordeaux (*Sem. Méd.*, August 17th) Lannois read, on behalf of Bard of Lyons, a paper on this subject, in which it was stated that the external application of gualacol may be dangerous, first by the sudden fall of temperature which immediately follows the application, and, secondly, by the nervous depression produced by repeated applications. Bard distinguishes the antithermic effect, which is transitory, from the antipyretic effect, which is lasting. In typhoid fever the method should not be employed on account of the long duration of the disease; in erysipelas and in pneumonia, on the other hand, it is very useful. In tuberculosis its effect is very useful. In tuberculosis its effect is favourable only in a certain number of cases of interstitial granular formations without complications, such as suppuration, peripheral pneumonia, etc.—Kondot (*ibid.*) stated that, applied to the skin, gualacol causes lowering of the temperature with profuse sweating, these two effects not always being of equal intensity. It sometimes happens that two or three hours after the temperature has begun to fall it rises again to a high level; this is a reactional pyrexia which must be taken into account. There are indeed cases in which the temperature, instead of going down, at once rises from one-half to one degree. Contrary to what is seen after the administration of other antipyretics, gualacol causes polyuria. It is important to regulate the dose, as alarming hypothermia has been seen in some cases. A solution of 50 centigrammes of gualacol in oil or glycerine should be employed. Applied to the skin the drug is useful in all febrile manifestations of tuberculosis. In fevers both in children and in adults it is sometimes very serviceable, especially in typhoid. The application should be accompanied by the administration of heart tonics.

(183) *Brewers' Yeast in Diabetes.*

At the French Congress of Internal Medicine recently held at Bordeaux (*Sem. Méd.*, August 21st) Cassat stated that he had obtained good results in three cases of diabetes by the administration of brewers' yeast in a daily dose of 30 grammes, although the administration of the substance could not be continued sufficiently long on account of the practical difficulty in summer of

preventing acetous or putrid fermentation. It was taken readily by the patients. The immediate effect was the expulsion, during the few minutes following its absorption, of a very large quantity of gas by eructation; then in the course of the first or second day extremely foetid diarrhoea with abundant gas occurred. After a few days tolerance was established, and the patient felt better than he had done for a long time; his general state improved, his appetite returned, his strength increased, and pain diminished. The weight of the three patients in whom the treatment was tried increased three, five, and eight pounds respectively after the yeast had been administered for a fortnight. The gain in weight was particularly remarkable inasmuch as one of them was phthisical as well as diabetic, and another had diabetes of the gravest type. On discontinuing the treatment loss of weight was soon observed again. As regards strength as tested by the dynamometer an improvement from 12 to 20 kilos. was noted in the right hand, and of 17 to 22 in the left. As regards the urine the urea remained stationary or increased, and the proportion of sugar diminished, in one case by three-fourths, and in another by two-thirds in the fortnight.

(184) *Calf's Pancreas in Pancreatic Diabetes.*

At the French Congress of Internal Medicine recently held at Bordeaux (*Sem. Méd.*, August 21st), Ausset stated that he had given to dogs from which the pancreas had been completely extirpated—as proved by post-mortem examination—calf's pancreas lightly cooked and mixed with the animals' food. The glycosuria caused by the operation always disappeared as soon as the treatment was begun, and this effect lasted as long as the administration of pancreas was continued. The treatment was tried in a diabetic man passing 38 g. of sugar in the twenty-four hours, with more than double the normal elimination of chlorides and phosphates, loss of strength, etc. On the second day of the treatment the amount of sugar fell to 4 g. and the quantity of salts eliminated became normal. On the ninth day the sugar had wholly disappeared and the urine remained normal for more than a month.

PATHOLOGY.

(185) *Death by Lightning.*

Dünck (*Münch. med. Woch.*, July 30th, 1895) describes the morbid anatomy in the case of a man struck dead by lightning. There was an abrasion of the skin on the left side of the forehead where the current entered. There were extensive hemorrhages over the left parietal, frontal, and temporal lobes. Fluid blood was found in the heart and veins. There was hyperemia of all the abdominal organs and chronic enlargement of the spleen, probably malarial in origin. The brain substance was very soft, but without oedema. The author

thus summarises the results that have been found in recorded cases of death by lightning or by the electric current: (1) The blood is deficient in coagulating power, which latter may even be entirely lost. (2) Circumscribed or extensive hemorrhages due to the tearing of vessels in the course of the current are generally present. (3) There is frequently a destruction of parts of organs. (4) The site of the entrance and exit of the current is usually marked by superficial or even deep wounds resembling burns. As regards the figures on the surface of the body further investigation is needed to establish their direct relation to the electric current.

(186) *Effusion and Absorption.*

HAMBURGER (*Vierteljahr. Arch.*, August 5th, 1895) points out the part that limitation of absorption plays in the production of passive effusions. The process of absorption is not a vital but a purely physical process: all tissues, living and dead alike, can take up a certain amount of fluid by imbibition either molecular, where the fluid is taken up by a homogeneous mass—for example, gelatine—or capillary, where the fluid is taken up by the pores of a porous mass for example, porcelain, or connective tissue. Given fluid in a pleural cavity, the cement substance between the cells, or even the cells themselves, take it up by molecular imbibition; then, by capillary imbibition it is drawn into the connective tissue, and thus reaches the lymph stream. This process, however, ceases unless the fluid thus drawn up, be quickly taken into the blood stream, and carried away, for a limited quantity of tissue can take up only a limited quantity of fluid at a time. It is well known that quickening of the blood stream favours absorption, and it is the slowing of the blood stream, which by its purely physical effect in limiting absorption is an important factor in the causation of passive effusion.

(187) *A Test for Distinguishing between Serous Exudations and Simple Transudations.*

RIVALLA (*Ref. Méd.*, April 24th, 1895) finds that if a drop of glacial acetic acid is added to a serous exudate (that is, an inflammatory effusion) a slight white cloud forms in the wake of the falling drop, which precipitate redissolves on the addition of more acid. No such reaction takes place in mere transudation, that is, non-inflammatory fluids. A good way of doing the test is to let fall a drop of the suspected fluid into 200-400 c.c.m. of distilled water, acidulated with 2 to 4 drops of glacial acetic acid. If the fluid is an inflammatory exudate a whitish streak follows the falling drop, and on the addition of more acid is dissolved. Examination of the precipitate shows that it belongs to the class of nucleo-albumina. The author's method presents a clinical advantage, in that a mere drop or two of the fluid (such as can easily be withdrawn with a hypodermic syringe) suffices to provide material for the test.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(188) Cerebral Diplegia of Children.

W. KOENIG (*Berl. Klin. Woch.*, August 19th, 1896) recalls that Freund found a resemblance between the symptoms of cerebral diplegia in children on the one hand, and those of Friedreich's disease and insular sclerosis on the other. As an instance of the occasional diagnostic difficulties in such cases he cites the following case. The patient is a boy, aged 7½, without family history of nervous disease. He was weakly from birth; the labour was protracted, and the mother was ill and suffered from a nervous shock whilst pregnant with the child. At 2 years of age a diagnosis of slight rachitis and imbecility could be made. Did not begin to talk and walk until the age of 4. At present the boy is mentally deficient, and easily flies into a passion. Gait is unsteady and somewhat spastic; he steadies himself by putting his feet apart. Inco-ordination in movements, not increased by closure of the eyes. Some tendency to fall backwards; tendon reflexes, if anything, increased; sensation natural; sphincters not normally; the head is small; no nystagmus. The tendency to make grimaces may be partly due to inco-ordination of the facial muscles. The signs are more marked in the lower than in the upper limbs. Strength in all the limbs is deficient, and more deficient in the right limbs than the left. Speech is somewhat of the "scanning" type. Koenig thinks the case is not one of Friedreich's disease. The absence of nystagmus and the child's imbecility both speak against Friedreich's disease, but still more so the fact that the disease was congenital and not progressive. He considers the case to be one of cerebral diplegia (Little's disease) with two unusual symptoms, namely, the disturbance in the speech and the inco-ordination. Although in some cases the diagnosis of congenital insular sclerosis has been made, it has not yet been verified by post-mortem examination. The family history does not support another diagnosis which might be offered, namely, congenital cerebro-spinal syphilis. Cerebral diplegia may in some cases be due to a bilateral meningeal hemorrhage occurring at birth when delivery is protracted. Such an explanation in this case would account for the imbecility, the muscular weakness, and the spasmodic movements, though with less certainty for the disturbance in speech. The cause of the ataxy remains a puzzle. Disease of the posterior columns of the cord has not yet been noted in cases of infantile cerebral paralysis. Hemorrhage might occur at birth over the cerebellum as well as over the cerebral hemispheres. In Huppert's case of con-

genitally small cerebellum difficulty in maintaining the equilibrium of the body had been noted during life. On the other hand Koenig narrates a case of his own where a girl with typical congenital diplegia died of general tuberculosis at the age of 10; in her case the cerebellum was found to have attained only one-third of what should be the normal weight, though during life disturbance in co-ordination had never been noticed. Koenig thinks that the anatomical basis of cerebral diplegia is probably very different in different children, and that during life it is not to be determined with exactitude.

(189) Dilatation of Stomach Simulating Heart Disease.

HAYEM (*Méd. Mod.*, No. 56, July 13th, 1895) describes a case of acute dilatation of the stomach accompanied by physical signs simulating heart disease. The patient, a man of 42, suffered for two years from severe gastritis with vomiting. No cause could be assigned except that he was in the habit of swallowing the smoke of his cigarettes. On admission to the hospital he was suffering from an acute attack of dyspnoea, 60 respirations per minute. This was accompanied by cyanosis and coldness of extremities. The pulse was regular, 70 beats per minute. There was soft oedema of the legs, pitting on pressure. The abdomen was exceedingly distended, and so painful to the touch as to suggest peritonitis. The stomach was very much dilated and resonant as far as some inches below the umbilicus. The liver was slightly enlarged and displaced downwards. Preordial dullness exceeded the normal limit, notably to the right. On auscultation a rasping systolic murmur was heard in the fourth intercostal space, while at the apex was heard a curious loud humming *bruit*, suggesting the noise made by a mill wheel; this was prolonged and not synchronous with the heart sounds. The urine was very scanty; no albumen; temperature 38° C. The stomach was washed out daily, and at the end of eight days the great distension of the abdomen, hyperæsthesia, oedema, and superadded heart sounds had all disappeared, and treble the quantity of urine was passed. The explanation of the symptoms is a mechanical one. The extreme dilatation of the stomach caused the diaphragm to rest motionless, and this displaced both heart and liver. The lung suffered primarily, the raised tension in the pulmonary artery accounting for the right cardiac enlargement. It is probable that there had existed a paronychiatic gastritis resulting in a gastric ulcer, and giving rise to stenosis of the pyloric orifice. All the signs of an obstruction of this nature being present. Treatment in such cases must be directed to combating the stenosis; if medical treatment proves unsuccessful, surgical measures must be adopted.

(190) Epistaxis and Heart Disease.

GRANDJEAN (*Soc. Méd.*, No. 33, June 23th, 1895) discusses the occurrence of

hysteria in patients suffering from cardiac disease, and illustrates this by two cases under his care. The first, a girl, aged 36, with mitral disease following rheumatism, was for several years subject to attacks of hysterical dyspnoea, fainting fits, and incomplete left hemianæsthesia. The second, a man, aged 40, suffering from aortic disease as a sequel to typhoid fever; there was general right hemiplegia with contractions brought on by walking and subsiding when the patient kept in bed. The right foot was held in the equinovarus position in walking. The thumb and index finger were not affected, and the patient could write and draw. There was complete right hemianæsthesia. The condition is more frequent in men than in women, and usually occurs in young subjects. Every form of hysterical manifestation may appear, but anaesthesia and other sensory troubles are common. There are often neurægias fairly easy to diagnose. Essential pain may present difficulties. When there is no pericarditis nor neighbouring neuralgia, but when great pain and tenderness to touch over the region are complained of, hysteria may be diagnosed. Hysterical dyspnoea may follow a cardiac dyspnoea. The state of the heart and pulse, absence of cyanosis or expectoration must be observed, also the absence of pulmonary congestion. Frequently there are fits or sensations of constriction about the throat, cries or other symptoms not met with in mitral disease. In aortic disease, however, the pain may be true angina. Two cases of this nature were accompanied by anaesthesia; one patient died of an acute attack of angina. Hysterical apoplexy may in cardiac cases be mistaken for coma brought about by cerebral embolus. The attacks are repeated, the hemiplegia becoming more complete after the second or third attack, or appearing several days after the first attack. There are usually accessory symptoms which materially aid in the diagnosis.

SURGERY.

(191) Treatment of Inoperable Malignant Tumours by Injection of Erysipelas Toxins.

FAUSTO CAMPANINI (*N. Pichem.*, July 1st, 1896), following Coley (see *Barrois*, July 6th, 1895 par. 15), has tried injections of erysipelas toxins in two cases of sarcoma, one of the nose and nasopharyngeal cavity, the other of the breast. In the former case he injected ½ c.c.m. of the toxin into the substance of the tumour. Half an hour afterwards the patient had a rigor; the temperature rose to a very high point, only returning to the normal about ten hours after the injection. During the pyrexial period the patient was in a condition of extreme drowsiness, answering questions with difficulty, and complaining of pain in the head, back, and limbs. There was suppression of urine, with intense thirst. The next day a second injection was made, the dose this time

being 1 c.c.m.; it was followed by the same symptoms, but even more alarming. In view of these results and of the fact that no modification was perceptible in the tumour, Campanini sought to attenuate the toxins by exposing them to a very high temperature and diluting them with distilled water (1 c.c.m. of pure toxins in 60 c.c.m. of distilled water). The injection of 10 c.c.m. of this fluid into two rabbits was not followed by any reaction. This attenuated toxin was then used for the patient, 30 injections being given in the course of a month. Although the proportion of toxin was progressively increased, the growth of the tumour was not appreciably checked. Histological examination of the tumour showed that there was no trace of a retrogressive process. The results in the other case were equally negative. Campanini therefore concludes that the treatment is useless, while the serious symptoms which followed the first injections indicated a grave degree of intoxication.

(122) The Infiltration Method of Local Anæsthesia.

At the recent meeting of the American Association of Genito-Urinary Surgeons (*Med. News*, June 22nd) Bransford Lewis, of St. Louis, described the Schleich method of producing local anæsthesia by the use of intracutaneous injections of very dilute solutions of various drugs. The principle of the method consists in injecting intracutaneously certain solutions, and annulling the sensibility of the peripheral nerves by the pressure of the infiltrated fluid, by the anæmia that it causes, and by the comparatively low temperature at which it is injected. The effects are produced by the fluid itself rather than by any particular drug that it may contain. As a matter of fact, the drugs used are of only incidental importance. In his various surgical procedures Schleich found the three following solutions, of graded strength, to answer all purposes: Solution No. 1: Cocaine hydrochloratis, gr. ii; morphine hydrochloratis, gr. j; sodii chloratis, gr. ii; aque destillatæ, ad f3ij. M. sterilisa et adde sol. n-idi carbolicæ (5 per cent.) gtt. 3. The other two solutions are practically the same, the only difference being that in solution No. 2 the amount of cocaine used is reduced to gr. ½, while in solution No. 3 only gr. ¼ of cocaine is employed and gr. ¼ of morphine. Bryson referred to a case in which he had performed complete castration for prostatic overgrowth under cocaine anæsthesia. Of late, in operating about the bladder, he had been inclined to use cocaine in preference to general anæsthesia. He had employed very dilute cocaine solutions, and the results obtained did not impress him very favourably. He would prefer to use cocaine in cases in which it was possible to strangulate the parts by a ligature, and so make sure that too much of the drug will not enter the general circulation too rapidly. Chismore said he has twice performed perineal section under the use of a very

weak solution of cocaine. In one of the cases the patient stated that he felt no pain whatever; in the other, the patient complained very much of pain when the deeper tissues were handled. Lewis, in closing the discussion, said that by the method described one could operate on the deeper tissues and in regions that could not be strangulated by a ligature. It had been employed in performing nephrectomy.

(123) Luxation of the Axis Forward.

BROCA (*Mercredi Méd.*, July) reports the following case. A girl, aged 11, had received a blow directly on the nape of the neck. The injury was followed by paralysis of the upper limbs. The head and neck were placed in a position of flexion, the power of rotation being lost. A transverse projection could be felt in the pharynx. A complete cure was effected by continuous extension made by a weight of 1 kilo. at the head and 2 kilos. at the feet. The author insists on the importance of examining the pharynx with the finger in such cases, and on the superiority of continuous extension to attempts at reduction, which may be dangerous.

(124) Sudden Death on opening a Retro-pharyngeal Abscess.

PIATOT (*Jour. de Clin. et de Thérap. Infant.*, July 11th) reports a case in which a child, aged 14 months, suffering from a large retropharyngeal abscess, died suddenly on an incision being made into it. Rhythmical tractions of the tongue, injections of ether and caffeine, and the application of hot compresses to the chest failed to revive the little patient. Every precaution had been taken to prevent the escape of the pus into the air passages, and on post-mortem examination no trace of pus was found either in the trachea or in the bronchi. There was no œdema of the glottis. Death is believed to have been due to syncope of reflex origin, though the exact mechanism was not apparent. The pneumogastric nerves were, however, pushed back and stretched by the abscess. The case is recorded so that operators may be on their guard against such an accident which the author, however, sees no way of preventing.

(125) The Treatment of Baboos.

At the recent meeting of the American Association of Genito-Urinary Surgeons (*Med. News*, June 22nd) J. K. Hayden, of New York, read a paper on the treatment of suppurative adenitis of the groin by injections of iodoform ointment, which he said had given him satisfactory results. The operative field having been shaved and rendered surgically clean, a few drops of a 4 per cent. solution of cocaine were injected beneath the skin where the puncture was to be made. The pus was then thoroughly squeezed out through a small puncture. The abscess cavity was next injected with pure hydrogen dioxide until the fluid returned practically clear. It was then washed out with a 1 to 5,000 mercuric chloride solu-

tion and injected with a 10 per cent. iodoform ointment. Then a cold mercuric chloride dressing was applied, with the idea of congealing the ointment. The patient should be kept quiet for forty-eight hours, although it was not necessary that he should be confined to bed. The dressings were removed on the third or fourth day. W. K. Otis said he had had considerable experience with this method of treating buboes, and in many instances he regarded it as the best. In most cases he had found that a single injection was not sufficient. Sometimes balsam of Peru was more effective.

MIDWIFERY AND DISEASES OF WOMEN.

(126) Secondary Tuberculosis of the Uterus Involving the External Os.

J. L. REVERDIN and F. BUSCARLET (*Rev. méd. de la Suisse Rom.*, August 20th, 1895) report this case. History: First seen, May 31st, 1892; aged 30; two confinements; since the first, five years ago, has had constant diarrhoea, except during second pregnancy. In February, 1892, copious menorrhagia and metrorrhagia; since then leucorrhœa, with pains in the lower part of abdomen, lumbar region, and groins. Present state: Much emaciated; examination of the lungs, heart, and liver, revealed nothing abnormal; pressure over lower part of abdomen painful; discharge not fetid; uterus anteverted with cervix near the vulva, pointing straight backwards. On it, a soft ulcer placed circularly, its base rose-coloured and covered with very fine yellow points. Behind the cervix in the posterior cul de sac is a hard swelling on either side. The sound passes 9 cm. Under ether the swellings formed by the appendages could be well defined. The uterine cavity and the surface of the ulcer were scraped and a red pulp mixed with little yellow masses was brought away. The bacteriological examination (by Massol) of this tissue, both from the cavity and the ulcer, showed numerous tubercle bacilli. It is rare for secondary tuberculous ulceration of the uterine cavity to spread to the cervix. The hæmorrhage in February, followed by leucorrhœa, was evidently due to the uterine tuberculosis. The woman died on July 26th, 1892, without any recurrence of the hæmorrhage, from exhaustion and diarrhoea.

(127) Vaginal Hysterectomy for Salpingitis.

QUÉNU (*Presse Méd.*, July 6th, 1895) operates in some cases by laparotomy, in others by vaginal hysterectomy. The vaginal method exposes the patient less to the risk of infection; on the other hand, the operator works to some extent in the dark, and a small centre of inflammation may escape being dealt with. There may also be some difficulty in determining whether the lesion is bilateral, the only condition in which hysterectomy is justifiable. Bilateral pain is not in itself a sufficient indication. A good general rule is, if the uterus is movable, to perform lapar-

otomy; the presence or absence of pus is immaterial, and adhesions, if they exist, are usually easily torn away. Many cases of non-suppurating salpingitis are set in the midst of a mass of rigid adhesions, rendering removal very difficult. In hysterectomy the appendages ought never to be left. The position of the uterus and appendages should be carefully ascertained: if they are placed low the operation should be *per vaginam*; if high laparotomy should be preferred. In the vaginal operation an incision is made in the middle line in the anterior or posterior *cul de sac*, as may be most convenient, and the uterus is denuded laterally by the index finger. The uterus is then totally divided in the middle line, and the divided halves seized with forceps and drawn down. By this means the two broad ligaments are drawn down and secured outside, and hæmorrhage is also prevented by the traction. The appendages are then freed in the usual manner. Artery forceps, which would have been greatly in the operator's way until this moment, are now applied from above downwards, three on each side, including the whole of the broad ligament, and hæmorrhage is effectually checked.

(193) Evil Results of Ventrofixation of Uterus.

MACKENRODT (*Centralbl. f. Gynäk.*, No. 28, 1895) removed the uterus from a woman who had undergone hysteropexy for prolapse about a year previously. Dragging and tearing pains were felt constantly, being referred to the site of adhesion of the fundus to the parietes. The patient became more of an invalid than she was before the operation. Mackenrodt therefore amputated the uterus. The supravaginal method was adopted by means of Paquelin's cautery, after tying off and separating the broad ligaments. The cervical canal was cauterised and the stump of the cervix sunk under the peritoneum. This method can be carried out with rapidity.

(194) Mucronated Fetus; Rigidity of Os; Digital Dilatation.

CHARLES (*Journal d'Accouchements*, Liège, July 14th, 1895) reports the case of a primipara, aged 19, who became pregnant after a period in the middle of September, 1894. At the fourth month she felt the movements of the fetus. After the seventh month they ceased, and then milk was freely secreted from the breasts, as often happens when the child dies. In the middle of April, 1895, labour set in, and was very lingering. The uterus for six weeks had ceased to increase in size, but the health remained excellent. Charles found the uterus contracting firmly, and the neck was effaced. The os, however, was quite closed and its lips glued together. Next morning there was no change. The patient was placed under chloroform. Not without difficulty the forefinger was forced into the os; the operator's hand became so tired that it had to be withdrawn. An assistant succeeded in introducing two fingers.

Then Charles resumed the process, and passed three and at length four fingers. The labour was then easily ended. The membranes were ruptured, and the mucronated fetus extracted with the fingers. It was under 10 inches long, and as the cranium was flaccid, dragging on the hair proved sufficient to effect extraction. The placenta came away spontaneously ten minutes later. A solution of sublimate was injected into the uterus. The patient recovered speedily.

(195) Hematosalpinx following Amputation of Cervix.

POZZI (*Gazette Méd. de Paris*, July 13th, 1895) reports a case in which the cervix had been amputated and complete atresia resulted through want of care in keeping the canal open. Double hematosalpinx, due to retained menstrual fluid, was the result. Pozzi removed the appendages through an abdominal wound. Symptoms of suppuration in the uterus set in. The uterus was therefore amputated; as the posterior fornix did not exist, and the body of the organ was retroverted, the operation proved easy. Three injections of antistreptococcal serum were given as serious septic symptoms followed the third operation. Recovery took place, and the patient regained her health.

(196) Gonorrhœa in the Newborn Child.

KORLANK (*Centralbl. f. Gynäk.*, No. 28, 1895) recently showed at a Berlin society an infant aged 14 days with gonorrhœal vulvo-vaginitis. On the fifth day the child showed signs of specific ophthalmia. Bleeding from the vagina took place from the seventh to the eleventh day, and then followed purulent discharge. Gonococci in moderate quantity were found in the secretion.

THERAPEUTICS.

(197) Trional as a Hypnotic and Sedative in Internal Diseases.

SPITZER (*Wiener klin. Woch.*, No. 23, 1895) gives his experience of the use of trional in 25 cases of various forms of disease accompanied by pain and insomnia. In 19 cases trional succeeded. These cases consisted of the following: lumbago, intercostal neuralgia, carcinoma uteri, chronic bronchitis, emphysema (2 cases), myelitis (2 cases), sciatica, mitral stenosis (2 cases), fatty heart, tabes dorsalis, pulmonary and laryngeal tuberculosis (5 cases). In 6 cases trional either failed or acted only for a short time, and had to be followed by morphine; these cases were phthisis (4 cases), myoma uteri and arterial sclerosis. Spitzer maintains that trional is a hypnotic not only in various mental conditions, but also in lung and heart diseases. He states that it is especially useful in intercostal neuralgia, sciatica, lumbago, and in the lancinating pains of tabes dorsalis. He considers it to approach closely to morphine in its effect, and suggests it as a substitute for morphine. Sleep is obtained usually

soon after the administration of the drug, and in most cases continues through the night. In no case was any injurious effect on heart or respiration observed. In a few cases gastric disturbance took place, and sometimes vomiting after awakening; this the author considers an idiosyncrasy, as is the case with morphine.

(198) A New Method of Treatment for Vomiting.

C. L. GREENE (*Med. News*, July 6th) "with considerable diffidence" proposes the following plan of treatment for cases of persistent vomiting which threaten life. He acknowledges that the plan is "crude and undeveloped," and he does not appear to have had an opportunity of testing its value in practice. In order to find an effective method of combating the condition, we must first, says the author, consider the means through which it proves fatal. These are chiefly two—(a) actual exhaustion from the violent and persistent retching; (b) starvation from the lack of power to secure and retain a proper amount of nourishment. Rectal feeding may partially overcome the latter, but in many cases it is impossible to prevent the retching. Whatever may be the cause of the act, whether local or reflex influences excite it, the actual process remains the same, and consists (a) in a slight contraction of the muscular fibres of the stomach itself, bringing about closure of the pylorus and opening of the cardiac orifice; (b) a coincident and vigorous contraction of the muscles of the belly wall; and (c) a rapid and forcible inspiration, with closure of the glottis, which fixes the diaphragm and furnishes a rigid surface against which the stomach is vigorously compressed and thus relieved of its contents. Greene says it appears to be admitted by modern physiologists that unless a stomach be overfull vomiting cannot be brought about in adults without fixation of the diaphragm, and this fixation is dependent upon the rigid ribs and pressure excited by the deep inspiration, and the column of air retained by the closed glottis. If, then, this be correct, and the trachea be opened, the patient certainly cannot vomit, and if patency of the trachea could be secured by intubation, a means of partial or complete control would be had. Acting on this theory, he has had constructed a modification of O'Dwyer's tube; the head of the tube, however, is much greater in height, and there is an opening on its anterior face, or rather its posterior aspect as viewed *in situ*. Applied to the cadaver, this tube fully meets the indications, and would be borne, there seems to be every reason to believe, with little more discomfort than would be caused by a tube of the ordinary pattern. The association between the centre for glottis closure and that of vomiting is so intimate as to suggest the possibility that mere prevention of approximation of the bands would prevent the proper carrying out of the remainder of the act, and if this

were the case the ordinary tube would be the proper one to use. It would seem probable, however, that any closure of the air passage, through whatever means brought about, would admit of the completion of the act, and that it were absolutely necessary to ensure a clear passage for the air, and thus rob the diaphragm of its rigid base of support. The applicability of this method of intubation to severe cases of hiccough or pertussis would also suggest itself.

(294) **The Effect of Onions on Diuresis and Perspiration in Healthy Persons.**

STAWSKI has studied this subject in the clinic of Professor Fasternacki, by experimenting on eight healthy persons from 22 to 35 years of age (*Inaugural Dissertation*, St. Petersburg, 1895; *Sajous's Universal Med. Jour.*, July, 1895). Each experiment lasted six days, and for three days previously the person was under control. The amount administered was from 60 to 100 grammes (1½ to 3½ ounces). Raw onions, to the amount of 100 grammes (3½ ounces), taken with a mixed diet, did not show any distinct diuretic properties, and did not affect perspiration. The weight of the body in five out of the eight cases increased during the experiments as well as afterwards. The quantity of excrements increased, this increase continuing even after the experiments in six out of the eight cases. Raw onions increase the appetite, produce vigour, and afterwards cause temporary inclination to somnolence. They also cause thirst and eructation, increase peristalsis, soften excrement, and favour its easy evacuation.

(295) **The Treatment of Itching in Urticaria.**

ERBLINER, of Aix la Chapelle, recommends (*Gaz. Méd. de Liège*, August 22nd) the following method for the relief of itching in urticaria. The affected surfaces are first wetted with cold water, and then rubbed for ten to fifteen seconds with a minute quantity of common table salt with the pulp of the wetted forefinger. After the friction, a small quantity of oxide of zinc ointment or rice or starch powder should be applied. The application soon causes a pleasant feeling of freshness, the itching diminishes or ceases, and the papules disappear. When extensive surfaces have to be dealt with, the saline frictions should be made gradually over limited areas lest too intense a mechanical irritation be produced. At the same time tepid bathing and appropriate dietetic and other treatment should be employed.

(296) **Treatment of Nocturnal Incontinence of Urine.**

STUMPF (*Allg. Wien. med. Zeitung*, July 9th) thinks the cause of nocturnal incontinence of urine is purely mechanical—namely, the pressure of the abdominal organs, which during sleep often lie above the bladder so that the contained urine presses on the vesical orifice of the urethra. Stumpf removes this

pressure by placing a pillow under the child's pelvis, thus raising it so that it forms an angle of from 130 to 150 degrees with the spinal column as the latter rests horizontally on the bed. A very low pillow is placed under the head. By this simple plan Stumpf cured 12 cases, including one of a woman aged 34; the incontinence ceased the first night it was tried, and although a few relapses occurred, a complete cure was effected in all the cases, so that after six weeks the patients could sleep in the natural position without risk of wetting themselves.

(297) **The Disinfecting Power of the Organic Sulphocyanates.**

MÜLLER (*Centralbl. f. Bakt. u. Parasitenk.*, Bd. xvii, 1895, p. 705) describes experiments carried out by himself with the organic sulphocyanates introduced by Edinger. Edinger brings these substances into a certain relation with bodies produced in man, so as to have in them at his command a medium which will protect against infective diseases or will reduce an infection which has already attacked the organism. Edinger believes that, in addition to certain living processes which take place in the human body, the so-called process of self-disinfection may also be brought about by definite chemical substances. From the fact that in the saliva are a series of ptomaines and also a certain amount of sulphocyanate of potassium, the type of the body to be synthesised was indicated. Of these bodies made by Edinger, Müller investigated three, and found that they had disinfecting properties in different degrees, and were all capable of being introduced into animals either subcutaneously or by the mouth in doses which were sufficiently powerful for disinfection.

PATHOLOGY.

(298) **Solitary Kidney.**

BALLOWITZ (*Virchow's Archiv*, August 5th, 1895) has collected as far as possible all the recorded cases of congenital absence of one kidney. Excluding cases of fused kidney, and of partial atrophy of one kidney, he finds 213 cases of complete absence of one kidney, upon which he bases the following conclusions: Such deficiency occurs almost twice as often in males as in females, a fact which may, however, be partly accounted for by the greater frequency of necropsies on males. As to age, 23 occurred in the fetus or newly born, most having some other congenital deformity, especially imperforate anus; the rest were about evenly distributed up to 70 years of age, after which only 7 cases occurred. Taking all cases together, the deficiency is more common on the left than on the right side; but while in males the left kidney is far more commonly absent than the right, in females the two sides show the defect equally. The renal vessels were generally absent, as also the ureter, on the abnormal side (the latter in all except 15 cases);

the suprarenal was missing in 31 cases. The solitary kidney was almost always normal in shape and position, but much enlarged. Microscopically the enlargement would seem to be due rather to hyperplasia than to hypertrophy. The bladder, except for absence of the opening of one ureter, was generally normal. In a large number of cases there were associated deformities of the organs of generation, especially of the female organs, and these were almost invariably on the side of the renal defect; they affected the conducting portion much more than the glandular portion—that is, uterus, vagina, and Fallopian tubes in the female, and vas deferens or vesiculae seminales in the male, rather than the ovaries or testicles. Finally, he points out the practical bearing of the subject—for example, the probability of calculus causing sudden suppression of urine in such cases, and also the danger of surgical interference; and suggests the possibility of diagnosing the condition by ascertaining the absence of the opening of one ureter in the bladder by means of the cystoscope; and also the likelihood of its occurring where any abnormality of the genital organs is found, especially if this be unilateral.

(299) **Urinary Toxicity in Variola.**

AUCRÉ AND JONCHÈRES (*Rev. de Méd.*, June, 1895) have investigated this subject. In the pathological state the factors influencing the toxic action of the urine are numerous, such as change of diet, disordered secretion, increased or diminished intestinal fermentation, etc. The method of procedure was that proposed by Bouchard. The 8 cases investigated are related in detail. As to the quantity of urine eliminated, it is sufficiently abundant during the eruptive stage; it is diminished during the secondary fever, and increased again during defervescence. Thus two periods of increased quantity are noted, namely, during the eruption and during defervescence, and two periods of decrease, namely, during the period of invasion and during suppuration. The second increase does not always occur on the same day of defervescence. The toxicity of the urine undergoes the same variations as the quantity. During the eruption, it is about normal. It diminishes during suppuration along with the rise of temperature, and remains stationary for several days before defervescence. The toxicity at this period may be very slight. During defervescence it is increased, and may at times become very considerable. The increase is usually most marked about the second day of defervescence. When very marked it lasts but a short time. In case of febrile complications, the toxicity may again diminish. The delirium frequently seen in variola is in all probability a toxic delirium. The uretoxic discharge is to be attributed to the sudden elimination of toxic substances accumulated in the body. In a case of hemorrhagic variola, the curve representing the urinary toxicity falls up to the time of death.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(110) Percussion of the Skull in Encephalic Lesions.

LEVY (*Il Policlinico*, August 15th, 1895) has practised direct percussion of the skull in sixty-seven healthy individuals ranging in age from 6 months to 88 years. On the whole the right side seemed more resonant than the left. The parietal regions were the most resonant, then the upper frontal and upper occipital. Opening or shutting the mouth had some slight influence on the percussion note. Stoppage of the nares and the respiratory act made little modification. The percussion note was louder in children with closed fontanelles than in those whose fontanelles were still open. The most important modifying factor is the thickness of the skull. Percussion in two cases of tuberculous meningitis gave no characteristic result. In one case of craniotabes and in three of hydrocephalus a marked resonance with vibratile trembling was noted in various parts of the skull, but the same sounds may sometimes be heard in healthy children with persistent fontanelles. As the result of experimental injections of fluid into the cadaveric skull cavity the author concludes that it is very unlikely that ventricular dropsy in the adult can ever produce any sensible change in the cranial percussion note; the same remark also applies to hydrocephalus externus, to softening, or cerebral hemorrhage. Nor except in the favourable local conditions (thin and partially separated bones) of young children with hydrocephalus is it possible to recognise any characteristic note. The author has never heard the so-called cracked pot sound in percussing these cases. Experiments directed towards the cause of the note seemed to show that it was independent of air in the adjacent cavities—that, in fact, it was a purely osseous sound. On the whole, given normal encephalic volume and density, the author thinks that cerebral changes, however grave, are never *per se* appreciable by percussion.

(111) Polymyositis with Neuritis.

MAX LEVY-BORN (*Berl. Klin. Woch.*, September 2nd, 1895) relates the case of a strongly made man, aged 52, who at the commencement of August, 1893, began to notice numbness in the fingers when he let his right arm hang down. In the middle of the month the arm began to swell. About August 30th pain was noticed along the inner part of the arm and upper part of the forearm, increased by movements of the elbow-joint; the rest of the limb felt numb. These unpleasant sensations were most marked when the arm was allowed to hang down. After August

28th the symptoms, which until then had been getting worse, began to improve. The skin was bluish-red, and the swelling seemed to be more in the muscles than due to edema of the skin. Sensibility was slightly diminished in the parts of the fingers supplied by the median nerve. In the electrical reactions only a quantitative change was noticed—namely, lessened irritability. There is no history of syphilis or alcohol, but the patient is stated during the previous year to have had "influenza," followed by "rheumatism in the joints" during which a tender swollen patch of about a hand's breadth appeared on the inner side of the left thigh, possibly due to myositis; the skin over this patch was blue and shiny; the patch lasted for about a week. The patient was treated by galvanism massage, etc. On September 30th the arm was less swollen, and the nerves in the internal bicipital groove could be felt distinctly thickened. On October 1st the patient could begin his work again, and on October 9th difference in the appearance of the two arms could still just be made out. In discussing the diagnosis, Levy-Dorn excludes syphilitic myositis and myositis secondary to suppurative or some infection. He does not think the affection was due to mere over-exertion, but considers it to have been a form of disease coming half way between the polymyositis described by Wagener (that is, the dermatomyositis of Unverricht or the pseudotrichinosis of Hepp) and the neuromyositis described by Senator.

(112) Stomach Diseases.

HAYEM AND LION (*Arch. gén. de Méd.*, August, 1895) begin a discussion as to the investigation and diagnostic application of objective signs. Notwithstanding the great advances recently made there are still many difficulties. The subject is divided into the physical and chemical investigation. The objects of the physical examination are to make out the situation, shape, dimensions of the stomach, its structural changes, the ease with which it can empty itself and the influence of adjacent organs upon it. The authors attach great importance to the influence of deformities of the chest as produced by the corset (corset disease). Three varieties of these constrictions producing gastric symptoms are described: (1) The submammary, causing ptosis (enteroptosis of Glénard) and displacement of organs; (2) the hepatic, producing constriction of organs without necessarily ptosis. Here the pylorus may be compressed between the liver and the vertebral column, giving rise to mechanical obstruction; and (3) the subhepatic, leading to upward displacement and respiratory difficulties. The authors then shortly describe the normal gastric functions, including the localisation of the lower limit of the stomach and the duration of digestion. Under the morbid conditions the following are discussed: (1) Premature evacuation of the stomach produced by chronic gastritis, with diminution of secretion and insuc-

clency of the pylorus. (2) Delayed evacuation without dilatation. Here the period of digestion is considerably prolonged. The anatomical substratum consists in a peristaltic anastomosis with hypertrophy and hypersecretion. It may last long without ending in dilatation. The diagnosis is chiefly made by chemical investigation and subjective symptoms. (3) Delayed evacuation with dilatation. Prolonged digestion with slow evacuation is the most common case. It may become the dilatation of the stomach, mechanical obstruction of the stomach, a gastritis with chronic changes, or mechanical obstruction. It is the first cause of the anastomosis between the organ hypertrophy and hypersecretion. This hypertrophy and hypersecretion is atony. Three phases may be recognised: (a) gastritis with atony and digestion, that is, during the day before the stomach is empty and after meal is taken; the stomach thus only becomes empty during the long repose of the night. This produces excessive distension which itself leads to dilatation. Nutrition is generally affected; there is wasting with excess of appetite; (b) phase of active dilatation or dilatation with hypertrophy. The organ still empties itself during the night. The stomach with excessive work to do, presents analogies to the heart in obstructed circulation; (c) phase of atonic dilatation. The stomach often contains more gas than fluid. Atrophy has succeeded hypertrophy. The mucous membrane becomes thinner, and the muscular coat loses its normal structure. Sometimes a stretching of the pylorus with augmentation of the gastro-intestinal angle is superadded. This the outcome of a local peritonitis, which latter is in all probability the result of the gastritis. These adhesions have been looked upon by some (Glénard) as supplementary ligaments, but they do not exist in the child.

SURGERY.

(113) Urinary Infection.

BAXY (*Arch. gén. de Méd.*, June, 1895) relates an instructive case. A man, aged 70, complaining of symptoms apparently of vesical origin, was sounded with negative results. In the evening of the same day a few drops of blood were passed *per urethrum*. Twenty-four hours later he had a severe rigor, which was repeated on the following day. When he was first seen by the author nothing abnormal could be made out locally. The urine was scanty, and contained a small quantity of albumen. The patient had had glycosuria for some time past. He was now thought to be suffering from some infection starting from the urethra. The next day there was a little edema of the scrotum and legs. A swelling then appeared in the perineum, consisting of a perianal phlegmon. Two abscesses appeared, one on the scrotum the other on the penis. When these were removed pus could be made to well up by pressure along the

urethra. Incisions were made, but the patient eventually died. Here there were two periods in the illness, the general symptoms preceding the local. The author emphasises the fact that glycosuria sometimes causes vague urinary symptoms, and draws attention to the dangers of catheterisation in these cases. A point of entry may thus be opened for some infection. In infections starting from the urinary apparatus the lesions are mostly renal. Fever is only one symptom in these infections, and it may be absent. The state of the pulse and respiration is more important. These urinary infections only differ from infections starting elsewhere in the intermittent fever observed in individuals with septic urine subjected to catheterisation. This fever, observed only after micteration, can be explained only by the entry of some pyrogenic substance into the circulation. The evolutions of these infections depends on (1) their place of origin, whether from the urethra, bladder, or kidney; (2) the agents causing them; and (3) the nature of the soil—for example, diseased kidneys. As regards treatment, it is necessary to guard against the stagnation of micro-organisms, hence their evacuation by washing out the bladder, incision, and drainage, etc. The elimination of poisons absorbed must be encouraged through the emunctories.

(214) Tuberculosis and Neoplasm of the Bladder: Surgery or Hygiene?

At the recent meeting of the American Association of Genito-Urinary Surgeons (*Med. News*, June 22nd), L. Bolton Bangs, of New York, read a paper with the above title. He reported three cases of tuberculosis of the bladder, which he stated were typical of many, and in which the hygienic treatment was followed by very beneficial results. Among the many troublesome cases of disease of the bladder one was called upon to treat, none was more difficult than those due to tuberculous infection. At first the symptoms in these cases were often obscure and so similar to those produced by other morbid conditions that the diagnosis was frequently doubtful, and in many even impossible. Later on the clinical picture became so characteristic that all doubt as to the diagnosis was removed. But at this stage treatment could effect but little. But if the disease could be discovered in its incipency and proper measures taken for its relief, it might be regarded as curable, certainly in the sense of being held in abeyance. Vitalisation of tissue was what these patients needed, and they required at least two years of good hygienic residence in a temperate climate; and besides climate they needed occupation. Surgical traumatism produced by overzealous efforts to relieve local symptoms seemed to result in more harm than good. The author also reported three cases of malignant disease of the bladder, in which he stated that a cure also depended upon an early diagnosis. Unfortunately, in these cases many of the early symptoms were overlooked or misunderstood. In con-

clusion, he stated that he had contrasted these two groups in order to present for discussion the points: (1) that cases of incipient tuberculosis of the bladder should be subjected to hygienic rather than to surgical treatment, and (2) that in the incipient stages of neoplasms surgical treatment of the most radical kind should be instituted. J. P. Bryson (St. Louis) said he was entirely in accord with the statements made by Bangs regarding the treatment of the tuberculous cases. In tuberculous cystitis perineal drainage was not to be recommended. In two of his cases the perineal wound became infected and failed to heal. The suprapubic route was altogether to be preferred when drainage is to be resorted to. In cases of vesical neoplasms the symptoms frequently came on late. If the new growth was situated toward the fundus, or at any considerable distance away from the vesical outlet, there was no reason why we should get any symptoms of its existence for a considerable length of time, and the first symptom was likely to be hæmorrhage. G. W. Allen (Boston) reported a case of tuberculosis of the bladder in which the symptoms entirely disappeared under hygienic treatment.

(215) Atrophy of Testis and Prostate after Section of Vas Deferens.

ISNARDI (*Rif. Med.*, June 19th, 1895) showed before the Accademia di Medicina of Turin an old man of 72, whose vas deferens he had divided six weeks before for enlarged prostate. For the last year the man had suffered from advanced symptoms of enlarged prostate rebellious to every treatment. The prostate was much enlarged, and the patient had to put himself into odd positions before he could micturate. Twelve days after operation the symptoms began to diminish, and disappeared in a month. He can now hold his water for seven hours during the night, and pass it voluntarily and without pain. The urine, which was before purulent and blood-stained, is now clear and normal. There is induration over the incision extending down to the epididymis, the testis is diminished, and the prostate impalpable.

(216) The Hysterical Breast.

This is a condition which Gilles de la Tourette (*Journ. de Méd.*, August 10th) considers of much importance, not only because it is a well-defined manifestation of hysteria, but also from the fact that it has given rise to errors of diagnosis and needless removal of the organ. It consists in a temporary enlargement of the breast, with considerable hyperæsthesia of the skin covering the organ. This hyperæsthesia, liable to vary, becomes much more marked during menstruation; there is then also more swelling, and considerable pain is complained of. On palpation at such a time it is possible to perceive one or perhaps two tumour-like masses in the substance of the breast, about the size of a hen's egg, but which are not painful, the

hyperæsthesia being cutaneous. The affection is often of long duration, more especially in those cases where there is faulty therapeutics, as often happens. It seems to depend on a hysterogenous band of hyperæsthesia at the level of the breast, which induces an œdema of the connective tissue of the gland. In this way are produced the local swellings, and even patches of white, pink, or violet under the skin.

MIDWIFERY AND DISEASES OF WOMEN.

(217) Perimetritis from Vulvitis in Infants. MARX (*Revue Obstét. Internationale*, July 11th, 1895) has several times observed symptoms precisely resembling those indicating acute inflammation of the appendages in the adult. A child subject to vulvitis, yet otherwise in good health, is suddenly seized with fever and nausea. Pain is felt in the hypogastrium, radiating along one or both thighs. Frequent desire to micturate and pricking feelings when urine is passing are often felt. Rectal exploration with the little finger shows characteristic deposit on each side of the uterus. Marx finds this physical symptom common, and believes that the tubes are generally involved in chronic vulvitis. In such a case the pain at puberty is very violent, and masturbation may light up old-standing inflammatory trouble. Old lesions of this kind are certainly liable to become acute in young recently married women through excessive coitus. It is quite a mistake to accuse the husband, or to suspect that the wife has recently suffered from specific discharge, in many such cases. The focus of disease has often dated from early childhood.

(218) Lateral Hematocolpos.

MURET (*Sem. Méd.*, May 8th, 1895) reported this case before the congress of Swiss physicians held at Lausanne. A girl, aged 18 years, had menstruated irregularly for some months, and suffered intense dysmenorrhœa. There was an elastic swelling rising above the symphysis pubis, and forming a well-marked prominence in the vagina, the latter being very straight and ending in a *cul de-sac*. On incising lowest part of tumour, about 2 litres of chocolate-coloured blood was evacuated. After this pain ceased, and menstruation became regular. Later, an examination under ether revealed the fact that the vagina was double. That on the right (the seat of atresia) was the best developed; its cavity was divided into two by a diaphragm with a large eccentric orifice; to its left an ovary could be felt. The left vagina, which was naturally open, narrowed considerably above, and ended in an orifice communicating with the right vagina. This coexistence of a single uterus non unicornis with two vaginæ is very rare, and is to be explained by a fusion of Müller's ducts, complete above but incomplete below. It was curious that the best developed vagina was atresic.

The presence of menses before operation was due to the communication between the two vaginæ.

(118) Tetany in Pregnancy.

H. M. THOMAS (*Johns Hopkins Hosp. Bull.*, May-June, 1895) describes a case in a woman, aged 33. There was no sign of the disease in the course of the first pregnancy, but during the remaining six, which occupied the space of twelve years, tetany was constant. The patient was always well during the first half of pregnancy, but afterwards daily attacks set in, and became more violent and alarming with each succeeding pregnancy. For three or four weeks before confinement she had no attacks, and only once during labour did she have spasms, but about a week after confinement she always had a severe attack, except after her seventh delivery. Whilst suckling she was free, except after her second pregnancy, when tetany had occurred for the first time. When menstruation reappeared she was subject to tetany at each period during cold weather, but was free from them in summer. In April, 1894, when she was comparatively well, there was no difficulty in demonstrating Trousseau's symptom, the facial phenomenon, and a very great increase in the electrical excitability of the nerves. Thomas believes that tetany depends on some abnormality in the function of the thyroid gland. The unusual demands made upon this organ in the later months of pregnancy make that condition favourable for the occurrence of the characteristic convulsions.

(119) Puerperal Fever without Localising Signs.

RAPIN (*Sem. Méd.*, May 8th, 1895) reported the following case before the congress of Swiss physicians at Lausanne. A multipara was delivered of stillborn twins by version; placenta removed. At first the lochia were fetid without fever, pain, or gastric trouble. Antiseptic intrauterine injections twice daily. On the 10th day the patient got up and appeared cured. On the 18th to 28th day, high fever and rigors once or twice a day. No localisation possible in any organ. Quinine, alcohol, and wet pack ordered, and on the 30th day uterus curetted. The latter brought away abundant deep granulations of lardaceous tissue. The uterine walls were soft and friable. Temperature fell the same day; one rigor in the evening; after that convalescence was rapid, and the patient was discharged with no apparent lesion anywhere. Rapin believes this case to be unique; it shows the value of the curette even in chronic cases after local signs have disappeared, and proves that the illness was due to septicæmia and not to septic infection.

(120) Alleged Ovarian Gestation.

LARSEN (*Centralb. f. Gynäk.*, No. 23, 1895) describes an instance of ectopic gestation which occurred in a primipara aged 33. The period ceased after August, 1891; on April 10th, 1892 spurious labour

set in. On September 27th, 1892 the sac was removed. It was fairly free, though it adhered to a few coils of intestine; it was connected with the uterus by a pedicle, which included the right tube and broad ligament. Removal was easy. The right ovary was not seen, the left tube and ovary were normal. The patient made a good recovery. The sac contained a flattened macerated fetus which had apparently developed to term, the placenta lay posteriorly. It had opened up the layers of the mesosalpinx, and came into intimate relation with the dilated and obstructed abdominal end of the Fallopian tube. In the anterior, which was the thicker part of the fetal sac, true ovarian tissue was detected, with follicles and ova. No evidence was given to show that the ovary was the primary seat of the abnormal gestation.

THERAPEUTICS.

(121) The Reaction of Sulphonal in the Urine.

LAFON (*Sem. Méd.*, May, 1895) reports the case of a patient who in 1891 was passing 180 g. of sugar in the twenty-four hours, and in whom, after some months' treatment, the sugar disappeared. Some months later he took, during a period of two months, from 0.75 g. to 1 g. sulphonal daily. During this time the analyses of the urine, which were made frequently, invariably showed a precipitate of yellow oxide of copper when treated with Fehling's solution. The same urine examined with the polariscope, with monochromatic yellow light, showed none of that deviation to the right characteristic of diabetic sugar, but a scarcely appreciable deviation to the left. Twenty examinations were made, and always with the same result. This reduction of the copper solution was not, in his opinion, due to any product of the transformation of sulphonal in the system, because a medicinal quantity of sulphonal added to the urine (1 g. per litre) gave exactly the same precipitate.

(122) Treatment of Advanced Cases of Phthisis.

OTIS (*Boston Med. and Surg. Jour.*, June 20th, 1895) summarises the therapeutic agents which are best calculated to alleviate the lingering sufferings of the last stage of phthisis. He calls attention to the frequent presence of sepsis, and holds that all treatment in these cases must be symptomatic. The diminished lung capacity necessitates an airy room, in which sunlight is required as a tonic antiseptic. Feeding is a difficult question; in bad cases there must be frequent administration of easily or partially digested food. The popain, charcoal and bismuth tablet of Wyeth may be of much service. Malt and creasote, with cod-liver oil in the absence of fever, should be given, and alcohol is to be used freely. Fever should not be treated unless causing unpleasant symptoms; inunction of guaiacol reduces the temperature very effectually but is

severely depressant. Rest in bed, with light nourishment and a glass of cognac half an hour or so before the expected rise, has a favourable effect on the temperature. Antipyretics of which phenacetin and sodium salicylate appear the best should be employed if at all to prevent the rise of temperature rather than to lower it after it has risen. Sweating is best controlled by aspirin in doses of 5 grain and upwards. It is free from the after effects of atropine. The distressing cough is due partly to the presence of material in cavities, partly to the irritability of the mucous membranes of the upper air passages. That from the latter cause can be much alleviated, as Dietzweiler has pointed out, by establishing a habit of self-restraint in the patient. Medicinally codeine in 1 per cent. solution is the best agent. The morning paroxysm of coughing is necessary for expectoration of the products accumulated during the night; it can be shortened and at the same time made easy and effectual by administering a glass of some warm alkaline drink with a little brandy or rum in it. Cough from catarrh of the upper air passages is often relieved by local applications. Vomiting may result from digestive disturbances or laryngeal irritation, and will require different treatment in each case. The various pains from which the patients suffer are best relieved by painting equal parts of glycerine and guaiacol over the affected area. Pleuritic pain at the base of the chest should be treated by strapping, as suggested by Roberts. Diarrhoea, when septic, indicates salicylic acid or naphthol; when due to tuberculous ulceration, opium and bismuth, with an astringent; this form requires careful dieting with peptonoids or peptonised milk. Hæmoptysis calls for the same treatment as in early cases; Darenberg recommends the application of ice to the trachea or vulva for five minutes twice a day. Insomnia may be relieved by light nourishment or a little stimulant at bedtime; if these fail, trional or chloralamid are the most satisfactory hypnotics. Edema of the lower extremities can only be alleviated by position, gentle friction with alcohol and water, and wrapping the limbs in cotton wool. The mouth and lips should be cleaned with an alkaline wash. The anæmia calls for iron whenever it can be borne. Otis finds a preparation called pepton-mægan the most satisfactory form for administration. For the cardiac debility strychnine is, as Mays pointed out, invaluable, and is in every way the most useful of all drugs in the treatment of the last stage of phthisis.

(123) Argonin: a New Germicide.

RUDOLF MEYER (*Zeitsch. f. Hygiene und Infektionskrankheiten*, XI, 1895) has investigated the bactericidal action of argonin, and compared it with that of silver nitrate, and also of Schaller's new disinfectant argentamin (ethylenediamine-silver-phosphate). Argonin

(first prepared by Rohmann and Liebreich) is a soluble compound of silver and casein. The solution in water is opalescent when dilute, opaque when concentrated; it is immediately cleared by the addition of ammonia or carbonate of soda. Argonin gives no precipitate with sodium chloride or ammonium sulphide unless the silver is set free from it by previous addition of an acid. Meyer finds that a solution of argonin 1 in 760, has the same bactericidal action on micro-organisms suspended in water as argentamin, 1 in 4,000, or silver nitrate 1 in 3,000; on micro-organisms in albuminous fluids its action is equal to that of argentamin, 1 in 4,000, or silver nitrate 1 in 1,000. The addition of a little ammonia to the argonin solution vastly increases its bactericidal power; exposure of gonococci to a 1 in 30,000 solution of ammoniacal argonin for five minutes completely stopped all growth. Meyer concludes that from the experimental side it must be admitted that this new silver preparation has a strong disinfecting power against certain bacteria, particularly the gonococcus. It does not penetrate very deeply into the tissues; it gives no precipitate with either albumin or casein, and concentrated solutions are neither corrosive nor irritant. The addition of a small amount of ammonia increases the bactericidal power enormously, and causes considerable penetration, but deprives the drug of its bland and non irritating character.

(233) Quinine Hemoglobinuria.

TOMASELLI (*Clinica Moderna* May 1st) describes a class of case found in the subjects of chronic malaria, in which the administration of quinine is followed by symptoms resembling paroxysmal hemoglobinuria. Half an hour or two hours after the quinine is given, the patient is suddenly seized with nausea, more or less marked tremor, and high temperature. He complains of a feeling of weight in the loins, and an imperative need to void urine. When the urine is passed, it is found to be sanguineous. Often there is vomiting, diarrhoea, and finally jaundice. Hematuria alone, without the other symptoms, may be present. The method of administration and the quantity of the drug used seem to have no influence in relation to this curious idiosyncrasy which appears to be more or less transmissible, since several members of the same family showed the same intolerance of the drug. The most important predisposing conditions seem to be malaria and the special idiosyncrasy. Quinine has also been known to cause urticaria, delirium, mania, and vesical spasm when given in malaria; the addition of opium may prevent the latter symptom. In the cases in which quinine causes hematuria, etc., it must be proscribed entirely; even mere rubbing of the skin with the drug has been known to cause hematuria in susceptible subjects. As a substitute the author uses salicin and

Fowler's solution, or alcoholic extract of eucalyptus.

(234) Argonin in Gonorrhoea.

JADASSOHN (*Archiv. f. Dermatol. und Syph.*, 1895) has used argonin in the treatment of gonorrhoea in 200 cases, 72 of which were in men and 128 in women; these embraced all stages of the disease. He considers that, although the gonococcus can in certain instances penetrate into the connective tissue, the disease is in general a superficial one, and lays down two postulates for the treatment of acute gonorrhoea: (1) To kill the gonococci as quickly and completely as possible in every spot where they can be reached; (2) to spare the mucous membrane as much as possible and to avoid increased inflammation, destruction of tissue, and unnecessary pain. His experience convinces him that argonin will not displace the other antigonorrhoeal injections in every case; the indications for the use of silver nitrate, argentamin, and argonin respectively have yet to be formulated. His conclusions as to the last named are these: (1) 1.5 to 2 per cent. solutions exert a rapidly destructive action upon gonococci; (2) strong solutions are devoid of inflammatory or corrosive action, and are hence adapted to the treatment of acute gonorrhoea of the anterior and posterior urethra in men and of the urethra and uterus in women; (3) it appears to lack astringent properties, so that purely anticatarrhal treatment will indicate the assistance of other remedies.

PATHOLOGY.

(235) The Thyroid Body and Graves's Disease.

THE question of the relation of Graves's disease to the thyroid body was discussed (*Sem. Méd.*, August 7th, 1895) before the French Congress of Alienists and Neurologists at Bordeaux. Briessaud reviewed the various theories of Graves's disease: (1) The oldest, that the heart affection is primary, and is caused through the sympathetic nervous system (Trousseau); (2) that the primary lesion is bulbar or central; (3) that the thyroid gland causes the disease by secreting toxic substances; (4) that the disease is only a concurrence of symptoms. The only constant symptom is tachycardia, for the goitre and exophthalmos may be absent, while the coexistence of Graves's disease and simple goitre in the same locality has never been shown to be more than a coincidence. The amount of hypertrophy of the gland is variable and not proportional to the severity of the symptoms, and it is quite contrary to facts to conclude from the anatomical changes that excessive thyroid activity is the cause of the disease, for the author found that of 25 adult thyroids, where no symptoms of Graves's disease were present during life, not one was healthy. The usual presence of goitre has gone against the bulbar theory; but Filehne and Durdafi produced exophthalmos, swelling of the thyroid, and

tachycardia simultaneously by cutting the retractor bodies in young rabbits. If this is confirmed, one must agree that the thyroid function may be vitiated by morbid bulbar impulse, and that this perverted function may again produce symptoms. As regards the internal thyroid secretion, all are agreed that it has an immediate action on the nervous system, and a secondary one on general nutrition. Notkine (*ibid.*, April 3rd, 1895) claims to have isolated from the thyroid body the substance (called by him thyroprotein) which causes myxœdema and its acute complications, the actual secretion of the gland being a ferment which converts the thyroprotein which is collected by, and stored up in, the gland into a useful substance (thyroidin). If Graves's disease is caused by over-activity of the gland there would be, on this hypothesis, no more thyroprotein left, and the organism would be saturated with thyroidin (hyperthyroidism). Renaud (*ibid.*, August 7th), in 1888, had described a lesion which among the variable ones of thyroiditis is never wanting in Graves's disease, whether the gland is hypertrophied or not. This is an intralobular cirrhosis obliterating the lymphatics except quite at the margin of and between the lobules, by reason of which the thyroid secretion passes directly into the veins instead of partly into the lymphatics. This, with the presence of a peculiar type of fever, led him to suppose that the disease was caused by a morbid poison, which normally underwent destruction in the lymphatics. The latter view is supported by the fact that an extract of an adult gland is harmless when ingested, being absorbed in the chyle and passing through the lymphatics. In the foetal thyroid the follicles secrete a mucous substance (thyromucin), in the adult a colloid (thyrocolloidin). This latter is normally produced in all the follicles which are connected with the lymphatics, but in exophthalmic goitre it is only found at the margin of a lobule, the central follicles being poor in thyrocolloidin, or, if freshly formed, filled entirely with thyromucin. This closure of the lymphatics, which in the thyroid take the place of an excretory duct, causes a hypertrophic cirrhosis (*cf.* biliary cirrhosis) with new gland formation of a foetal type. Renaud concludes that the normal function at the periphery of the lobules being maintained is sufficient to prevent myxœdema by pouring thyrocolloidin into the blood. In the centre, however, only thyromucin is absorbed, and this he looks upon as the poison in Graves's disease. In their attempts to produce hyperthyroidism Ballet and Enriquez injected extract of adult thyroid, that is, thyrocolloidin, and it remains to be seen whether Graves's disease could be brought about by injecting extract of foetal gland, that is, thyromucin. This exophthalmic goitre is neither purely of bulbar nor of thyroid origin, the secretion of the gland being controlled by a centre in the medulla (*cf.* diabetes).

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(320) Root Paralysis of the Brachial Plexus.

RAYMOND (*Presse Méd.*, March 23rd) classifies paralysis of the brachial plexus as follows: (1) Simple, limited to such and such a branch, for example, the circumflex nerve. Instances are not uncommon. (2) Complete, of three kinds according to seat of causal lesion (a) where below or beyond the plexus—several simple associated paralyses; (b) where affecting plexus itself, determining paralyses proper of the brachial plexus; (c) where found on this side or above the plexus on its roots. This form constitutes radicular or root paralyses. Paralyses classed under (b) and (c) are total or partial. No essential symptomatic differences exist between total paralyses of the plexus proper and total root paralyses. It is not so when these two varieties are partial. Partial root paralyses are of two clear clinical types, namely, (1) A superior, more frequent, known also as the Duchenne-Erb type. In the typical form of Erb the paralysis affects the deltoid, biceps, brachialis anticus, superior longus. To their paralysis is sometimes added that of the supraspinatus, infraspinatus, clavicular portion of pectoralis major, superior brevis, forming Duchenne's obstetrical type. (2) An inferior type, relatively rare, known also as the Klumpke type. Here the muscles paralyzed are those innervated by the median and ulnar nerves. In Erb's typical form the causal lesion affects the fifth and sixth cervical motor roots, that is, a part of their fibres or those destined for the four muscles mentioned. In Duchenne's obstetrical type a great number or almost all the fibres of the same roots are affected. In the inferior or Klumpke type the lesion concerns the first dorsal pair and oculo-pupillary phenomena coexist. Intermediary forms exist between these sharply marked types. Since a distributory nerve branch derives its fibres from roots distant from each other, paralysis of such nerve is widely different in distribution to that of the nerve roots. Total paralyses of plexus or roots present (1) abruptness of onset, usually traumatic; (2) early appearance of pains in the limb, sometimes fleeting, sometimes permanent; (3) the motor paralysis is contemporary with the pains; (4) anaesthesia, usually total, with the exception of a triangular zone on the inner surface of the arm—the anaesthesia is often deep, affecting the muscular sense; (5) muscular atrophy, when present, starts at the scapular clonure to gain later the arm and forearm; (6) trophic disturbances, namely, oedema, cyanosis of the skin, lowering of local temperature, etc.; (7) in certain cases oculo-pupillary

troubles (myosis, diminution of palpebral slit, retraction of globe, etc.). Partial root paralyses, besides the varying forms of motor paralysis mentioned above, present (8) anaesthesia. In the superior type this coincides with the neuritic pains, and quickly disappears. It concerns three distinct zones: (a) the zone of skin about the shoulder supplied by the circumflex nerve; (b) the external part of the forearm innervated by the musculo-cutaneous nerve; (c) the thumb and index finger supplied by the median nerve. In the inferior type anaesthesia is the rule, occupying more or less the skin innervated by the ulnar, internal cutaneous, or median nerves. As to etiology, cold and lead poisoning are rare causes, traumatism (surgical and obstetrical intervention) most frequent. Hemorrhagic compression has been recorded.

(321) A Curious Gastric Concretion.

PAUL MANASSE (*Berl. klin. Woch.*, 1895, No. 33) reports the case of a man, aged 41. He took alcohol too freely, and last year complained of anorexia, headache, etc., had a coated tongue and slight tremor. His symptoms were attributed to alcoholism, and after a month's treatment he was much improved. Some months, however, later he died of a rapid tuberculosis of the lungs and diaphragm. Besides this the necropsy revealed a deep chronic ulcer of the stomach situated close to the pylorus, and causing adhesion of this part of the stomach to the liver. By the ulcer was found a calculus of flattened cylindrical form, measuring 10 cm. in length, 5 cm. in width, and 4 cm. in thickness, and weighing only 75 g. It was very dark green in colour, of a resinous appearance, showing a laminated structure. Chemical examination confirmed the view that the concretion was of a resinous material, resembling shellac. The patient was a joiner, and Manasse thought that he probably habitually drank some of the alcoholic solution of shellac used in his trade, and that the shellac, precipitated in the stomach, gave rise to the calculus. His master, when asked about it, said that the man had habitually drunk shellac polish, and that he had repeatedly warned him on that account. In this case there was only one concretion, but in Carl Friedländer's case there were many shellac stones in the stomach and intestines, and they gave rise to fatal ileus. It appears that in the case of Langenbuch the two concretions (one in the stomach, one in the intestines) were likewise of shellac.

(322) The Clinical Value of the Phenyl-hydrazin Test for Sugar in the Urine.

WILLIAMSON (*Medical Chronicle*, August, 1905) discusses the clinical value of the phenyl-hydrazin test for sugar, and draws attention to a very simple method of performing the test. A test tube is filled for about half an inch with hydrochlorate of phenyl-hydrazin in powder, then for half an inch with acetate of soda in dry powder; the tube is half

filled with the suspected urine, which is boiled for two minutes. It is allowed to stand, and the deposit examined some hours later. If sugar be present the deposit contains numerous clusters of needle-shaped crystals of a bright sulphur yellow colour. If performed according to the above simplified method, phenyl-hydrazin is a most valuable confirmatory test for sugar in the urine; the reagents keep well. The test is very easily performed, and is very suitable for clinical work. It is very sensitive—more sensitive than Fehling's test and the fermentation test—and will give a distinct reaction with diluted urine containing 0.015 per cent. of sugar. But it is not too sensitive, and gives no reaction with normal urine. If in performing the test the test tube is heated in a water bath the method is usually recommended, the method is somewhat troublesome for clinical work; and by prolonged heating very minute yellow crystals can be obtained in normal urine. Hence the latter method is too sensitive for clinical work. The nature of these minute crystals is somewhat doubtful, but their formation is prevented by the action of yeast on normal urine for forty hours. If the simplified phenyl-hydrazin test gives no reaction with a urine that reduces Fehling's solution, then the reducing substance is not sugar. Many substances besides sugar reduce Fehling's solution slightly (uric acid, creatinine, hippuric acid), but give no reaction with phenyl-hydrazin. Besides the various forms of sugar, glycolic acid and pentose form yellow crystals with phenyl-hydrazin, and also reduce Fehling's solution; but their occurrence in the urine, except as the result of the administration of sugar or in the slightest trace, is exceedingly rare. The great value of the phenyl-hydrazin test (simplified method) is as a negative test. A urine which gives no reaction may be declared quite free from sugar for all practical purposes.

SURGERY.

(323) The Action of Erysipelas Serum on Malignant Growths.

KOPPELHORN (*Wiener klin. Wochenschr.*, 1905, Nos. 33 and 34) has tried the action of three different strengths of serum from sheep inoculated with erysipelas streptococci in 15 cases of malignant disease; 13 of these were carcinomas, 1 sarcoma, and 1 malignant lymphoma. In almost every case the injection was accompanied by violent burning pain in the tumour, often lasting some hours. Severe headache and pains between the shoulder and in the loins were almost the rule; while many of the patients suffered also from joint and pleuritic pains. Erythema, with grave general cyanosis, followed by great weakness, were seldom absent after the injection; in one case two rigors followed a single injection. As a rule injection was followed by a rise of temperature, the highest being 105.5°, the average 101.2°. The rise was usually

with the rigors, but in one case the temperature reached 103° without a rigor. The fever came on half to one hour after the injection, and lasted four to six hours. There was no albumen in the urine. Other occasional consequences were nausea, vomiting, noises in the ears, diarrhoea, palpitation, epistaxis, and dyspnoea. Injection of the primary tumour had no effect on the secondary growths, but rather led to an increase in the size of the glands. Injections into the metastases did not affect the primary growth, but the metastases themselves became a little harder than before owing to an increase of connective tissue. The carcinomatous nests were, however, unaffected. Primary non-ulcerated growths behaved like injected metastases. There was prolonged swelling and tenderness after the injection at the seat of which an abscess formed in one case. In another the tumour broke down, and discharged carcinomatous masses without pus. Ulcerated growths showed well-marked reaction to injection. The base took on a healthy appearance, the stinking secretion disappeared, and the edges became flatter and eaten out. In some cases the whole basis and margin softened, and numerous islets of soft red tissue shot up on the healthy soil. Histological examination of these, however, showed granulation tissue, containing cell nests with perfectly formed cancer cells. The secondary growths were in no instance affected. The only action upon malignant lymphoma was clearing up of a gangrenous ulcer, while a sarcoma of the ilium became larger after injection, and the patient developed sciatica, which had not before been present. Kopsstein hence considers the action of this serum to be purely local, the tumours undergoing alteration only in the immediate neighbourhood of the injections. Even where diminution of the growth occurs, which is mainly in ulcerated cases, no prospect of cure can be held out. He strongly endorses Bruns's view that this new method has not in the least advanced the non-operative treatment of malignant disease.

(432) Actinomyces.

CHOUX (*Arch. gén. de Méd.*, April, 1895) begins a study of this subject. In man the lesions are associated with suppuration, whereas in animals small hard tumours are formed resembling sarcoma. The identity of the micro-organism in these cases has been proved. The lesions in animals occur in association with the lower jaw tongue, pharynx, and respiratory organs. In man they appear most often in the neck. The parasite provokes a round-celled growth, the cells in contact with it undergoing degenerative changes. Thus a small abscess is developed containing the parasite in the form of a yellow granule. It tends to make its way to the surface but also invades the deeper tissues. Cavities and osteophytes are produced in bone. In the lung the lesion is either peribronchial or intrapulmonary. It varies in size from a millet seed up to

a cherry, or even an apple. It may make its way through the pleura and chest wall. The heart muscle and pericardium may be involved secondarily. In the alimentary canal the lesions may be superficial or deep. In the former case the parasite invades Lieberkühn's glands and forms plaques; or it may penetrate deeper, and, in the case of the caecum, simulate an appendicitis. In the abdomen adhesions are formed. Actinomyces may also involve the genito-urinary organs and also the brain. Joints near the disease may also be implicated. Distant or metastatic lesions may occur. The author then begins an account of the various clinical types. The most common manifestation of the bucco-cervical type consists in a hard swelling, beginning mostly in the upper neck, and particularly behind the angle of the jaw in the near neighbourhood of a carious tooth. There is marked induration about it, and fistulae subsequently appear. In the thoracic form the disease may have spread from a neighbouring primary focus or it may be metastatic; most often it is primary. It has been known to penetrate veins, and thus spread by embolism. Occasionally in the primary form acute symptoms have been present at the outset, but more often it begins more gradually, with pain in the side, increasing dyspnoea, etc. There may be signs of effusion; if it involves the apex, it may be put down as tuberculosis. Eventually an indurated patch, which may soften, appears on the chest wall due to the invasion by the parasite. The tendency is to the invasion of all neighbouring tissues.

(433) Trephining in Empyema.

REY (*Gazz. degli Osped.*, July 11th, 1895) recommends trephining through the rib in cases of pleural empyema. Intrapleural antiseptics can be well carried out by this method, and the integrity of the chest walls is better preserved, thus facilitating the re-establishment of respiration on the affected side. The author makes an incision 4 or 5 centimetres long over the eighth or ninth rib, about 6 centimetres from the costal angle, and then applies a trephine with a crown of 1 centimetre's diameter. After the disc of bone is removed the pleural cavity is washed out with sublimate solution and boracic lotion, and the largest possible size of drainage tube inserted, extending 4 or 5 centimetres into the pleural cavity. If necessary, other parts of the same rib may be trephined. The author has had considerable success with this revival of an ancient practice in the treatment of empyema.

(434) The Treatment of Obstruction of the Common Gall Duct.

MCGRAW (*Annals of Surgery*, August, 1895) is strongly opposed to the operation of cholecystenterostomy for jaundice caused by calculi in the common ducts, and holds that though it is easy of performance and gives speedy relief, it belongs to the period of development in

the surgery of the gall ducts, and cannot long retain the place which it now holds. The operation, which has been frequently performed since the introduction of Murphy's button, though it gives relief, fails to cure. The stone which caused the obstruction remains in the common duct, irritating it by its presence, and threatening suppuration with all its dangerous consequences. The adhesion established between the gall bladder and bowel will inevitably produce at times great traction on one or other of these organs, and interfere with their movement and with the performance of their proper functions. Again, the adhesions produced by gall stones are often more serious and cause more disturbance—colicky pains, flatulence, chronic dyspepsia—than the passage of the gall ducts themselves. After the operation, whilst the gall bladder takes on itself the function of the common duct, the latter becomes to all intents and purposes an abnormal gall bladder, which may contain stones and be irritated and inflamed. It is not yet known how long the artificial fistula between the gall bladder and the intestine will remain open and permit the free flow of bile. The tendency of such orifices, it is pointed out, is to gradually contract and close. The only rational procedure in cases of obstruction of the common duct by stone is, the author holds, removal of the obstructing body. If the patient be so exhausted by long-continued jaundice that a prolonged operation is inadvisable, the surgeon should establish a biliary fistula through the abdominal wall, as that procedure would give as much relief as the operation of cholecystenterostomy, without injuring the intestines or establishing new adhesions within the abdomen.

MIDWIFERY AND DISEASES OF WOMEN.

(435) Twin Labour: Placenta Praevia Centralis.

KAHN (*St. Petersburg med. Week.*, No. 16, 1895) relates a very complicated labour. The patient was 23 years old. She had borne one child. Her last period was in May, 1894. Three floodings occurred. On October 30th Kahn found her very anæmic. The uterus reached to the umbilicus, and was contracting; fetal heart sounds were audible; the placenta was presenting. At 11 p.m., severe hæmorrhage having come on, in spite of hot irrigations and the tampon, delivery was hastened. The os already admitted three fingers. In attempting to separate the placenta from its attachments some time was lost, as there were firm adhesions. Kahn therefore pushed his hand through the middle of the placenta. A great quantity of liquor amnii escaped. A male fetus, 7 inches long, was then extracted with ease; the head presented. Then the feet of a second fetus could be felt through a second bag of membranes. Hæmorrhage ceased for awhile, and restoratives were given. A few hours later,

as the patient looked very ill, delivery was hastened. The first placenta still adhered firmly, and had to be separated—a task which proved very difficult. Then a dead female fetus, smaller than the first twin, was extracted. Lastly, the second placenta, adherent to the posterior part of the uterine cavity, was detached with considerable trouble. The cavity was packed with iodoform gauze. The patient rallied, and was warned not to get up for three weeks. On the eleventh day she stepped out of bed and immediately fainted. On recovering, she noticed that her right arm and leg were weak and she could not speak easily. Next day coma set in and ended fatally.

(335) Defective Development of Sternum in a Child aged 3 Months.

HOCK (*Prag. med. Woch.*, July 4th, 1895) writes of a child which was born with an abnormal appearance about the front of the chest. The integuments were sound, but the left lung protruded near the apex, and when the child cried the hernia formed a mushroom-shaped mass as big as a walnut. On examination it was found that the manubrium was entirely wanting. The clavicle and first rib were symmetrically attached to a firm band of fibrous tissue, leaving between it and the body of the sternum a gap through which the hernia protruded. At three months the child was well and fairly developed. The pectorales did not seem to be absent. It appears that deficient development of the upper part of the sternum is rare. In total absence of the sternum the child may survive.

(337) Tubal Abortion and Operation.

PINKING (*Centralbl. f. Gynäk.*, No. 29, 1895) recently exhibited before a German society a specimen illustrating tubal pregnancy which had ended in abortion at the fourth week. The ovum was discovered, quite uninjured, amongst clots in Douglas's pouch, and the ampulla of the tube showed, under the microscope, all the signs of ectopic gestation. Though the abortion was complete, internal hemorrhage was so severe that an operation had to be performed. The patient recovered. This case proves that surgical interference is needed in complete, just as in incomplete, tubal abortion.

(338) Breech Presentation: Rupture of Child's Perineum by Midwife.

SAWICKY (*Pragled. Chirurgien*, vol. II, part 3, 1895) writes of a breech case which the midwife mistook for a vertex presentation. After a few hours the child was delivered, the breech coming first. A rupture of the perineum was detected. A month later Sawicky was consulted, as the child suffered from incontinence of urine and feces. There was the usual eczema, with cystocle, constriction of the perineal rent, a very patulous vaginal opening, and slight prolapse of the rectum. The anus was involved, the rent extending through the external sphincter. The

eczema was cured and then the parts repaired by Tait's operation. The anterior part did not unite, so the vulva still gaped whilst the posterior part of the perineum and the anal ring assumed their normal condition. There was no more incontinence of urine or feces. The mother had been normally delivered eight times before, the vertex presenting on all those occasions. Laceration of the child's perineum occurs sometimes in breech presentations—which was not suspected at first in this case owing to the previous history—through the child's anus being mistaken for the mother's or uteri, and dilated in consequence by the finger of the midwife.

THERAPEUTICS.

(339) Sulphonal, Trional, and Tetralon.

BRESSLAUER AND JOACHIM (*Centralbl. f. d. gesammte Therapie*, August, 1895) compare the value of these hypnotics: (i) Sulphonal has certain disadvantages. Its action is slow, owing to its being nearly insoluble, and sleepiness rather than sleep is produced. After long use (1) vomiting and constipation; (2) ataxia of the lower limbs with paralyzes and muscular spasms; (3) anuria, ischuria, and hematuria have been observed, some of these cases ending fatally. The authors have had no bad results since they made a rule never to give it for more than three days in succession, in doses not exceeding 2 g. *pro die*, and to regulate the bowels and kidneys. It should be exhibited always in hot water (tea, etc.) in as good solution as possible. (ii) Trional acts excellently in neurasthenic insomnia, chronic and periodic mania, etc. The authors (contrary to the experience of many) have had good results also in melancholia, and hallucinations accompanied by violence, even 0.5 g. having a sedative effect. Experiments have shown that animals can be poisoned in exactly the same way as with sulphonal, and in man up till now 4 cases of poisoning (2 fatal) have been recorded. Its action is cumulative and delayed from 15 minutes to 3 or more hours after administration, but this is not nearly so marked as with sulphonal. Sleepiness continues in some cases during the next day and even night. Symptoms of poisoning were observed in a number of cases after continued administration, namely, dulness, giddiness, headache, anorexia, obstinate constipation, ataxia of the lower limbs, and sometimes oliguria or even strangury. Noises in the ears, cutaneous hyperaesthesia (Friedländer), any marked action on the heart and respiration or epigastric pain (Koppers, Römer) were never observed. Such transitional cases lead up to the more marked ones of chronic poisoning, where the symptoms are very like those of sulphonal poisoning, ending in hematuria, hyperemia, hyperemia of the urine, and death. Reinecke recently reported a case in which 40 g. spread over three months, caused

severe poisoning. The fact of this idiosyncrasy makes the following rules necessary: (1) Trional must never be given continuously in larger doses than 1 to 2 g., and always in a large quantity of warm fluid—soup, tea, etc.—in which it is readily soluble. (2) After administration for four to six consecutive days, breaks of several days must be made. (3) The patient should take some natural alkaline mineral water during the course. (4) Constipation must be corrected. (5) If hematuria be present, the drug must be discontinued at once, diuretics and free evacuation of the bowels obtained, and the blood neutralized with 4 to 6 g. sodii bicarb. *pro die*. If these precautions be taken, trional is one of the best and relatively safest hypnotics. (iii) Tetralon has all the disadvantages of sulphonal without its power, its action being more sedative than hypnotic. If given, all the precautions necessary for sulphonal and trional must be taken.

(340) Administration of Thymin in Euphthalmic Goitre.

R. H. CUNNINGHAM (*N. Y. Med. Record*, June 15th) gives three cases of euphthalmic goitre in which a diet of thymin produced good results. Case 1.—Miss B., aged 20, first seen October 2nd, 1894, had been told by several physicians that she had Basedow's disease. Her immediate complaint was of weakness and insomnia. Her hereditary history was noteworthy. Her deceased father had prominent eyes, suffered from insomnia, and died of pneumonia two years ago. Her paternal aunt had prominent eyes and a slight swelling in the neck, had complained much of palpitation and general weakness. Her death was said by the doctor to be due to "heart trouble." Miss B.'s brother, aged 25, has prominent eyes, but is strong and active. Except for measles Miss B. enjoyed good health until two years ago. Shortly after a great grief she began to suffer from palpitation on slight exertion. Next the eyes gradually became prominent, but insomnia has only troubled her for a year. She also complains of mental depression, loss of energy, excessive right-sided sweating at night, sensations of flushing, tremor of the hands, and occasional headaches. The appetite is poor, the bowels constipated. On examination euphthalmia is present in fair amount, both Von Graefe's and Stellweg's symptoms being present. Slight increase in convergence. Apex beat 124, strong, regular, no displacement, not much evidence of hypertrophy. Thyroid moderately enlarged, soft, compressible, a moderate knot over it. Slightly anemic, red corpuscles 4,000,000 per c.mm., haemoglobin 60 per cent. Thyroid tablets (5 gr.), one t.i.d. were given, and trional for the insomnia. October 4th. Feels worse, has slept no better. Heart beats increased to 136, irregular at times, respirations 28. The thyroid tablets were omitted, and fresh lamb's thymus given, minced fine and taken raw. October 10th. Has taken

the gland slightly broiled, as taken raw it produced sickness. Heart now 120, regular, respirations 20. Has slept better, no other change. October 20th. Has slept well for the past few nights (without a hypnotic), has taken the thymus raw for three days without nausea. Pulse 100, respirations 18. March 10th, 1895, feels as well as ever; the neck swelling has gone, is not tired by considerable exercise. Pulse 72, is sleeping well. Eyes no longer prominent, colour has returned to cheeks. Case II was irregular over his treatment, but improved in many respects. He presented lessened energy, severe insomnia, palpitation, fatigue, and moderate dyspnoea on slight exertion, prominent eyes with lagging upper lids on looking downwards, slight horizontal nystagmus on rapid convergence, slightly enlarged thyroid, pulse 100 to 110, a well-marked, fine-waved tremor of the hands. These symptoms had increased progressively for four years. After an irregular administration of slightly cooked lamb's thymus for two weeks, the pulse fell to 78, and perfect regularity. Slept better and felt stronger. Eyes much less prominent. Von Graefe's symptom obtained only by searching examination. Later still the eyes were apparently normal, pulse 76, capacity for hard work greatly increased, tremor of hands quite gone. In Case III, presenting the usual symptoms, 12 to 15 thymus gland (5 gr.) tabloids per day were given, with great improvement, especially as regards the ocular symptoms and enlarged gland.

(241) *The Treatment of Chronic Constipation without Medicine.*

J. SCHREIBER (*Wien. med. Presse*, Nos. 21 and 22, 1895) calls attention to the great change in the treatment of chronic constipation during the last ten years. Before he had adopted the mechanical treatment he was unsuccessful in relieving 10 per cent. of his patients; since then he has had only three failures in 100 cases. His course of manipulation extends over six weeks to three months, and consists in systematic massage of the large intestine for 8 to 10 minutes daily. A considerable amount of power is employed, and the rubbing and pressure are directed by anatomical considerations. The cure is assisted by gymnastics and exercise; if necessary, mild aperients may also be employed. The diet also is carefully regulated. Before massage is begun the absence of floating kidney, uterine or ovarian disease must be ascertained. Schreiber distinguishes four forms of chronic constipation: (1) in strong, healthy, often young patients; due to hereditary predisposition or sedentary life, or to no ascertainable cause; (2) from the endless forms of digestive disturbance; (3) in patients weakened by neurasthenia or anemia; (4) in the corpulent. In all these the mechanical treatment is the most certain means of cure. It is of the greatest service in the first form. In the second it will not succeed unless combined with severe

and rigid dieting. In neurasthenic cases it must be associated with the means usually employed in the treatment of that disorder, such as change of air, distraction, wet packing, electricity, mental influences, and pleasant occupation. The treatment of chronic constipation by purgatives and enemata undoubtedly lessens the suffering, but at the same time depresses the energy of the intestinal muscles; the longer medical treatment has lasted, the more difficult and tedious will be the mechanical cure.

PATHOLOGY.

(242) *Changes in the Blood in Syphilis.*

JUSTUS (*Wien. klin. Rund.*, June 16th, 1895) gives his views on this subject, and compares them with those of Semmola. In 1889 Semmola advanced the following propositions: (1) Constitutional progressive syphilis not treated with mercury causes a diminution of hæmoglobin and of red corpuscles. (2) If a syphilitic person in whom this diminution is observed is treated with mercury, from the first day of treatment there is an increase of hæmoglobin and of red corpuscles. (3) If, however, the mercurial treatment is continued longer than necessary, so that the mercury loses its specific power, its toxic action will produce a diminution of hæmoglobin and red corpuscles. (4) If mercury is given to a healthy subject, there appears to be a rapid diminution of hæmoglobin and red corpuscles. Justus comes to the following conclusions: (1) In untreated syphilis the hæmoglobin is more or less diminished, and this diminution varies with the severity of the disease and its tendency to spontaneous recovery. (2) A sudden diminution of hæmoglobin follows inunction or injection of a large dose of mercury. (This is directly contradictory to Semmola's statement.) (3) The diminution caused by mercury varies according to the severity of the disease and to the condition of nutrition; with injections of mercury the fall of hæmoglobin can be repeated after several injections. (4) The cure of the syphilitic lesions begins when the fall of hæmoglobin ceases, and is followed by a rise. (5) The sudden fall of hæmoglobin due to mercurial treatment is a specific peculiarity of the blood of syphilitic persons only, and does not take place in healthy individuals or in other diseases. (6) This specific reaction of the blood is established at the time when swelling of the gland occurs; it disappears at the time when the existing syphilitic lesions attain the height of their development. Justus concludes that a specific change occurs in the blood of syphilitic persons, and this points to a specific means of treatment applicable only to the blood of syphilitic individuals. This specific condition of the blood, established by the action of mercury, precedes the affection of other organs, and the disappearance of this specific reaction, or the involution of the specific blood

change, occurs before retrograde changes appear in other organs. If syphilis is not treated the evolution of the fall of hæmoglobin, and also the slow increase of the same afterwards, are seen: if the disease is treated the fall of hæmoglobin is greater and more sudden, and the rise is also quicker. The cure by mercury is in all cases not absolute, but only varies according to the duration of time. The application of the above statements to the diagnosis is as follows: In doubtful cases and in cases of late syphilis with a fresh train of symptoms, a diminution of hæmoglobin, after inunction or injection of mercury, is characteristic of syphilis.

(243) *The Microbe of Scruvy.*

THESTI AND BERI (*Gazz. degli Osped.*, August 10th, 1895) have succeeded in isolating from a piece of scorbutic gum a micro-organism, which they believe to be the cause of scruvy. The microbe stains in all the aniline dyes, resists Gram's stain, is perfectly round, and generally united with one or more of its kind. Its culture renders gelatine fluid, and gives rise to a sand-like deposit. Inoculation of these cultures into guinea-pigs and rabbits gave rise to fever, and the necropsy showed hemorrhagic stains in various parts of the body, and nodules of connective tissue new formation. Experiments were made in four cases, and in three out of the four the above mentioned results were obtained; in the fourth case the authors attribute their negative results to the fact that the patient had improved considerably under treatment. The difference found by the authors differ considerably from any that are usually present in the oral cavity of man.

(244) *Modifications of the Colourless Blood Cells inside the Blood Vessels.*

MARQUEVITCH (*Arch. d. Sci. Biol. publiées par l'Institut. Imp. de Med. Exp. à St. Petersburg*, vol. III, 1895, No. 5, p. 428), by connecting the two sides of the heart with a cannula passing from the right subclavian artery to the right subclavian vein and ligaturing the carotids, vertebrals, and the aorta beyond the origin of the innominate artery, was able to confine the blood to the pulmonary circulation, and therefore cut it off from the hæmatopoietic organs. By removing blood from the right carotid at intervals and counting the numbers of the various kinds of colourless blood cells, he was able to conclude that the numerous varieties described by Virchow, Max Schultze, Hayem, Ehrlich, and many others are but stages in development. Thus he found that the young forms diminish, while the adult (large mononucleated cells of authors) increase in numbers. The old cells (polynucleated) increase in numbers, but not sufficiently to account for the variations in the other forms; they must therefore undergo, in part, disintegration. The effects of oxygen, tuberculin, chloroform, and warming were also investigated.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(144) Spastic Cerebral Diplegia.

OPPENHEIM (*Berl. klin. Woch.*, August 26th, 1895) narrates two cases showing inheritance of the affection known as spastic cerebral diplegia or bilateral athetosis. The mother, aged 31, has shown signs of the affection from early life, probably from her birth. She has weakness together with rigidity and athetosis of both sides, as in the affection on which Clifford Allbutt and many others have written. In her case, however, a peculiarity is that the parts supplied by the cranial motor nerves (the oculomotor nerves excepted) are more paralyzed than other parts of the body; articulation, phonation, deglutition and mastication are all affected. She can hear and (a noteworthy fact) is intelligent, but is absolutely dumb. She cannot voluntarily utter a sound, even when pricked with a needle, but under the influence of emotion, as in crying or laughing (psychical reflex acts) sounds are given forth. She can close her eyelids, but not with any degree of force. She cannot point her lips as if to whistle. She can open her mouth, but with difficulty and with exaggerated grimaces. Saliva often dribbles from the lips. She cannot spit out. The movements of the tongue are very limited. Mastication takes place with difficulty, and movements of the head evidence the difficulty in swallowing. The muscles of the lips, tongue, etc., are not wasted, and the electrical reactions are normal. The movements of the eyes are natural. She has not learned to read or write. The athetoid movements in the upper extremities are best marked when the hands are open, almost absent when they are closed. The spasticity in the lower extremities is great, and she walks with the feet in the position of talipes equino-varus. The spinal column is deformed, probably owing to weakness and contracture of the muscles of the back. The sphincters are not affected. There is apparently anaemia, but the other senses are normal. Oppenheim is satisfied that her intellect is not weak. She learned to walk at 6 years of age, and walked as she does now. She had epileptic-like attacks when she was 9, but they have not recurred since then. The second patient is a girl aged 10, the natural daughter of the first patient; she suffers in the same way as her mother, but in a lesser degree. She learned to talk last year, but her speech resembles that of bulbar paralysis, and she accompanies it with grimaces and movements of the whole body; her gait is also less spastic than that of her mother, and there is no talipes equino-varus. Like her mother she is intelligent. Oppenheim says

that what one finds as anatomical basis for this affection may be enumerated as porencephalus, diffuse atrophy, sclerosis, and, though seldom, microgyria. This year, at the necropsy of an analogous case, in which there were also the symptoms of a bulbar paralysis without atrophy, he found porencephalus and microgyria. There was defect of development in both cerebral hemispheres, especially in the Rolandic areas and their neighbourhood, but the defect was most marked in the lower part of these areas, where the centres for the face, etc., are situated.

(145) The Diagnosis of Diphtheria.

LANDOUZY, at the Académie de Médecine (*Presse Méd.*, August 3rd, 1895) read a paper insisting on the necessity for examining all sore throats bacteriologically. Clinically it is almost impossible to distinguish many of the forms—for example, the herpetic from the diphtheritic. Cases are quoted where the clinical diagnosis was diphtheria, but bacteriologically only staphylococci, streptococci, or pneumococci were found in the exudation. The results of 860 cases investigated thus are given: In 364—that is, in 42.3 per cent.—Loeffler's bacillus was found, and of these 260 showed pure cultivations of Loeffler's bacillus, 25 contained an admixture of streptococci, 70 contained an admixture of staphylococci and other cocci. Of the cases in which Loeffler's bacillus was not found a few showed pure cultivations of streptococcus, but the majority showed a mixture of various micro-organisms. A further difficulty in the clinical diagnosis occurs where faucial syphilis simulates diphtheria, and the difficulty is increased when it is suggested that probably the two conditions may be combined. It is in such cases that the value of bacteriological investigation is seen.

(146) The Health of Workmen in Calson.

A CALSON is a modified diving bell, by means of which workers on the bed of the water can have direct communication with the external world. The atmospheric pressure in the workroom and shaft is proportional to the depth below the surface. Investigations, at present incomplete, into the health of the workmen employed in such a calson, to ascertain the effects of pressure, were begun by v. Schröter, Mager, and Heller in February, 1894, when all the workmen were thoroughly examined (lungs, heart, ears, urine, and blood) (*Wien. klin. Woch.*, June 27th, 1895). Since then they have been kept under constant observation. Results: As long as the pressure did not exceed 1.5 atmospheres, no symptoms appeared beyond slight pains in the joints and temporary noises in the ears. If greater than this, the following symptoms, with few exceptions, beginning suddenly a quarter to one hour after leaving the calson perfectly well, were noticed: 1. The ears. Permanent noises in the ears, hemorrhages into the tympanic

membrane or tympanum, and sometimes Meniere's symptoms. Some degree of deafness was present in all these cases. 2. The extremities. Violent pains with no objective signs, or with tenderness along nerve trunks, or with uniform swelling and oedema of one or more limbs, or with exudation into the joints, or, lastly, darting joint pains especially in the knees of such intensity that the men felt as though struck by lightning; this was often accompanied by a feeling of numbness in the limb. All the above symptoms usually vanished in three to five days. The most serious cases began either with sudden loss of consciousness, often lasting some hours, without much cyanosis or dyspnoea, or with the latter, in which case they soon ended in collapse and death. Post mortem in one such case oedema of the lungs was present.

SURGERY.

(147) Castration for Prostatic Enlargement.

A. H. LEVINGS (*Philadelphia Med. News*, August 17th) reports two cases of bilateral castration for enlargement of the prostate. (1) A man, aged 77, had had recourse to the catheter eighteen years before, and had had thirteen years of complete catheter life. During the last year of catheter life, it became impossible to pass any instrument into the bladder. Suprapubic cystostomy was then performed, and an artificial urethra established. For three or four years after this his condition was fairly satisfactory; then he began to suffer great pain, the cystitis became worse, and the prostate was found to be constantly increasing in size. Castration was performed on May 14th, 1895, at which time the prostate was as large as a coconut. Thirty-six days afterwards the patient passed a small stream of urine by the urethra, the first time for eighteen years. He had continued to do so, with increasing size of stream, up to the date of report, and so far as could be determined by rectal examination the prostate had diminished by about one half, while the cystitis was much improved, and the severe pain had practically ceased. (2) A man aged 64, had had seven months of catheter life, and was also the subject of tuberculosis of both testicles. Castration was performed on June 23rd, 1895, and in two weeks the man was walking about the hospital, almost wholly free from pain; the urine had become acid and almost clear; the catheter was no longer necessary, and the residual urine had entirely disappeared. On July 15th, by rectal examination, the left prostatic lobe was scarcely to be felt, while the right was much reduced in size. The patient was discharged in excellent condition. Levings concludes as follows: "It would seem that after castrating thousands upon thousands of women in the prime of life, often, I fear, upon the slightest pretext, it is hardly consistent to hold up our hands in horror at the idea of castrating some men at an advanced age for the relief of an other-

wise incurable and most distressing condition, if the operation should offer a reasonable hope for a permanent cure."—At the meeting of the American Association of Genito-urinary Surgeons J. B. Bryson (*Med. News*, June 29th) reported the following case: A man aged 74 first showed evidence of beginning prostatic atrophy at the age of 35. When he came under observation there were 6 ounces of residual urine and marked diurnal and nocturnal frequency. Cystitis and pyelonephritis developed. Two separate attempts to enter upon catheter life failed on account of the great difficulty of entering the bladder and the recurrence of cystitis. Dilatation of the heart and pulmonary emphysema supervened. Complete castration was performed four months ago. This was followed by a marked and satisfactory diminution of the enlarged prostate, without change in the frequency of urination, day or night, and with but a slight decrease in the amount of residual urine. The pyuria and pyelonephritis remained practically the same as before the operation. Hayden also reported a case of double castration for prostatic hypertrophy in which there was marked relief of all the symptoms and the general condition was greatly improved. A. T. Cabot said he was inclined to believe that the early good effects which followed the operation were largely or partly due to the diminution of the blood supply to the prostate. He reported a case in which he had performed double castration and litholapaxy at one sitting. The patient, aged 75, was in a rather shaky mental condition. After the operation he became maniacal. Great improvement followed the injection of testiculin. E. Martin had seen a number of J. W. White's cases, and could confirm his statements as to the good effects of castration. He reported a case of his own in which the operation had given a very satisfactory result. Belfield pointed out that it evidently failed in many instances, and he would be unwilling to perform it until he had had his finger in the prostatic urethra. He had seen three cases in which the operation was urged, and in which stone was found in the bladder. E. E. King, of Toronto, said that in the two cases of double castration reported by him, and included in White's statistics, death could not be attributed to the operation itself. The first patient died of pneumonia on the fifth day. At the necropsy the prostate was found to be reduced in size about one-half, and its glandular and stromal elements showed evidences of shrinking. The second patient died on the thirteenth day, and the necropsy revealed a pyelonephrosis. In both cases there was a marked improvement in the urinary symptoms. Glenn expressed the opinion that prostatic hypertrophy was largely the result of early gonorrhoeal infection. In the one case of double castration—included in White's list—in which he was the operator death could not be attributed to the operation.

(449) The Surgical Treatment of Meningitis.

MANNOTTI (*Il Policlinico*, August 1st, 1895), experimenting on dogs with regard to the above subject, concludes that after weak subdural injections of sublimate solution (1 in 4,000) tuberculous meningitis may not only be alleviated, but completely cured. Moreover, the involution of meningeal tuberculosis may be verified even if treatment be carried out at an advanced stage of the disease, and results in the development of more or less firm adhesions between the dura and the pia mater. The mechanism determining involution seems in many points identical with that observed in peritoneal tuberculosis. The superficial underlying cerebral cortex appears to undergo slight atrophy, but the experiments are not as yet sufficiently prolonged to say what the ultimate condition of the cortex will be. The sublimate solution apparently does not act merely as an antiseptic, but probably by setting up inflammatory reaction. In acute suppurative meningitis the injections seemed of no advantage. About 1 or 2 grammes of warm sublimate solution were used at each injection.

(450) Carcinoma of the Displaced Cæcum.

HANS FÄSSLER (*Berl. klin. Woch.*, August 26th, 1895) relates the following case observed in Curschmann's clinic. A man, aged 60, was admitted with marked cachexia and symptoms of intestinal obstruction. As there was no evidence of the obstruction being due to syphilitic or tuberculous stenosis or adhesions producing kinking, or to a palpable tumour, a growth in the intestinal wall was diagnosed. It was localised by Curschmann in the right flexure of the colon owing to the situation of the distended coils. No definite tumour could be felt, but a resistance was made out in the right loin. Operation was advised, and the abdomen opened in the right hypochondriac region. The growth was found here apparently situated in the hepatic flexure. Resection was not attempted, owing to metastases, etc. An artificial anus was made, but the patient died. At the necropsy the growth was found in the cæcum, which was displaced upwards. There was a total absence of the ascending colon, the cæcum passing directly into the transverse colon. There are, according to Curschmann's previous researches, two forms of displaced cæcum, namely: (1) in which the colon is of normal length or even increased in length. Here the cæcum is so twisted that the fundus is directed towards the diaphragm and covers in a part of the ascending colon; or (2) the ascending colon is congenitally short or absent. The latter was the case here. The case shows that the clinical localisation of the tumour may be influenced by the dislocation of the cæcum. Malignant growths in a dislocated cæcum have not in the author's knowledge been described. The possibility of a growth as well as of perityphlitic processes in a displaced cæcum should be borne in mind.

MIDWIFERY AND DISEASES OF WOMEN.

(451) Evisceration in Protracted Cross-Birth.

MERMANN (*Centralbl. f. Gynäk.*, No. 36, 1895) relates 5 cases in which he found evisceration sufficient to allow of speedy extraction, when transverse presentation had rendered labour dangerously long. All recovered but the fifth patient, who died on the tenth day of pneumonia, attributed by her family doctor to some accidental chill not associated with delivery. The first patient was a primipara, aged 29. The membranes had ruptured five days before delivery; the child had been dead at least a day; turning could not be effected. After evisceration turning proved easy, and the exhausted patient recovered. The second case came under Mermann eighteen hours after the membranes had been ruptured by the midwife, who applied a tampon as there was flooding. The right arm was prolapsed and oedematous; the shoulder impacted in the brim; the cord much prolapsed, swollen, and livid. The mother's abdomen was tympanitic. The uterine contractions were very painful, the temperature over 100°. After an attempt to turn, evisceration was performed, and a large child extracted by pulling with the finger hooked into the thorax. The patient recovered after an attack of parametritis. In the third case the waters had escaped seven days before delivery, and the child had been three days dead. Version had been attempted several times in vain. After evisceration the child was seized round the abdomen (as in Case 1) and turned, and delivered with ease. In the fourth the shoulder of the dead child was firmly impacted in the contracted pelvic brim, and the waters had slowly dribbled away. The scissors used for the funis served for evisceration; the child was then delivered by traction on the arm; recovery was rapid. In the fifth (noted above as a fatal case) both arms were prolapsed, and the left shoulder impacted. The waters had escaped three days before delivery. Attempts to turn had been made with the aid of chloroform. Evisceration was undertaken, and the child extracted by pulling on the interior of the thorax. The patient died well till pneumonia set in.

(452) Dystocia from Double Monster.

DULORAY (*Bulletins de la Soc. Anatomique de Paris*, April, 1895) attended the labour of a primipara, aged 20. The period ceased on August 20th, 1894. On March 12th Duloray diagnosed hydrops amnii, suspecting twin pregnancy. On April 10th labour began. Duloray found the os well dilated and a head presenting, second position. He fancied that he heard foetal heart sounds, but it proved afterwards that the twins had been dead for a fortnight. After several hours' dystocia the waters escaped in abundance and the pains ceased. Three hours later he felt the head presenting still, and could detect above it a shoulder not corresponding to the head, and something like a foot.

He applied the forceps, and delivered a macerated head, but the body could not be extracted until he pulled very hard. Then a cracking noise was heard, and the fetus came out with its body wide open, the intestines running upwards into the uterus. On exploration he detected the head of a second fetus, and delivered it with ease; its abdomen was wide open. The footlike extremity which had puzzled Duloz before the delivery of the first twin was a mal-formed hand. The cord was inserted into a point on the abdominal wall which came away with the second fetus, and it was common to the twins. The mother made a good recovery. The twins were united by the sternum and pubes. There was a common heart; the other viscera were separate, the anus imperforate, the testes undescended. Harelip and cleft palate, absolutely symmetrical in the twins, were present. There were minor deformities in the extremities.

(133) Lactation and Syphilis.

HAYAS: *Centralbl. f. Gynäk.*, No. 32, 1895) has published in a Hungarian medical journal an important communication on the moral and medical aspect of this question. He concludes that a syphilitic infant should be suckled by its mother, or, if she cannot secrete milk, by a syphilitic nurse, or, if there be no such wet nurse available, by artificial feeding. It is wrong and dangerous for a healthy nurse to suckle a child whose parents are syphilitic.

(134) Puerperal Tetanus.

WALKO, of v. Jaksch's clinic (*Deut. med. Woch.*, September 5th, 1895) relates a case occurring in a woman, aged 23, and treated by Tizzoni's antitoxin. The disease began about ten days after delivery with sudden trismus. On admission there was marked spasm of the jaws and the head was drawn back. From time to time there were general spasms. Vaginal examination by Rosethorn revealed little of importance. The body of the uterus was dextroverted. There was a laceration of the cervix, which bled when touched. There was very little secretion from the uterus. The first injection of antitoxin was given on the day of admission. On the following day there was some improvement, but twenty-four hours later the patient relapsed, and died on the next day. Eighteen injections of 0.2 g. of the antitoxin were given at intervals of about five hours. A considerable leucocytosis was observed. The bacteriological examination of the lochial secretion, blood, colostrum, etc., gave negative results. In spite of these negative results as regards the presence of the tetanus bacillus or of tetanus-producing properties in the secretions, there was no question of the nature of the disease. In addition two other cases of puerperal tetanus occurred about the same time. Extirpation of the uterus was carried out, and the tetanus bacillus was found in the lochial secretion. Both cases followed a rapidly progressive and fatal course. The author then refers to the

antitoxin treatment of tetanus and to the divided opinions as to its value. Mostly improvement has been noted at varying intervals after the injections. Beneficial effects have been very rare in severe forms of tetanus. The author says that in the majority of cases tetanus is not a fatal disease; according to Albertoni, 186 out of 176 recovered, namely, 78.9 per cent. It is a question as to whether in severe cases even larger doses should be employed. The treatment should be begun early. A difference in the properties of the antitoxin obtained from different sources is possible.

(135) Edema and Apoplexy of Ovary from Torsion.

POTHEBAT AND LENOIR (*Bull. de la Soc. Anat. de Paris*, vol. ix, part 13, 1895) examined two uterine appendages removed for what appeared to be left salpingitis and retroflexion. The left ovary was as big as a moderate-sized orange. Its pedicle was twisted three turns from left to right, but not firmly; the Fallopian tube was still permeable. On section, the swelling of the ovary was seen to be due to great edema, with extensive extravasations of blood. The essential ovarian tissue had disappeared. At points there were collections of new growth which the observers considered to be myxoma. The right ovary was as large as a small Tangerine orange; its pedicle was not twisted. Unlike its fellow, it contained a few Graafian follicles, but none held ova. There was no effusion of blood, but the ovary was oedematous, and appeared to be the seat of myxomatous infiltration.

THERAPEUTICS.

(136) Thyroid Feeding.

ZUM BUSCH (*Dermatol. Zeitschrift*, September, 1895) gives the results of thyroid feeding observed by him in various diseases. He likewise tried it for a considerable time in two healthy men, and noticed in them no effect at all except slight change in the body weight, and in the amount of urine and urea excreted. These negative results in healthy people correspond with the experience of Leichtenstern and Wendelstadt. On the other hand, in patients with cutaneous affections various general effects were observed. The loss of weight was usually considerable, especially at the beginning of the treatment; there was considerable increase in the amount of urine and of urea excreted, the amount was often doubled, and the pulse frequency was often increased by ten or twenty beats. Disagreeable symptoms were seldom observed, but when observed they consisted in great frequency of pulse, palpitation, headache, faintness, tremors, and sweating. The appetite was usually good, but vomiting occurred in two cases, both of children treated with rather large doses. In spite of the observation of Ewald, that thyroid feeding never produced albuminuria or glycosuria. In one case it so happened that though

temporary glycosuria had been observed before the thyroid feeding was commenced, it never reappeared during the treatment. In all the five cases of myxedema treated the improvement was rapid and striking. The fifth case was particularly interesting. The patient was a woman, aged 51, who was admitted with the symptoms of Graves's disease, and whilst under observation the symptoms of myxedema supervened, and partially replaced those of the Graves's disease. The myxedema was got rid of by the thyroid treatment, but the exophthalmos and Graefe's sign were left as remnants of the Graves's disease. Out of 24 cases of psoriasis 11 were cured and 7 were improved by the treatment; in a few cases even tolerably large doses seemed to have hardly any effect. It does not seem at present possible to distinguish beforehand those cases of psoriasis which are benefited by the treatment from those which derive no benefit. Out of 12 cases of chronic eczema 9 were cured, 2 improved, and 1 got worse under the treatment. At the beginning of the treatment some of the cases showed an apparent exacerbation before improvement showed itself. A girl, aged 25, with slight ichthyosis, improved somewhat under treatment. Two cases of epithelioma and 3 cases of chronic ulcer of the leg remained unaffected by the treatment. Four cases of lupus vulgaris were treated. The thyroïdin appears to cause a local reaction somewhat resembling, but milder than, that caused by tuberculin. The lupus tubercles gradually disappear in some places, whereas fresh ones unnoted before spring up in other places. The diseased tissue becomes sharply defined under thyroid feeding, and thus perhaps operative treatment may be facilitated. Zum Busch believes that with proper care thyroid treatment in skin affections is not more dangerous than that with arsenic or many other drugs. He thinks it may sometimes be of service where other methods have failed, and that in chronic skin eruptions the combination of local external treatment with internal thyroid treatment is likely to give good results.

(137) Serum Treatment of Cancer.

At the second French Congress of Internal Medicine, recently held at Bordeaux, Roumet of Marseilles (*Presse Méd.*, August 24th) stated that he had injected non-ulcerated cancerous tumours (epithelioma, sarcoma, cancer of breast) into the veins or into the subcutaneous cellular tissue of four cases and ten dogs, and afterwards inoculated patients suffering from cancer with serum obtained from animals into which the same anatomico-pathological variety had been injected. In each case 2 ccm. of serum were injected on alternate days into the subcutaneous areolar tissue of the abdomen. The injections varied in number from 36 to 40. The injections are not painful, and seldom give rise to abscess; they are sometimes, however, followed by fever, urticaria, and scarlatiniform

eruptions. In two cases symptoms of collapse came on, but quickly passed off. The injections often improved the general condition, but the amelioration never lasted more than thirty-five weeks if the patients had reached the cachectic stage. The pains often became considerably less during the course of injections and recommenced on their discontinuance. The treatment also had a favourable effect on the frequency and profuseness of hemorrhage, bleeding in some cases having completely ceased during several weeks. As regards the tumour, the cases treated included 5 ulcerated cancers of the breast, 2 non-ulcerated tumours which had recurred after operation, 6 inoperable advanced and recurrent cancers of the uterus, 1 cancer of the tongue, 4 cases of epithelioma of the lip, cheek, penis, and scrotum. In none of these cases did the treatment effect a cure. The oozing of blood in ulcerated cancers was often checked, but the fungating growth was not appreciably diminished. In one case a considerable malignant ulceration of the neck of the womb became almost completely cicatrised, while another ulceration following the removal of a cancer of the breast diminished by two-thirds. The thickening around the tumours often markedly diminished. In 2 cases of recurrent cancer of the breast, with adhesion of non-ulcerated skin, shrinkage to the extent of one-third took place, and the skin over the tumours became more movable. The author insists that the injections are not dangerous; he thinks it possible that by using them before and after operations for cancer recurrence may be delayed. Ferré confirmed the fact that partial improvement might be obtained by such injections; and he cited a case in which serum from an ass which had first been injected according to the method of Richet was used with advantage.

(154) Vaccination in Whooping-Cough.

G. CAVALIERI (*Gazz. d. Osped.*, June 1st) reports that in 1894 he had more than 200 cases of pertussis under treatment. Almost all therapeutic measures proving useless it occurred to him to try the effect of vaccination. He vaccinated more than 100 children suffering from whooping cough, but only in 64 of these did the vaccine take. Of the 64, only 1, a baby of four months, died, whereas before the vaccine was used there had been many deaths. The vaccination had a favourable effect on the course of the disease, both diminishing the violence of the paroxysms and shortening the duration of illness, the vaccinated cases recovering in from three to three and a-half weeks, while the unvaccinated cases either died within the same period or took eight or nine weeks to recover.

PATHOLOGY.

(155) The Infection of Anthrax.

SCHIMMELBUCH AND RICKER (*Fortschr. der Med.*, Bd. xiii, 1895, Heft 7-9) in 786 D

a previous communication showed that in a mouse amputation of the tail which had been ten minutes earlier the seat of inoculation with anthrax was not sufficient to prevent death from general infection. In the present communication they extend the research, and report the results of inoculations with spore-bearing anthrax cultures into deep wounds involving the muscles of the back, and into superficial wounds involving only the skin and subcutaneous connective tissue. Half an hour to 5 hours after inoculation the animals were killed either by a blow on the head or by asphyxia, and portions of the internal organs sown on agar plates. In 7 out of 10 cases in which mice were inoculated growth occurred in one or more of the internal organs; in one animal, killed only half an hour after inoculation, anthrax bacilli were found in the lungs, liver, and kidneys. Analogous experiments with rabbits gave negative results. In the more superficial wounds a similar procedure was carried out, but only 2 out of 11 mice gave positive results, and that only when four hours had elapsed between inoculation and death. The absorptive power of subcutaneous tissue for anthrax spores is, therefore, less than that of the deep muscular layers. Cultures free from spores are absorbed in a similar way. Other micro-organisms were investigated and found to be absorbed in exactly the same manner, nor is there any great difference imported by the size of the micro-organism. Cultures were obtained most commonly from the liver, the lungs and the kidneys, much less frequently from the spleen and the heart. The rapidity with which micro-organisms are taken up suggests that they pass directly into the divided blood vessels and do not travel by the lymph stream. It must be remembered that the experiments were made in fresh wounds; when wounds are older the conditions of infection and absorption of bacteria are different.

(156) Internal Localisation of the Gonococcus.

BORDONI-UFFREDUZZI (*Archives Italiennes de Biologie*, Tome xxii, Fasc. iii, 1895) records observations and experiments which appear to furnish conclusive evidence that the gonococcus is able to diffuse itself in the internal parts of the organism, and to give rise to inflammatory conditions. A case observed by Mazza is first referred to, in which bilateral pleurisy and poly-arthritis developed during an attack of gonorrhoea. The pleuritic effusion contained micrococci, which presented, microscopically and on cultivation, the characters of Neisser's gonococci. The author relates a case of gonorrhoea in which multiple arthritis developed. A quantity of fluid was taken from a joint, with bacteriological precautions. In the pus cells of this fluid the author discovered micro-organisms having the characters of the gonococcus as regards microscopical appearance and peculiarities of staining. After cultivation on a

mixture of agar-agar and human blood serum micro-organisms were obtained which had the same characters as those in the pus cells. In order to furnish more conclusive evidence, the urethra of a healthy young man who had never suffered from gonorrhoea, and who had not had sexual connection for four months, was inoculated with a small quantity of material taken from the second generation of a cultivation of the micro-organism. (The inoculation was performed with the man's consent.) The parts were examined for the gonococcus before the inoculation, but only the ordinary bacilli of the smegma were found. The glans penis, and meatus were then washed in sterilised water, and the micro-organisms deposited in the urethra a little beyond the meatus. A typical attack of gonorrhoea was the result, and gonococci were found in the discharge.

(157) Etiology of Tropical Multiple Neuritis.

MAX GLOGNER, of Samarang (*Vierteljahrsschr. Arch.*, Bd. 140, Heft 3), says that most of the cases of beri-beri on which he made his observations had been a considerable time under observation, and suffered from a slight intermittent fever. Scheube and Baelz had noted such a fever as occurring in 45 or 50 per cent. of all cases of beri-beri. Glogner has already recorded that in most of his cases he found living amoeba-like organisms present in the red corpuscles. Although these organisms greatly resembled the plasmodia found by Laveran and others in cases of malaria, Glogner, after taking into consideration the clinical differences between malaria and beri-beri, came to the conclusion that the micro-organisms in the two diseases were probably different in spite of their similarity in appearance. However, in a further series of cases, in which multiple neuritis had commenced with fever, Glogner found not only the amoeboid organisms, but also the pigmented, sickle-shaped, and oval forms described by Laveran. In other cases of multiple neuritis, which likewise began with fever, he could find none of these microbes; he has, therefore, come to the conclusion that these microbes must not be regarded as the cause of beri-beri, but rather as a sign that the patients really had malaria, of which the multiple neuritis was a sequela; in fact, that the multiple neuritis followed malaria, just as in Europe it has been observed to follow diphtheria, enteric fever, influenza, etc. Leyden long ago suggested that the circulation of ptomaines in the blood was the cause of multiple neuritis following infectious diseases; Glogner thinks that such a ptomaine occurring in cases of malaria may cause a multiple neuritis, which in the tropics may be set down as beri-beri. In this supposition he is confirmed by statistics of the geographical distribution of the two diseases. He believes that what has been called "beri-beri" is not always etiologically the same disease.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(303) Motor Aphasia.

PARVOST (*Rev. Med. de la Suisse Romande*, No. 6, June, 1895) describes a case of Jacksonian epilepsy accompanied by motor aphasia but without agraphia, conclusively proving that the former may exist without the latter. The patient was a man of about 60, who had suffered from neurasthenia with indefinite symptoms for some years. He began to experience a difficulty in expressing himself; this was followed by an epileptiform attack with complete loss of consciousness, and afterwards by a series of fits. In these the patient hesitated in his speech, took his chin in his left hand, turned the head convulsively to the right, and had an access of clonic convulsions in the right facial region, with grinding of the teeth. The fits occurred every fifteen minutes and lasted about one minute and a-half. They were followed by temporary loss of speech, and at the end of a day by lasting aphasia. The intellect was throughout unimpaired, and he was able to write freely without hesitation or mistakes, and to write what had been dictated to him during the fit immediately afterwards. There was no paralysis nor alteration of sensibility whatever. A syphilitic lesion, probably a gummatous tumour, involving Broca's convolution, was suspected, but a very doubtful history of the disease was obtained. The treatment was gr. x of pot. iod. every three hours, and two mercurial inunctions daily. The fits ceased abruptly after lasting over a week; speech returned at once, all neurasthenic and other symptoms disappeared, and in a few months he was practically cured. Six months later the symptoms returned, but were marked by an attack of complete right hemiplegia which supervened. Subsequent treatment had proved ineffectual. The aphasic phenomena were remarkable, being unaccompanied by paralysis during the attacks, or by word-blindness, word-deafness, or verbal amnesia. The patient could always read and write except after one or two major epileptic attacks. The condition is rare, the centres of speech and writing being so closely placed that they are generally involved in the same lesion. The question is discussed whether there exist in the brain special accessory centres developed by use, and whether the multiple centres said to preside over the function of language are among them. There is too great a tendency to regard language as a special and isolated phenomenon among the manifestations of the nervous centres, and the development of an automatic act such as writing may be simply controlled by a special adaptation of conducting fibres

uniting the different sensorial centres. A study of aphasia in violinists, pianists, typewriters, and others trained to express their ideas by automatic means involving more highly specialised action than writing, may help to elucidate the true theory of this subject.

(304) Epidemic Cerebro-optic Meningitis. RIGHI (*Rif. Med.*, June 24th and 25th, 1895) reports three cases of this disease in which he found the diplococcus of Fraenkel in the blood, the urine, and in one of the cases in the faeces. In each case the diplococcus was actively virulent and gave rise to cultures which proved active upon inoculation. The cases occurred in children of 16, 3, and 13 years respectively, and formed part of an epidemic of the disease which occurred in Sassari. The first two patients died; the third, which was a milder case, recovered. But even in this case the diplococci were freely found in the blood and urine, so that it cannot be said that the diplococci are only associated with severe cases.—QUADU (*Rif. Med.*, July 8th and 9th, 1895) reports another case (one of the same epidemic) in a child aged 6, who recovered, and in whose blood the same diplococcus was found. This case was also interesting from the fact that it was complicated by the development during the disease of a periarticular abscess about the left knee-joint and by a left otitis media with perforation. In each case the pus contained the diplococcus, that of the ear also containing the staphylococcus cereus albus and a slender somewhat recurved unfamiliar bacillus. In addition to the otitis and abscess the patient also suffered from arthritis of the right shoulder-joint.

(305) Spontaneous Hemophilia in Brothers.

DALAND AND ROBINSON reported three cases to the Philadelphia County Medical Society on January 9th, 1895. There was no family history of the disease on either the paternal or the maternal side, except that in the mother the operation of tooth extraction was attended with rather more than the normal amount of hemorrhage. One of the three subjects of the paper was perfectly well up to the age of 16 months, when he developed epistaxis, which came on frequently and uncontrollably, and was ultimately fatal (age not stated). There were no other mucous membrane hemorrhages, and purpura was absent, but at the age of 3½ years he developed hydrocephalus. The other fatal case terminated with hemorrhage from the mouth during the eruption of the molars (aged 18 months). The child was anemic and ill-nourished and skin eruption was noticed. The first hemorrhage came on when the teeth began to be cut. Three other children (one boy, one girl, sex of other not stated) died young without any hemorrhages. The case under observation was a boy aged 13. Nothing abnormal was noticed till the age of 8 months, when he had cholera infantum for 3 months, during the last fortnight of which a purpuric

eruption appeared on the abdomen, neck, legs, and, to a less extent, arms; no hemorrhage from mucous membranes. He remained well till 5 years; then he had an attack of arthritis, especially affecting the elbows, knees, and wrists, and accompanied by fever and acid sweats. This was relieved by salicylates, but has recurred about every two months—within 48 hours after exposure to cold or wet—till the present time. Since the age of 5 there have been about 50 attacks of hemorrhage from the mucous membranes, usually nasal, always preceded by grinding of the teeth or flushing of the face, so that the father could always predict them. There has been no return of the purpura, but there is considerable ankylosis from the arthritis. There is great diminution of the coagulability of the blood, which during an attack was found to contain an immense number of microcytes; there were 7.5 per cent. of red corpuscles and the hemoglobin was 62 per cent. No ordinary hemostatic treatment was of any avail till an enormous quantity of blood had been lost. The hemorrhage then yielded to the local influence of cocaine (which the authors praise very highly) and ice, and the internal administration of ergot. The authors call particular attention to the premonitory flushing of the face, the attacks of arthritis, which were probably due to effusion of blood into the joints and the fact that the attacks of hemorrhage became more violent when the patient was removed from an altitude of 1,800 to one of 2,300 feet. They record that the ordinary condition of great hemorrhage from slight lesions was present, and suggest that the initial claudicatio infantum was really a gastro-intestinal purpura.

(306) Trypsin Digestion and the Internal Secretion of the Spleen.

A. HERZEN (*Rev. Gén. des Sciences*, June 15th, 1895) revives the theory as to the influence of the spleen on pancreatic digestion, which Schiff was the first to put forward in 1862. It has long been known that the digestive action of pancreatic juice on proteids is not continuous but intermittent, and that it appears regularly with the process of gastric digestion. Schiff showed that in animals from whom the spleen had been removed, neither the pancreatic juice nor an infusion of the pancreas had any digestive influence on proteids. Herzen has combined Schiff's views with Heidenhain's researches on zymogen. He finds that the volume of the spleen at any moment varies directly as the amount of trypsin in the pancreatic juice, and inversely as the amount of zymogen. Thus the maximum quantity of zymogen is present during starvation, when the trypsin and splenic distention are at their minimum. Six or seven hours after food the conditions are exactly reversed. Furthermore, admixture of infusion of congested spleen greatly aids the pancreatic digestion of proteids. The blood of the splenic vein has a similar action, that from other vessels none. Herzen concludes that in the living pancreas the

protrypaine is transformed into active trypsin by the influence of a substance produced in the spleen in quantity proportional to the intensity of its congestion. The substance finds its way to the duodenum through the general circulation.

SURGERY.

(664) Intra-cranial Resection of the Trigeminal.

KRAUSE (*Centralblatt für Chirurgie*, 27, 1895), in an abstract of a paper read at the twenty-fourth Congress of the German Surgical Society, states that during the last three years he has, in very severe and obstinate cases of facial neuralgia, recommended and practised removal of the Gasserian ganglion, together with its posterior root, by the intra-cranial method. Resection simply of one or more of the branches of the trigeminal, it is pointed out, is not sure in its results, and in facial neuralgia well-marked histological changes occur in the Gasserian ganglion, whilst its peripheral nerves present but slight deviations from the normal structure. The removal of this ganglion, the author asserts, is followed by remarkably slight disturbance which are not to be compared with the terrible pains by which the patient was previously afflicted. In Krause's operation a womb-shaped flap of bone, together with the coverings of skin and muscle, the base of which is seated just above the zygomatic arch, is formed in the temporal region, the bone being divided by a circular saw, which is worked either by an electro-motor or by a dental engine. This flap, still remaining attached at its base, is turned down, and the exposed dura mater is carefully detached from the bone of the middle cranial fossa, and elevated together with the brain by a broad retractor. The middle meningeal artery is now tied and divided near the foramen spinosum. The third and second branches of the trigeminal are next carefully exposed and cut through at the round and oval foramina, and finally the ganglion and its posterior root, after separation of the dura mater, are removed by torsion. In three of his cases the author succeeded in detaching the posterior root as far back as the pons. The first branch, which as it is closely connected with the wall of the cavernous sinus cannot be exposed by the use of the knife, is usually torn through in the removal of the ganglion. The flap of skin, muscle, and bone is replaced and fixed by sutures. In the author's practice the average duration of the after-treatment is fourteen days. Some of his patients, he states, were allowed to move about on the eighth day. In comparing his operation with that practised in this country by Rose, the author points out that in the latter the ganglion is not freely exposed, and that consequently there must be some uncertainty as to its complete removal. Moreover, there is a risk of wounding the Eustachian tube near the opening in the cranial

wall, and of consequent septic meningitis. The chief danger attending the intra-cranial operation is hæmorrhage. Not only is there free bleeding when the dura mater is detached from the base of the skull, but also the middle meningeal artery may be cut before it has been secured by ligature, and the cavernous sinus may be accidentally wounded. In some cases it has been found necessary to perform the operation in two stages, and to defer removal of the ganglion until after the arrest of hæmorrhage by prolonged plugging. Another probable source of danger is compression of the brain whilst this organ, together with the dura mater, is being raised from the floor of the middle cranial fossa. The author has never, in his own practice, observed any bad results from this temporary compression, but he insists on the necessity, more especially when operating on the left side, of raising the brain carefully and slowly. Of 51 intra-cranial operations performed by different surgeons 5 were fatal. It is stated that no relapse of facial neuralgia after extirpation of the ganglion has yet been recorded. Although the operation is followed by complete anesthesia of the cornea and conjunctiva, the author has never had to deal with any severe or persistent affection of the eye. Removal of the Gasserian ganglion, he concludes, is indicated only in very severe cases of trifacial neuralgia in which all other methods of treatment, both medicinal and surgical, have failed.

(667) Extirpation of Large Sacro-Lumbar Spina Bifida.

TANEINI (*Rif. Med.*, August 6th, 1895) reports the case of a child 2 years old who had a large spina bifida in the sacro-lumbar region. The tumour was as big as a child's head, of smooth surface, and extending from the last sacral vertebra up to the second lumbar, whilst laterally it almost reached the anterior iliac spines. It was elastic and transparent. Palpation excited little pain. The author excised the tumour, having first removed some of its contents with a fine trochar. On opening the sac nerve fibres were seen crossing the walls: these were carefully dissected off. The vertebral cleft was lozenge-shaped, and measured 6 cm. by 3 cm. The spinal cord was of normal shape and aspect. A drainage tube was inserted, and the wound sewn up. Healing occurred by second intention, but forty days after operation, the child being quite cured and in good condition, was sent out of the hospital.

(668) Obstruction of the Ejaculatory Ducts.

At the meeting of the American Association of Genito-Urinary Surgeons (Philadelphia *Med. News*, June 29th) E. C. Burnett, of St. Louis, reported a case of early obstruction of the ejaculatory duct. The patient was an unmarried man, aged 35, who at the age of 5 was operated on for stone in the bladder,

left lateral lithotomy being performed. The patient stated that his testicles almost always pained him for a day or so after sexual indulgence. Sexually he states that he was perfectly normal, excepting that he had never had an emission of semen. The external genitals were well developed. Upon the introduction of an endoscope into the urethra the prostatic portion of the canal was found to be extraordinarily short and the verumontanum was so small as to be barely distinguishable from the surrounding tissue. Palpation through the rectum for the seminal vesicles disclosed the fact that they were not appreciable to the touch and that the prostate was barely definable. During one of his examinations Burnett noticed the scar on the left side of the perineum, and on inquiry he was informed of the lithotomy performed thirty years before. In this incident in the patient's early history lay the solution of the question as to the cause of his aspermatism. Obviously in the performance of the operation the ejaculatory ducts were torn across becoming permanently occluded and through the occlusion of these ducts there followed arrest of development of the prostate gland and seminal vesicles. Obstruction of the ejaculatory ducts is given as one of the causes of atrophy of the seminal vesicles but Burnett could find no reference to any such influence upon the prostate.

(669) Enlarged Bursa about the Knee. RONCALI (*Archiv. di Ortoped.*, Aug. 12, f. 1, 1895) describes seven cases of enlarged bursa about the knee, six of which were operated upon with complete success; in one (an interesting case of enlarged bursa under the quadriceps extensor, and not communicating with the joint) the patient refused operation. The seventh case was of a man, aged 25, who fell on his left knee in January, 1893, eight days after which the knee became swollen, and remained so for five months, then entirely disappeared. In August of the same year he noticed a swelling in the left popliteal space, which was rapidly increasing, causing a sense of weight and weakness in the limb, but no pain or fever. The popliteal artery could be felt beating over the tumour. On examination the swelling was seen to be divided into two parts by a sulcus, the upper section, as large as an eight months foetal head, the lower and outer about the size of an orange. Pressure on the tumour caused no diminution in its size or alteration in the form of the joints. The circumference at the upper margin of the patella equalled 58 cm., as against 36 cm. on the right side; below the patella 42 cm. left, 32 cm. right; left calf 38 cm., right 37 cm. An incision was made over the tumour, and the bursa, with three cysts, firmly adherent to the posterior surface of the capsule of the joint was removed. There was no communication with the joint. The patient was able to leave the hospital two months after with perfect freedom of movement and completely cured.

MIDWIFERY AND DISEASES OF WOMEN.

(970) Hydatidiform Mole and Malignant Decidua.

FRANKEL (*Archiv f. Gynäk.*, vol. xlix., Pt. 3, 1895) has recently added to our knowledge respecting the malignant changes which sometimes take place in the uterus after gestation. Undoubtedly malignant decidua is often, on clinical evidence, associated with hydatidiform mole. Small portions of a mole of this class usually remain behind after the greater part has been expelled. The superficial epithelial layer (syncytium) of the chorionic villi proliferates considerably when a vesicular mole develops. It is precisely from this abnormal development of epithelium that the cancerous change known as malignant decidua is evolved. The deeper cellular investment of the chorionic villi (Langhans's layer), according to Frankel, takes no primary part in the development either of the mole or of the cancer.

(971) Placental Circulation and Morphology.

BUREAU (*Report. Universel d'Obstét. et de Gynéc.*, August 25th, 1895) attended a patient who had taken morphine for seven years, and who when he saw her took as much as 15 grains of that alkaloid daily. She was pregnant for the fourth time. At length she was spontaneously delivered of a child with talipes of one foot. As the cord was divided Bureau collected the blood of the placenta and umbilical vessels. On chemical analysis morphine was detected in the blood.

(972) Casein in Woman's Milk.

WRÓBLEWSKI (*Centralbl. f. Gynäk.*, No. 32, 1895) has made researches into the comparative properties of casein in woman's and casein in cow's milk. The casein is different in the two kinds of milk. In woman it contains less carbon, nitrogen, and phosphorus, but more hydrogen and sulphur. The solubility of the casein differs, and different chemical changes go on when cow's or woman's casein is submitted to gastric digestion.

(973) Foreign Bodies in the Uterus.

ALBERTIN (*Provence Méd.*, Nos. 11, 12, 1895) collects 24 cases. Two are original. In one case a laminaire tent remained nearly eleven months in the uterine cavity, and in the second a carbon rheophore was left behind, and did not come away for a week. In neither instance was there any symptom of irritation, and both the tent and the rheophore were expelled spontaneously.

THERAPEUTICS.

(974) Trional as a Hypnotic.

RODRIGUEZ (*Thèse de Paris*, 1895) reports the results of experiments as to the hypnotic effects of trional in 30 cases of ordinary illness. The doses used were sometimes small (1 to 2 g.), some-

times larger (2 to 4 g.); the weaker doses particularly produce the hypnotic effect, while the stronger have a sedative action in cases of irritation. The drug was given in cachets, a hot liquid being swallowed immediately after it. The average duration of sleep produced was about seven hours; it came on from three-quarters of an hour to an hour after the administration of the drug. The sleep was quiet and easily interrupted, but quickly renewed. Trional was especially successful in insomnia due to pain; no serious symptom followed the taking of the drug. In 4 cases it seemed to cause nightmare, and in 4 others there were some passing disturbances on awaking, such as nausea, headache, vertigo, uncertainty of movements, and tinnitus. In 2 cases sweating without apparent cause was noted. The only instance in which the drug failed was in a woman suffering from cardiac astylosia. The author sums up that trional has a sure hypnotic action; that in therapeutic doses it has no effect on the circulatory, respiratory, or digestive apparatus, while its action on the temperature and on the secretions is insignificant—Moncorvo, of Rio de Janeiro (*Bull. de l'Acad. de Méd.*, September 3rd) has investigated the therapeutic effects of trional in children. He first tried it in the insomnia of neurotic children and in sucklings suffering from digestive disturbances. Encouraged by the prompt and sure effect of the drug and by its harmlessness, he proceeded to try it in the insomnia which is common in the exanthemata, particularly in the two first stages of measles, small-pox, and scarlatina. The drug also acted satisfactorily in the case of children suffering from malaria, in which insomnia is common as an early symptom. Given in small doses (20 to 25 centigrammes) before bedtime in such cases trional almost invariably succeeds. It was also used with much advantage as a means of subduing the phenomena of cerebral excitement in pernicious cases of malaria. The insomnia, which is often so troublesome in cases of cerebral irritation, was always mitigated or prevented by trional given in a dose usually not exceeding 50 centigrammes half an hour before the time when it was desired to produce sleep. In 2 cases of tuberculous meningitis the sedative action of trional on the brain was "truly wonderful." The drug was also tried with satisfactory results as a remedy for the psychical disturbances of cerebral sclerosis. In one case, that of a girl, aged 9, who since the age of 3 had been the subject of right hemiplegia, probably due to left cerebral hemiatrophy, trional in a daily dose of 50 centigrammes had an extremely good effect, and although the treatment was continued for several weeks, no disagreeable by-effect was noted. The drug was also used with advantage in the insomnia which frequently accompanies subacute or chronic tuberculous in young subjects. Moncorvo found trional least successful in insomnia accompanying painful

affections, such as diseased bone and neuralgia. The drug was well borne, no disagreeable effect on respiration, circulation, or cerebral activity being observed. It was given, as a rule, in hot argued milk, by which means its somewhat bitter taste was almost entirely masked. In older children it was given in cachets, a little hot tea or milk being swallowed immediately afterwards. The dose varied from 20 centigrammes to 1 g. in the twenty-four hours. Moncorvo sums up as follows: Of all substances possessing hypnotic effects which he has used in infantile therapeutics he has found none speedier or more certain in its effect than trional, which is also better borne by children than any other narcotic. Lastly, it has a sedative action on the brain, which renders it useful in nervous or psychical excitement dependent on interfections or on lesions of the encephalon or its coverings.—S. Wolfe (*Med. and Surg. Reporter*, June 8th) has found trional superior in promptness, ease of administration, and absence of bad or disagreeable after-effects to most, if not all, other hypnotics. When a dose of 15 gr. is given, sleep usually ensues within half an hour, if at all, and this result seems but little altered whether the drug be administered in a warm vehicle (it does not readily dissolve) or given as a dry powder or in capsules. It is often so prompt that the patient sleeps within a very few minutes after injection. The dose in some cases must be larger than 15 gr., although he would not advise more in any case unless the susceptibility of the patient had been first ascertained; in many cases he believes 10 gr. would prove efficient. It may be safely repeated at least once in a night, and in an hour if necessary. He gives a few illustrative cases, and sums up as follows: (1) Trional deserves a high rank amongst hypnotics. (2) It has a useful range of application in catarrhal inflammations. (3) It deserves trial in neuralgic and myalgic affections. (4) It may be found useful in chorea and other neuroses.

(975) A New Use for Thyroid Extract.

J. W. WHITE (*Univ. Med. Mag.*, August) reports the following case: In March, 1894, a young girl who was dressing in front of a mirror in a private carriage attached to a train was thrown violently forward, her face striking the mirror, which was broken into many pieces. A large crescentic wound of the soft parts of the right cheek was inflicted. The wound was quickly cleansed and the edges brought carefully into position with interrupted sutures. Healed union, entirely by first intention, followed, and the scar appeared satisfactory. In the following October it had become greatly hypertrophied and caused great disfigurement. Absorbent ointments, pressure by means of plaster, and other means of local treatment having been tried to no purpose, she was (in January, 1895) put upon thyroid extract, from two to four tablets of "a well-known preparation"—each tablet containing 5 grains—being given daily.

All local treatment was discontinued, the scar being only covered with a film of collodion to prevent abrasion or irritation and to keep up gentle pressure. On several occasions marked elevation of temperature and quickening of pulse occurred; once to an alarming extent, but in a few weeks a perceptible change was noted, and at the end of about six weeks the scar had in almost its entire extent come down to the level of the surrounding skin and the dense base had disappeared. White does not claim that this was a case of true keloid, but he points out that the clinical distinction between keloid growths and hypertrophied cicatrices is, after all, based on the size of the growth and on its course than upon any more definite differences. He reports the case "for the sake of the suggestion to which it leads up of the trial of thyroid extract in other conditions involving the skin, intractable to operative surgery, and either on the border line of malignancy, like keloid, or definitely malignant."

(574) External Application of Guaiacol in Orchitis.

Pietro Pucci (*Gazz. d. Ospedali*, June 16) reports the case of a man, aged 66, who had suffered from repeated attacks of ague. Inflammation of both testicles suddenly came on without any apparent cause, and this was followed within two or three days by an acute attack of malarial fever. Sulphate of quinine was given for a week without any effect on the fever, while belladonna was applied to the testicles, equally to no purpose. An ointment composed of 2 g. of guaiacol and 20 g. of vaseline was then prescribed, about 2 g. of it being painted over the scrotum thrice daily, and the quinine being discontinued. The result was that the fever was almost at once subdued, and the orchitis was entirely cured in a week. The immediate effect of the guaiacol was an intense burning sensation at the place where it was applied. This lasted about ten minutes, but half an hour after the application the pain was distinctly mitigated, and finally ceased on the third day of the treatment.

(575) The Brazilian Lantana and its Alkaloid.

N. LUGO-YINA, of Oienfugas (*Rev. de Ciencias Medicas*, July 30th), draws attention to the antimalarial properties of the Brazilian lantana, a verbenaceous plant which grows in the South American forests. It has long been esteemed as a specific in the "marsh fevers" by the inhabitants of Brazil, La Plata, Peru, under the name of "Sacred Herb." Its introduction into scientific therapeutics about ten years since is due to Buiza, of Lima, who gave it in the first instance to two patients, the one with acute articular rheumatism, the other with typhoid fever of ataxic form, in both cases with most satisfactory results. The active principle of the herb was separated by Negrete, and named "lantanine." Buiza says of it: "Administered the new alkaloid to 32 patients attacked with

fevers of a different character and intensity, with the most flattering results, etc. Like quinine, it produces a moderate effect on the circulation, determining a slowness of the chemical phenomena of nutrition, and usually a diminution of temperature. In larger doses it is a powerful antiperiodic, superior to the salts of quinine, as it possesses the advantage of being tolerated even by the most delicate stomachs. Intermittent fevers, rebellious to sulphate of quinine, have yielded to the administration of 2 grammes of 'lantanine.' The dose is from 1 gramme to 2 grammes during the day, best given in pills of 0.10 gramme each, to take two every two hours. Intermittent fevers may be cut short at the onset by taking five pills, repeated twice or thrice at intervals of 10 minutes. This treatment succeeds in 85 out of 100 cases." The author quotes favourable results obtained by others, and himself has exhibited the drugs in other indications than those furnished by Buiza. He has obtained good results in some cases of "facial neuralgia," and in two cases of "metrorrhagia of a marked paludal character." Five obstinate cases of intermittent fever, which did not yield to quinine or lantanine were cured by giving the two remedies either together or alternately. Three cases of intense "catarrhal fever" were successfully treated with it, in one of them in alternation with antipyrin.

PATHOLOGY.

(576) Experimental Physiology of the Nervous System.

BEUTNER (*Neurol. Centralbl.*, August 15th, 1895) points out that in the newborn animal the earliest date at which a given portion of the nervous system functionates corresponds in time with the completion of development of the nerve fibres and nerve cells of that part. Hence absence of the usual results on electric stimulation or on destruction of a given portion of the nervous system means incomplete development of nerve fibres and cells connected therewith; but presence of such results does not necessarily mean completed development of that particular part, for it seems that one part may do duty for another until the development of the latter is completed: for example, consciousness in newborn animals would seem to be located in the earlier developed lower centres instead of in the higher centres as in older animals. He considers that experiments on the newborn animal will be of the greatest value in determining the functions of the various portions of the nervous system; a combination of the ordinary degeneration method with electric stimulation, or with destruction of the parts containing the degenerated tracts, being the only method that is of real service. The results of certain experiments thus made are given, showing that Goll's column has some share in the maintenance of equilibrium—a fact illustrated clinically by Romberg's sym-

ptom in tabes dorsalis (for in animals also the loss of equilibrium is aggravated by blindfolding); and also that the lateral cerebellar tract plays an important part in the same function.

(577) Toxicity of the Aqueous Part of the Breath.

LAVIARATO (*Arch. Ital. de Biol.*, 1895, Tome xxiii, p. 279) investigated the toxicity of the aqueous vapour expired by healthy and by sick persons. Expired air was received and the aqueous vapour condensed in suitable apparatus, the fluid obtained was then injected into rabbits with the following results: (1) Aqueous vapour from persons suffering from diseases of the respiratory tract with fever, injected into rabbits produces a fever which lasts three to six days, general torpor and diminution of reflexes. (2) These effects are less accentuated in the case of patients who have no fever. (3) The aqueous vapour of febrile patients having no respiratory trouble causes no fever or only very slight fever in rabbits. (4) The vapour of healthy individuals has no appreciable effect. (5) Identical results are obtained when the liquid is sterilised.

(578) Crossed Cerebro-Cerebellar Atrophy.

MINGAZZINI (*Neurol. Centralbl.*, August 1st, 1895) discusses the cause of atrophy of the opposite half of the cerebellum with unilateral cerebral lesions. It is to be sought in the accompanying affection of the tract whose course is the thalamus and red nucleus of the same side and the peduncle of the opposite side. Cases are adduced in support of this, and it is stated that no single case of crossed cerebro-cerebellar atrophy has been found on record where the thalamus on the side of the cerebral lesion was intact. Further, 2 cases of Jacksonian epilepsy are quoted; in one there was atrophy of the ascending parietal convolution unilaterally with very slight atrophy of the posterior part of the thalamus of the same side, and of the pyramidal tracts on the opposite side; no cerebellar atrophy; in the other, although there was no difference in weight of the cerebral hemispheres, the thalamus of one side was markedly atrophied, here the cerebellum of the opposite side was also markedly atrophied; hence it is concluded that atrophy of a certain part of the thalamus causes crossed atrophy of cerebellum, but lesions of one side of the brain, without lesion of thalamus, do not cause crossed atrophy. There is a tract divisible into three parts: (1) from cortex to thalamus, (2) from thalamus to red nucleus, (3) from red nucleus *via* decussation to opposite half of cerebellum. Cases where unilateral lesion of cerebrum is not followed by crossed atrophy of cerebellum would thus be easily explained either by the probability of some of the three portions of the tract escaping, or by the necessary part of the thalamus not being involved.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(184) Diabetes.

WORMS (*Bull. de l'Acad. de Méd.*, July 23rd) as the result of researches reported in a previous communication to the Academy in December, 1893, came to the conclusion that in persons engaged in brain work and leading a sedentary life the proportion of glycosurics was 7 per cent. This conclusion he arrived at by examining the urine of 100 such persons, taken more or less at random. Further examinations of the same series of patients have raised the proportion of diabetes to 10 per cent., which he gives as representing the average frequency of the condition in any series of 100 scientists, artists, business men, doctors, lawyers, etc., between 40 and 60 years of age. Bertillon's statistics have shown that diabetes is on the increase, the mortality from diabetes in Paris having almost doubled between 1863 and 1892. All the cases discovered by Worms in his investigations are examples of the milder type of diabetes, in which the glycosuria can be controlled by diet; the patients have no particular symptoms, and with proper care may live almost indefinitely. As to the relative frequency of mild diabetes compared with the grave form of the disease, Worms quotes his own observations during the last thirty years. From 1863 to 1889 he had 41 cases under observation. In 1889 only three of these cases (one being in a child) had died within two years of the discovery of the condition, giving a percentage of 7 per cent. of serious cases. Of the rest 22 still survive, among them being an old lady, aged 88, whom the author has had under observation for thirty-three years, and in whose urine he has found no sugar for the last two years, her health in other respects being excellent. He is inclined to think that the proportion of grave to mild cases of diabetes does not exceed 5 per cent. With regard to the question whether mere glycosuria is likely to pass into diabetes with cachexia unless care be taken, Worms is not prepared to give a decided opinion, but he thinks that too much importance should not be attached to moderate glycosuria, even persistent, which is not accompanied by appreciable organic deterioration. He points out that even in those glycosurics who follow a fixed treatment and live always under the same conditions, the quantity of sugar varies within wide limits, great increase taking place under the stress of moral impressions or physical exertion. He cites many instances in his own practice in which diet and methodical treatment keep the quantity of sugar low or cause it to disappear for long periods, sometimes for years, even when the patient has returned to ordinary diet. It would, how-

ever, be rash to predicate cure in any given case. Worms having often seen glycosuria recur after long periods of absence of sugar. As regards treatment, he says that diet must be the foundation of any system of therapeutics, but it should be rigidly adhered to only at the outset, when the degree of reducibility of the sugar in the individual case is being tested; if kept up too long it does harm and predisposes to coma. In the way of medication he believes most in quinine. Treatment, he adds, succeeds best in patients who are not anxious about their condition, which is always aggravated by worry.

(185) An Epidemic of Malignant Pneumonia at Poltinecola.

MALENCHINI (*Lo Sperim.*, August 6th, 1895) draws attention to a small epidemic of fatal pneumonia occurring in Florence in autumn, 1894, and spring, 1895. The cases as a rule began without cough or pain, but with fever and general malaise. Physical signs of pneumonia as a rule did not appear for three or four days. Opaque albuminuria was a constant feature. Most of the cases died, and at the necropsy patches (chiefly central) of pneumonia were found, mostly in the lower lobes and of mixed catarrhal and fibrinous types. A lance-shaped encapsulated diplococcus was found in the blood and lungs. The prevailing theory in Florence as to the cause of the epidemic was to the effect that it was due to infection from certain imported parrots. The author discusses this theory, and refers to a similar epidemic in Paris also supposed to be due to parrot infection, and where a diplococcus of similar nature was found in the incriminated birds. On the whole Malenchini does not consider the parrot theory proved in the Florence epidemic, but in view of the results of Nocard, etc., in the Paris epidemic he is not inclined to dismiss it as a vain and futile supposition.

(186) Syphilitic Endocarditis and Myocarditis.

O. ISRAEL showed this specimen before the Charité Aerzte (*Berl. Min. Woch.*, September 9th, 1895). The heart was hypertrophied, but only slightly dilated. No circulatory obstruction could be proved at the mitral orifice. Islets of fibrous tissue were present at the base of the papillary muscles, and the muscles themselves had undergone fibrous changes. Fine strands of fibrous tissue were seen in the slightly brown cardiac muscular tissue. The dilated left auricle presented peculiar appearances. The wall was rigid, with only the remains of a few yellowish-brown muscular fibres. The auricular appendix was greatly shrunken. Very irregular and easily detached excrescences were found on the inner wall of the auricle, and were especially well marked on the upper surface of the mitral valve segment. The gummatous formation in the heart muscle could only be due to syphilis. In the liver fibrous changes with the remains of gummata were found. There was induration of the

uterus with chronic endometritis also of syphilitic origin. Huber recounted the symptoms observed during life. The patient, aged 47, presented the appearance of hepatic cirrhosis. The pulse, 126, was small and irregular at first, but improved under digitalis. A systolic murmur was heard in the left second and third intercostal spaces, with an accentuated second sound. There was no clinical evidence of syphilis. Eight days after admission there was a profuse and fatal hæmorrhage from the stomach. In the dissection Klempner pointed out that this was apparently the first case in which an endocarditis was demonstrated to be of syphilitic origin, and that the diagnosis of such a lesion was now within possibility.

(187) The Movements of the Fontanelle. HUTCHINSON AND ELDER (*Edin. Hosp. Repts.*, III, 268) have obtained a number of tracings of the pulsation of the anterior fontanelle in young children. They exhibit a double pulsation, arterial and respiratory. The arterial pulse is almost invariably anacrotic, in which respect it corresponds with the tracing from a limb, or any considerable part of the body taken as a whole. The whole fontanelle is depressed with inspiration and bulged with expiration, owing in all probability to a suction of the venous blood out of the cranium during inspiration, and a damming of it back during expiration. Under pathological conditions the lowering of pressure during inspiration may be great enough to affect cerebral activity. During sleep the mean intracranial pressure is low, the arterial waves are small, the respiratory undulations well marked. Chloroform produces similar effects. The fontanelle is more tense, the arterial waves lower, and their summits more rounded than in the vertical. Movements evidently cause a marked increase in intracranial pressure, and this is particularly marked when the child cries.

(188) Pulmonary Hypertrophic Osteoarthropathy.

DAVIS (*Journ. American Med. Assoc.*, June 1st, 1895) records a case which he brought before the Association in May, and gives a bibliography of the disease. He does not consider it a pathological entity like acromegaly but regards it as a symptom group often associated with chronic lung affections, rarely with diseases of other organs and with syphilis. These give rise to a toxæmia, which like that of phosphorus, arsenic, and certain infectious, tends to involve bones and joints in inflammation. Davis's patient was a boy, aged 4 years, who had pneumonia at 1 year, and since then was never free from cough, with frequent and copious purulent expectoration. One year after the pneumonia the ends of the fingers and toes became deformed by enlargement, while the wrists and ankles increased greatly in size. There was no enlargement of the jaws; the lower lip was somewhat hypertrophied. The spine was straight. When exhibited there were signs of

fluid (probably purulent) almost filling the left pleural cavity. There was no deformity of the bones of the body or enlargement of those of the upper arms. Both wrists were considerably broadened and thickened, but their movements were unaffected. The metacarpals were normal, the first phalanges of the fingers much enlarged, the second now little affected, and the terminal act enormous and characteristically broadened and thickened. The nails resembled parrot beaks. Similar changes were to be seen in the feet. The lower ends of the femora were much enlarged, but there was no fluid in the knee-joints. No joint tenderness was observed. The urine and sputum had not been examined. Davis quotes the pathological observations which have been made by others on this disease, and emphasises the points of diagnostic differentiation from acromegaly afforded by the disproportionate enlargement of the terminal phalanges in pulmonary hypertrophic osteoarthropathy, together with the absence of deformity of the inferior maxilla. With regard to treatment, Moussois has observed improvement in one case after the drainage of the antecedent empyema, and Gillet after drainage of a tuberculous cavity. H. Schmidt found that a case of supposed syphilitic origin recovered after a course of specific treatment. Desmons and Binand have recently observed considerable improvement in a patient treated by subcutaneous injection (during several months) of tissue extract from the lungs of healthy sheep; Davis thinks this method deserving of further trial. He intended to treat his own case first by aspiration of the effusion, with thorough drainage of the pleural cavity should pus be found.

SURGERY.

(186) Prostatectomy.

At the meeting of the American Association of Genito-Urinary Surgeons, J. P. Bryson, of St. Louis (Philadelphia Medical News, June 29th), presented a tabulated report of twenty-seven operations of "prostate-myomectomy" by the suprapubic route. The series was commenced when this method of attacking the prostate was in its infancy and the technique far from perfect. The ages of the patients ranged from 50 to 78 years. The mortality for the entire series was a little over 25 per cent., but this does not represent the true death-rate of the operation; 3 cases should be excluded, 1 of which died from hemorrhage from sarcomatous disease of the prostate and 2 from pyelonephrosis. Eliminating these three, there were 24 cases with 4 deaths, a mortality of 16.6 per cent. A radical cure was effected in 13 of the cases, as evidenced by the absence of residual urine, a good rest at night, and a practical cure of the cystitis. In 2 cases no benefit whatever appeared to have resulted; these patients were aged respectively 72 and 78 years, were far advanced in senile de-

generation, and were operated on mainly in the hope of relieving the most distressing symptoms of "prostatism," namely, frequent and painful urination and inability to get rest or sleep either by day or by night.—Eugene Fuller, of New York (*ibid.*), reported six successive successful cases of prostatectomy, and described a method of operating whereby the prostatic hypertrophy is enucleated. Ordinarily, suprapubic cystotomy is first performed, then an incision is made through the floor of the bladder; this incision extends from the lower margin of the vesical opening of the urethra backward for about an inch and a-half, and is made with rough serrated-edged scissors, in order to avoid hemorrhage. The forefinger of one hand is then introduced through this cut, while the fist of the other exercises counter-pressure upon the perineum, in order to bring the growth well within the reach of the forefinger. By manipulation the obstruction can gradually be enucleated, the hypertrophy coming away in one or several pieces. After the enucleation, a perineal incision is made for dependent drainage, the inner edge of the drainage tube entering the bladder through the lower vesical incision made for the enucleation. The suprapubic vesical and abdominal incision is then tightly sutured, with the exception of a small space for a drainage tube. Fuller has never seen trouble from hemorrhage, either primary or secondary, by this method of enucleation, and felt safe in closing the suprapubic cut. He claimed that by this method the mortality is reduced, and excellent results obtained. Bell said his own experience of prostatectomy had not been so favourable as that of Bryson and Fuller. He had operated in 5 advanced cases, all in very old men, and of these 2 died. In both instances death took place several days after the operation, apparently from toxemia. On post-mortem examination nothing was found that could account for the fatal issue.

(187) Traumatic Rupture of the Urethra: Restoration after Thirty-six Years.

At the meeting of the American Association of Genito-Urinary Surgeons (*Med. News*, June 29th) G. Chismore reported the following case: The patient was a brewer, aged 43. At the age of 6 years, in order to avoid constantly wetting the bed at night for which he had often been punished, he tied a string about the penis near the scrotum. The constriction thus produced entirely severed the urethra and corpus spongiosum and divided fully one-half of the corpora cavernosa. Two attempts were made in Germany to restore the urethra by plastic operations but both failed. Several months ago he came under the author's observation, who first made a perineal section through which the urine was allowed to pass and then denuded the tissues of the old wound, precisely as is done in attempting to close an old torn perineum. The two ends of the urethra were then cut off squarely, a staff introduced, and then

the severed portions of the corpora cavernosa were closely drawn together by means of a deep line of buried catgut sutures. Accurate approximation of the under surface of the urethra was obtained by three catgut sutures; no attempt was made to suture the upper or deeper half of the urethra. The corpus spongiosum was carefully sutured and the integument then brought together. On the second day after the operation the man had an attack of delirium tremens. On the thirteenth day the catheter was removed and the perineal incision permitted to close. The man now passed his urine entirely through the normal urethra, the severed ends of which had united so closely that the introduction of a bulbous sound failed to reveal the line of union. Since the operation the man had had two erections without pain.

MIDWIFERY AND DISEASES OF WOMEN.

(188) Uterine Ricornia in an aged Multipara.

GRIFFON (*Bull. de la Soc. Anat. de Paris*, vol. ix, part 13, 1895) recently dissected the genitals of a woman, aged 72, who died in a home. She had borne three daughters, all now living. No abortion nor twin pregnancy had occurred. The uterus consisted of two perfectly distinct and symmetrical cornua, lying almost horizontally and divergent from each other. Each had a distinct os internum, but there was but one cervix beyond the normal level of the middle of the cervical canal. The common portion was very short and wide. Each cornu bore a normal tube and ovary. The os externum, portio vaginalis, and vagina, as well as the ureters and kidneys and all anatomical structures beyond the genital tract were free from abnormalities. A very deep vesico-rectal peritoneal fold was discovered, giving a strange appearance to the parts when the peritoneum was opened. It ran from the bladder to the rectum, and was fixed to the groove formed by the junction of the cornua. It divided into two both the vesico-uterine and Douglas's pouches.

(189) Ectopic Gestation. Rupture of Hematocoele into Bladder.

SCHWARTZ (*Centralbl. f. Gynäk.*, No. 36, 1895) relates a case of rupture of a tubal gestation sac, with acute symptoms. The patient was 42, and, as is so often the case, she had not been pregnant for many years. Notwithstanding the urgency of the symptoms and the weak and anæmic state of the patient, it was not considered advisable to operate. A large hematocoele had developed, and Schwartz thought that there was less risk in leaving the patient quiet than in opening the peritoneum. The pregnancy had hardly passed the second month. The result of the case was not in all respects satisfactory. It was three days before the collapse passed away. Fever and rigors set in, with sharp pain referred to the symphysis.

At the end of a fortnight there was severe dysuria, and clot, pus, and sloughy tissue were passed from the bladder. For four weeks the discharge of foreign matter continued, pieces of fetal skeleton also came away. The hamatocoele grew smaller and smaller. At the end of the seventh week a rigor set in, followed by pneumonia. This complication was traced to septic infarcts. Several articulations afterwards became inflamed. At the end of six months the patient seemed, according to Schwartz, to be safe at last, but there were distinct pleural adhesions and extreme debility.

(290) **Tubo-ovarian Abscess: Vomiting of Ecchymata after Operation.**

HUMISTON (*A Year's Work in Operative Gynecology*, Cleveland, U.S., 1896) publishes details of a very advanced case of disease of the appendages. On the right side was a large intra-ligamentous ovarian hemorrhagic cyst, on the left a small tubo-ovarian abscess. Both appendages were removed. A Mikulicz tampon was used to check the oozing. The operation lasted forty-eight minutes, in the course of which period 13 fluid ounces of ether were administered. Incessant vomiting began twenty-four hours after the operation, with fever and high pulse. Humiston declares that the vomiting was terrific, and by reversed peristalsis enemata were passed out of the mouth. Death occurred on the morning of the fourth day. There was no necropsy.

(291) **Hyperemesis Gravidarum: Difficulty in Inducing Abortion.**

CHARPENTIER (*Réper. Univ. d'Obstét. et de Gynéc.*, August 26th, 1895) observed uncontrollable vomiting, from the beginning of pregnancy, in a secundipara, aged 28. At the third month the state of the patient was so grave that it was necessary to provoke abortion. A rubber bougie was passed into the uterus, and another on the following day, then a dilating bag, then Hegar's dilators from the smallest to the largest. Lastly, nitrate of silver was applied to the uterine cavity. The ovum remained unexpelled. These proceedings took five days. The patient was ultimately put under chloroform, and the ovum was detached by the finger. The patient recovered. She was hysterical, and Charpentier believes that hysteria is often the cause of uncontrollable vomiting in pregnancy.

(292) **Menstruation and Ovulation Independent.**

BYRON ROBINSON (*Amer. Gynec. and Obstet. Jour.*, Aug., 1895), in a discussion on menstruation, noted that all evidence favours the theory that ovulation and menstruation are independent. Ovulation, he remarked, occurs before birth in man and other animals. Women menstruate who possess ovaries totally incapable of ovulating from disease. Menstruation frequently continues after removal of the ovaries, and is not required for the ripening and discharge of ova. The sow seems to

ovulate continually and progressively, but the ova ripen in greatest number at rut or oestrus. Robinson believes that sufficient evidence exists to show that no follicle ruptures at many of the menstrual rhythms. Women who do not menstruate can become pregnant. If ovulation and menstruation occurred together coitus between healthy subjects just after the period would far more frequently be followed by pregnancy. Lastly, ovulation, in a modified form, continues during pregnancy.

(293) **The Maternal Impression Theory.**
HARTMANN (*Munch. med. Woch.*, 1895, No. 9) describes the birth and anatomical structure of a double monster (*cephalothorax copagus*), and notes that the mother was alarmed, when pregnant, by seeing in a forest a newborn fawn showing a similar monstrosity. She considered that that adventure was the cause of the malformations in her child, and Hartmann seems inclined to support her opinion.

THERAPEUTICS.

(294) **Borax in Epilepsy.**

FÉRÉ (*Rev. de Méd.*, September, 1895) reports the results of the treatment of 122 cases of epilepsy by borax. The drug was given in large doses (2 g., rising gradually to as much as 20 g. a day), and in some cases for many months. In about two-thirds of the cases (71.31 per cent.) the treatment had no effect. In about a fifth (19.67 per cent.) some doubtful or temporary improvement was noticed, less than the benefit derived from bromides. In the remainder (9.01 per cent.) the improvement was marked, though the duration of the observations was too short to permit it to be stated that the improvement was permanent. The great drawback to the use of the drug is the frequency with which its continued use in large doses produces toxic symptoms. To this subject Féré devotes the greater part of his paper. The earliest as well as the most frequent symptoms are due to derangement of the alimentary tract. Nausea and vomiting preceded as a rule for a few days by loss of appetite, and heaviness and burning in the pit of the stomach. In some cases these symptoms may be diminished or removed by administering intestinal antiseptics, or by giving the borax dissolved in glycerine instead of water. Extreme dryness of the skin with suppression of the fatty secretion, as well as dryness of the mucous membranes, may also be produced by the large doses of borax requisite in the treatment of epilepsy. The hair also is affected: it becomes dry, and may fall out, producing complete baldness. Various lesions of the skin may be produced by borax, among others (1) psoriasis in persons predisposed to that affection. The most common affection is a form of (2) eczema resembling seborrhoeic eczema. The affection begins as papules or circles with red squamous borders, which first appear generally on the lower part of the trunk or abdomen

and on the upper limbs. In that is to say, parts of the body where the sebaceous secretion is most scanty. Fine branny desquamation of the hairy scalp with or without loss of hair may accompany the appearance of a form of the skin affection to which the term seborrhoeic acne is applied. These skin affections disappear when the administration of borax is suspended, and may be kept under during its use by giving intestinal antiseptics or by resort to local treatment by oxide of zinc, sulphur, or salicylic acid. Other less common affections of the skin are (3) the appearance of red plaques which may be confluent and very extensive, may present resemblance to the rash of measles or scarlet fever, and may be followed by desquamation. (4) A papular eruption accompanied by pruritus and followed sometimes by desquamation. The continued administration of borax produces in some cases a cachectic state, characterized by wasting, a waxy tint of the skin, discoloration of the mucous membranes, puffiness of the face, and sometimes general oedema. In a certain proportion of the cases of oedema there is albuminuria, and in such cases anæmia may develop with great rapidity. Borax appears in the urine in health half an hour after ingestion, and may continue to be excreted by the kidneys for weeks after the suspension of treatment. On the whole Féré concludes that borax is more efficacious than the bromides in a small proportion of cases of epilepsy, and that therefore it should be tried when the bromides fail. It must be regarded, however, as a dangerous remedy owing to its power of producing or aggravating lesions of the kidneys even when given in small doses.

(295) **Erysipelas Toxine in Malignant Disease.**

CZERNY (*Munch. med. Woch.*, September 3rd, 1895) relates his experience of the treatment of malignant disease with erysipelas toxine. Although he has often seen no good effect, but even a more rapid development of tumours, after a spontaneous erysipelas, yet he recollects 2 cases in which an undoubted beneficial influence was exerted upon carcinoma. The author has used dried erysipelas and prodigious toxine after Coley's method. In 1 case of a woman, aged 35, a sarcoma of the parotid appeared during pregnancy, and grew at first slowly, but later rapidly. When she presented herself, there was a mass as large as the fist behind the ear, the parotid was hard, and a mass of growth was present in the external meatus. The facial nerve was paralyzed. As extirpation offered no hope, the toxin treatment was begun, and 12 injections were made. The growth became greatly lessened in size, the parotid gland soft, and the facial paralysis disappeared except from the frontal branches of that nerve. The author says that a marked favourable if not specific action was noted upon the carcinoma in this case. It is to be remembered that tumours occurring during pregnancy have some-

times been known to diminish considerably afterwards. The author then refers to 3 cases of recurrent sarcoma in the naso-pharyngeal space in which he used the same treatment, but the number of injections was too small to produce a very striking effect. He has also treated 4 cases of carcinoma with no very real benefit. In 1 case of advanced carcinoma of the upper jaw, an extensive softening of the growth with subjective improvement occurred. Putting his results alongside Coley's more extensive experiences, he concludes that (1) the injection of these toxins causes fever, etc., and always local inflammatory signs; (2) these manifestations disappear in a few hours, but after frequently repeated injections there may be loss of appetite, wasting, etc.; (3) the injections exercise a specific action upon sarcomatous growths, and may even bring about a cure; (4) as the results are uncertain, such treatment should of course never take the place of operation, but should be adopted in inoperable or recurrent growths. Perhaps it might be used to prevent recurrence in sarcoma; and (5) in carcinoma at most a retardation of growth has been noted, but no cure.

(294) Serumtherapy of Cancer.

SALVATI and GARTANO (*Rif. Med.*, Aug. 19th and 20th, 1895) give the result of their clinical experience in the treatment of cancer by injection of serum derived from a horse which had been previously inoculated (through the trachea) with an infusion of triturated sarcoma. Five patients suffering from undoubted cancer, mostly relapses after previous operation, were subjected to the treatment. No ill results were observed after injection. The lancinating pains in the majority of cases disappeared completely for a time—after 10 to 20 injections—but as a rule returned again with their previous intensity. Hemorrhage from the ulcerated surface was a frequent occurrence after injection. The tumours were observed to diminish in size in the early part of treatment. Still, notwithstanding the manifest improvement at the beginning of treatment no real arrest of growth took place in any of the cases, so that one cannot speak of the treatment of malignant growths by injection as in any sense a cure.

PATHOLOGY.

(295) Histological Appearances of the Heart Muscle in Valvular Lesions.

BANTI (*Centr. f. d. Path. u. path. Anat.*, 1895, Bd. vi, Nos. 14 and 15) considers the microscopic changes in the heart wall with the object of explaining the failure of compensation which occurs at the end of cardiac disease. He divides the cases according as the aortic or the mitral valves are affected, and finds that the lesions are somewhat different. Aortic disease is frequently caused by atheroma, and this degeneration affects the orifices and walls of the coronary arteries. The nutrition of the heart

thereby is interfered with, and there results simple or degenerative atrophy of the muscular elements with coincident hyperplasia of the connective tissue. Small necrotic areas may also be found which lead to the formation of definite scars. This process is a sclerosis or cirrhosis, and is termed by the author "arterial cirrhosis." In the case of mitral disease the process is different as the cause of the valvular lesion is usually different. Banti investigated hearts of persons dying in each of the three following conditions: (1) In the period of full compensation, as the result of an intercurrent disease; (2) during that early astylosic condition known as heart fatigue (*Ermüdung des Herzens*), death occurring usually from some complication, such as embolism; (3) after a more or less prolonged period of cardiac cachexia. In the first series he found pure myocardial hypertrophy without any recognizable microscopic change. In the second series there was marked dilatation of the coronary veins and their sub-epicardial branches, and microscopically this dilatation was seen to extend to the capillaries between individual muscle bundles. The intermuscular connective tissue also underwent a change, becoming granular and cloudy. Some of the muscle cells showed vacuolar degeneration. These changes clearly show venous congestion and oedema of the muscular bundles and connective tissue. In the third series the dilatation of the coronary veins was often enormous, while their walls were thickened, white, and rigid, so that they resembled arteries rather than veins. Microscopically this change was shown to be a sclerosis. From these veins there proceeded in all directions bands of fibrous tissue, which led to atrophy of the muscular bundles. Here one has therefore a "venous cirrhosis." The author concludes that heart failure therefore depends upon the scarcity of muscular elements in those cases in which the fibrous tissues increased, but that this is also aided by an insufficiency of reserve force, which is the essential cause of heart fatigue, and which cannot be recognised by any definite lesion of the muscular elements.

(296) The Presence of Streptococci and Mastitis in Cows as a Cause of Acute Gastro-Enteritis in Man.

HOLST (*Festschrift till Professor Heiberg*, Christiania, 1895) gives an account of four epidemics of acute gastro-intestinal catarrh, which took place in Christiania, presumably as a result of drinking infected milk. In each epidemic the persons affected were found to have received milk from the same source. The milk was almost invariably taken unboiled, and the symptoms commenced some hours afterwards. The illness lasted half a day in most cases; in two or three it lasted several days; it was afebrile. The milk in each case contained numerous pus cells, with masses of diplococci and streptococci, which, on cultivation, yielded

"*streptococcus longus*." Injected into animals it caused fatal peritonitis, with the production of masses of the same streptococcus. On investigation it was found in each epidemic that in the cattle shed from which the suspected milk was obtained there was a cow suffering from mastitis: the milk of this cow also contained "*streptococcus longus*." It was stated in each epidemic that the milk from these cows had not been used for food previously but had been delivered by mistake on the day on which the cases occurred. In the first epidemic the suspected cow also suffered from diarrhoea, but this possible source of error was not present in the others. Injections of these cocci into rabbits and mice caused diarrhoea in some cases, in others there was hyperæmia of the duodenum and streptococci in the blood of heart and spleen, and in the peritoneal fluid. The author took 200 c.c.m. of these cultures, and had colic, sometimes vomiting, rarely diarrhoea. On further experiments these results ceased and did not occur in two other doctors. Animals treated with more virulent cultures had diffuse intestinal catarrh or diarrhoea; streptococci were found in all their organs. The author regrets the incompleteness of these investigations, but concludes that mastitis caused by streptococci in the cow is capable of communicating to milk diarrhoea-causing properties. He has, indeed, found in milk under normal conditions numerous cocci in chains, which appear harmless. He has often found streptococci in diarrhoea of unknown origin. Sometimes these caused peritonitis or diarrhoea in animals. In one case diarrhoea in a child was said to be caused by boiled meat containing the "*streptococcus longus*," which was also found in the child's stools. But the "chains" produced no effect on animals. In one case of diarrhoea the streptococci present had no effect on animals, but in the author caused shivering and increasing colic without diarrhoea for some days.

(297) Changes in Nerve Cells in different Functional States.

LUJANO (*Lo Sperim.*, August 6th, 1895), as the result of an experimental study of the above subject, concludes that the activity of the nerve cells is accompanied by a state of turgescence in the protoplasm of the cell substance. Fatigue induces a progressive diminution in the size of the cell. In moderate degrees of activity the nucleus undergoes no change in volume; when the activity is continuous and protracted the nucleus undergoes changes analogous to those occurring in the cell substance, but less marked. Probably the first phases of cellular activity excite a slight increase in the chromatic substance of the cell body; the later phases, accompanied by fatigue, cause a diminution and more diffuse distribution of the same. In the nucleus an increase in volume is observed which yielded slowly *puri passu* with the oncoming of fatigue.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(300) Auto-intoxication and Skin Diseases.

BLASCHKO (*Berliner Klinik*, September, 1895) discusses the present position of our knowledge regarding this question. The key thing to the old humoral pathology which attributed skin affections to dyscrasia, improper mixing of the blood fluids, and, though the local origin of many of them has been proved by Hebra and his school, there can be no doubt that a large number of such diseases arise from internal causes. Among these causes, one which has of late been put prominently forward is auto-intoxication. According to Bouchard, this is a perpetual danger in the healthy subject whose organs, as well as innumerable micro-organisms in his alimentary tract, are continually forming chemical substances of which any excess or abnormality in production is liable to lead to toxic effects. These are still more likely to result from the formation of abnormal chemical products under the influence of disease. Bouchard and other French authors include among the toxemias all affections resulting from acute or chronic putrefactive processes in the alimentary canal, taking dilatation of the stomach as the type of chronic auto-intoxication. Various skin diseases, particularly acne of the skin with reddening of the tip of the nose in young girls, are attributed to gastrotoxis; but Bouchard uses this term in a very loose way, ignoring the recent researches and the laws deduced therefrom as to its exact diagnosis. The nature of the "autotoxic dermatoses" can best be elucidated by the study of such "toxic dermatoses" as the drug eruptions. Of these the main characters are as follows: (1) Certain drugs produce by preference certain eruptions, but one and the same substance may cause very various manifestations, of which potassium iodide affords a very good example. (2) The same eruption—for example, urticaria—may result from the action of the most different medicines. (3) These eruptions are comparatively rare, due to idiosyncrasy, which may be natural, or result from the continued use of the drug, which in other instances establishes a protective habit. (4) They are generally acute, and belong to the group of erythematous and exudative affections; more chronic outbreaks are rare, and genuine eczema and psoriasis are unknown outside the true parasitic affections. (5) They appear alike in whatever way the drug was administered, and are therefore due not to reflex action but to the direct toxic effects of the poison in the blood. Similar eruptions may result from the presence of any foreign substance in the

blood: thus, the emptying of an echinococcus cyst into a branch of the portal vein has set up urticaria. In such a case the boundary between toxemia and auto-intoxication may be hard to define; somewhat akin are the rashes so often observed after the operations of serumtherapy. Auto-intoxication is also dependent upon idiosyncrasy: in the cases under consideration there is loss of power of resistance to a poison acting on the cutaneous circulation. It is possible to enumerate groups of skin affections which probably originate from poisoning by bacterial proteids (=auto-intoxication). Among erythemas may be reckoned: (1) the typical acute exanthemata, morbilli, rubella, and scarlatina, which approach nearest to the toxic erythemas. In variola, varicella, and the other acute exanthemata there is also the local action of the micro-organisms on the skin to be considered. (2) Erythema in the course of acute and chronic infectious diseases, such as cholera, septicemia, etc. Here again the affection may be complicated by the presence of bacteria in the skin. (3) The erythema of uremia and of icterus. (4) Dermatitis exfoliativa, of which Blaschko quotes a case which he believes to have arisen from auto-intoxication. In all these cases substances have been found in the urine indicating the occurrence of putrefactive changes in the intestine. Urticaria in many cases undoubtedly arises from auto-intoxication; here again idiosyncrasy plays a most important part. Acne vulgaris is probably unconnected with digestive troubles, with which, however, acne rosacea is usually associated. That the latter is really an auto-intoxication can hardly be regarded as proved when the uncertainty of its relation to the alimentary tract is considered. Still more uncertain, in spite of the popular views as to "impurity of the blood," is the autotoxic origin of eczema. Some have considered this proved by the local reaction of tuberculin and other materials (especially amines) injected into the circulation of patients suffering from lupus. Blaschko, however, points out that this reaction does not occur in the healthy skin, and is strictly comparable not to the development of eczema but to the appearance of an acute exacerbation in the course of an already established disease. In France the old humoral pathology has never become quite extinct, and modern observers, such as Quinquaud and Gigot-Scard, still attach too much importance to the toxic origin of skin affections. Tominasoff has also written a book in which he attributes an enormous number of cutaneous diseases to auto-intoxication, basing his views on the daily estimation of the various constituents of the urine in 8 cases, a method which cannot but be reckoned fallacious when the enormous number of substances in the circulation which may act upon the skin is considered. Blaschko concludes that the number of skin diseases of which auto-intoxication is the proven cause is very small, but that it is a possible factor in the production of

many more, whose origin can be definitely established only by the combined efforts of dermatologists, clinicians, and physiological chemists.

(301) Tuberculosis of the Spinal Cord.

HASKOVSKY (*Archiv. de Neurol.*, September, 1895) reports the case of a woman, aged 23, who after slight lung symptoms developed tingling and pricking sensations in the lower limbs, with slight weakness. After three months the weakness rapidly increased in a few hours to almost complete paralysis, with diminished and soon absent reflexes, retention of urine and feces. There was also sensory disturbance in both lower limbs and the lower part of the abdomen, tactile sensation being almost perfect, while there was complete analgesia, and loss of sensation of heat and cold; a few weeks later tactile sensation had also disappeared, muscular atrophy was apparent in both lower limbs, and similar symptoms, but much less marked, had appeared in the upper limbs. Death took place a few weeks later. The autopsy showed advanced phthisis, with extensive disease of the spinal membranes and cord, the lesions being most intense in the upper dorsal region, especially about the posterior roots; the infiltration was partly diffuse, partly nodular. Several observers have noted the occurrence of primary tubercle of the spinal cord, and it would seem that the lumbar cord is the part most frequently affected; secondary tubercle of the cord, sometimes but not always involving the membranes, is much commoner, the dorsal being the part most frequently affected in these cases. The symptoms in either are generally as in the case mentioned those of myelitis, the nature of which can only be suspected from the presence of tuberculous lesions elsewhere. Even at a necropsy the tuberculous nature of a myelitis may be entirely overlooked unless the cord is examined microscopically.

(302) Alcoholism in Children.

MONNAY (*Annales Médico-Pédic.*, 1895, p. 337) records several cases of alcoholism and dipsomania in children. The tendency is in some cases hereditary; often it is the result of some psychical disturbance. Many cases are due to the ignorance of mothers, who quiet their infants, even while at the breast, with wine or spirits. The pernicious habit of parents taking their little ones into public houses, and there allowing them to share the drinks, is pointed out. The risk of alcoholism must always be considered in ordering alcohol for children, and where there is a history of alcoholism in a child's antecedents it is best to avoid it altogether. Dipsomania, generally hereditary, occurs both in boys and in girls. In the latter especially about the time of the first menstruation. Delirium tremens has been seen at 5 years old and cirrhosis of the liver, with definite history of abuse of alcohol, at 24 years. Children who have suffered from the effects of alcohol are specially liable

to epilepsy, hysteria, moral insanity, etc. The prognosis in such cases is bad, the tendency to excess generally persisting.

SURGERY.

(392) Treatment of Perforating Ulcer by Nerve Stretching.

CHÉPAULT (*Presse Méd.*, September 14th) reports 5 cases of perforating ulcer successfully treated by stretching of the plantar nerves. After many unsatisfactory attempts to deal with this affection by amputation, excision of the ulcer, and scraping, the idea occurred to the author that stretching of the nerves distributed to the region occupied by the perforating ulcer might give some good results. Rejecting cases of non-trophic perforating ulcer which may be regarded as unamenable to this plan of treatment, he tried nerve-stretching with an unexpected degree of success in 2 cases in which the perforating ulcer was due to peripheral neuritis, and in 3 others of spinal origin. The 5 patients, all of whom had suffered for many years, and undergone useless amputation, were in the course of a few days after stretching of the plantar nerves, relieved of the ulceration and of the concomitant trophic disturbances. As 4 patients were kept in bed for only twenty-four hours after the operation, and the fifth was thus confined for eight days, these good results could not be attributed to the rest which so often effects a transitory improvement in cases of perforating ulcer. These patients have remained quite free from their affection after intervals from the date of operation of eight, seven and a-half, seven, six, and three months. The author has practised stretching twice of both the internal and external plantar nerves, once of the internal plantar alone, and twice of the internal collateral nerve of the great toe. It might, he states, be found necessary in some cases of perforating ulcer to stretch the musculo-cutaneous and external saphenous nerves. In most instances it would be advisable, for the sake of avoiding infection of the wound, to operate at some distance from the perforating ulcer, and so to stretch the common trunk of the plantars behind the internal malleolus, the musculo-cutaneous above the external malleolus, and the short saphenous nerve at the outer border of the tendo Achillis.

(393) The Clinical Phenomena of Cervical Rib.

EHRLICH (*Beiträge zur klin. Chir.*, Bd. xiv, Hft. 1) publishes an analysis of ten collected cases of cervical ribs with reference to the symptoms, local and functional, of this abnormal condition. In seven of these cases the supernumerary ribs were found on the left side. The local symptoms are: a bulging prominence at the outer margin of the sterno-mastoid, just above the clavicle, and a well-marked pulsation in the supra-clavicular region. On palpation a bony tumour can be felt and

traced as far as the spine. The outer extremity of this tumour is in some cases free, in others connected with the first thoracic rib. The functional symptoms are due to obstruction of the circulation in the subclavian artery, and to pressure on the brachial plexus. The circulatory disturbance is shown in the corresponding upper limb by pallor of the skin, reduced temperature, absence of pulse, arrested growth of the nails, gangrene of the fingers, and muscular atrophy of the whole arm. The nervous disturbances are chiefly neuralgic pains and paresthesia. Motor disturbances in the parts supplied by the brachial plexus have not been noted. All these evils usually disappear after the removal of the cervical rib.—Schnitzler (*Centr. f. Chir.*, No. 37, 1895) reports a case in which the presence of a cervical rib on the left side was associated with a forward dislocation of the sternal end of the corresponding clavicle. This displacement, which was not accounted for by any history of injury, is attributed by the author to pressure of the outer end of the cervical rib on the middle of the posterior surface of the clavicle. In this case, as there were no functional symptoms, and as the use of the upper extremity was in no way impaired, it was thought advisable to refrain from operative treatment.

(394) Suture of the Vas Deferens.

PARLAVECCHIO (*Gazz. degli Osped.*, August 31st, 1895) in operating for a right strangulated hernia, had the misfortune accidentally to lacerate the vas deferens. To remedy this the author thereupon cut the two ends of the vas obliquely, so as to form a larger surface, and sutured them together with four Lambert sutures of fine silk. Torsion of the vas was carefully avoided, the stitches held well, and beyond the application of a scrotal suspender no special modifications in the ordinary post-operative treatment were adopted. The wound healed by first intention. The patient came to report himself two years after. The hernia was then quite cured; there was no swelling, no cyst of the vas deferens, no diminution of sexual desire, no atrophy of the testicle, no loss of sexual vigour, and no disturbance of micturition or defecation. The author was unable to examine the state of the prostate *per anum*, but there were no symptoms pointing to any alteration in that organ.

(395) Subcutaneous Emphysema after Intubation.

BAUER (*La Pédiatr.*, No. 7, July, 1895) reports two cases of diphtheria in children where after intubation subcutaneous emphysema occurred. In the first case that of a child aged 4, suffering from mild nasopharyngeal diphtheria, as difficulty of respiration came on, intubation was performed. Violent coughing occurred, and the tube was expelled but replaced. The day after emphysema of the neck and upper abdomen occurred, and rapidly spread to the back. The tube was removed, the emphysema remained unaltered at first, but ultimately entirely

disappeared, and the child left the hospital cured. The second case was very similar. The tube was kept in two days, and finally removed on account of emphysema, which lasted in this case five or six days, but finally disappeared. The author supposes the emphysema was due to alveolar rupture induced by the violence of the inspiration, and that the tube simply acted as a "determining factor." In 280 cases of intubation Bauer has only observed these 2 cases of emphysema.

MIDWIFERY AND DISEASES OF WOMEN.

(396) Vaginal Hysterectomy on a Large Scale.

LANDAU (*Berlin. klin. Wochenschr.*, September 23rd, 1895) has removed the uterus through the vagina 277 times during the past nine years; 13, or not quite 5 per cent., of the patients died. In 112 of these cases the disease was cancer or sarcoma of the uterus; 8, or a little over 7 per cent., died; 1 sank from diabetic coma, 1 from obstruction, and 1 died from sepsis due to abortion, which complicated the disease and the operation. In 56 of the series the uterus was removed for fibroid; in many instances the tumour reached as high as the umbilicus; 4, or over 7 per cent., died, 1 sinking from failure of the heart's action on the twenty-second day, and another from chronic nephritis on the nineteenth day; 169 patients underwent the operation for bilateral chronic septic or inflammatory disease of the appendages; 1, or less than 1 per cent., died, the fatal end being due to diffuse septic peritonitis; 1 suffers yet from a small enteric vaginal fistula. The remaining 107 have all been restored, in most cases after years of discomfort or pain, to perfect health. Landau adds 2 cases of vaginal hysterectomy for acute puerperal sepsis with multiple collections of pus in the pelvis: 1 of the 2 died of purulent peritonitis. Landau did not operate in the same manner in all the 277 operations; sometimes he removed the uterus entire, in other cases he bisected it vertically, whilst in some he removed it by morcellation.

(397) Actinomycosis of Ovary (?)

REGNIER (*Prager Zeitschrift f. Heilkunde*, vol. xv, 1895, parts 4, 5) reports the case of a woman, aged 38, in a mining district, who had suffered from sharp pricking pains in the hypogastrium, with somewhat rapid development of a tumour and emaciation. An oval mass very tender and scarcely movable, filled the right side of the hypogastrium and pelvis, the uterus was separate and the right ovary could not be distinguished from the swelling. The parietes were infiltrated; nevertheless an exploratory operation was thought advisable. It proved incomplete. A part of the mass was cut away, together with the infiltrated muscular and aponeurotic layers of the abdominal wall. The rest of the growth was dissected away from intestine which was injured, and from the

greatly thickened vermiform appendix. Its precise seat was not determined; on examination, it was found to be a mass of granulation tissue containing the actinomyces. A small piece of some hard foreign substance was found in the characteristic tissue, outside the vermiform appendix, which had been amputated with the cautery. This foreign body had probably conveyed the fungus into the body, and after perforation of the appendix had infected adjacent structures, though it is not absolutely certain that the ovary was diseased. The patient recovered, but from deposit appeared in the abdominal cleatrix and hypochondrium three months later. The patient refused further treatment.

(309) *Fatal Eclampsia; Parametric Stricture of one Ureter.*

FAYRE (Vitchow's Section, Vol. cxli, Part 2, August, 1895) publishes an important clinical note. A woman, seized at eight months pregnant, was taken on February 3rd with headache, vomiting, and pelvic pain. A faint trace of albumen was found in the urine. Digitalis and ipecacuanha were given. After temporary improvement she was seized in the evening of the sixth with a series of violent convulsions. The temperature rose to 101° after one fit, but a few hours later, after another fit, it was as low as 94° . Urine was scanty, and highly albuminous. Milk, digitalis, and large doses of chloral were given, and the patient was bled. Twenty-four hours after the fits began the temperature was 102° . Three hours later the patient died. Favre points out that many obstetricians maintain that rise of temperature in a pregnant woman attacked with fits is pathognomonic of true eclampsia gravidarum, fall of temperature signifying uræmia. At the post-mortem examination the left ureter was found pervious and otherwise normal. The right was widely dilated from the kidney to the brim of the pelvis. Below it seemed to run into the uterus. On careful dissection it was found to be completely obstructed by parametric deposit, which was firmly pressed upon by the pregnant uterus. The placenta contained white infarcts; the fetus was relatively small. The right renal pelvis was hydronephrotic. The substance of the gland was markedly variegated, the cortex being bright red, the medulla deep blue. The capsule was easily separable. The left kidney was also inflamed, but the inflammatory process was uniform on its glandular substance. The liver was fatty, with numerous hemorrhagic foci.

(310) *Menstruation in Hot Countries.*

JOHANN (Supposed Influence of Tropical Climate on Menstruation, Calcutta, 1895) agrees with Playfair in the opinion that the influence of climate on the catamenia has been unduly exaggerated. He has collected statistics of 3,194 cases under observation at Calcutta during the last four years, including European and rich native women seen in private practice, and poorer natives under treat-

ment for various diseases in the Eden Hospital, Calcutta. He found but very little difference in the percentages for various ages between the Europeans who had passed their youth in Europe and the women of pure European blood born in India; 23.4 per cent. of the former and 25.8 per cent. of the latter began to menstruate when 13 years old. Hence the climate seems to have no influence on the catamenia of women of our race. Indeed, the European bred girls showed a larger percentage of menstruation beginning at 12 than the native-born Europeans (13.4 per cent. against 10.8). Amongst the Eurasians a difference was at once noticeable, the type approaching that of natives between 12 and 14, but diverging again in the direction of the European type between 14 and 16. Such women are much influenced by native habits. In the class of pure natives, Hindus and Mohammedans, but chiefly the former, the greatest percentage of dates of first menstruation occurred at 12 (38 per cent.). Joubert shows that early menstruation is determined in native women by precocious knowledge and too early sexual excitement.

(311) *One Hundred and Thirty-three Cases of Placenta Prævia.*

BOSS (Centralbl. f. Gynäk., No. 35, 1895) collected these cases, which occurred between April, 1884, and April, 1894, in two institutions in Breslau. In one of the hospitals the proportion of placenta prævia to normal labour was 1 in 216, in the other 1 in 42—a remarkable difference. In 27.9 per cent. the placenta was central, in 61.6 lateral, in 10.5 marginal. The percentages of presentations were as follows: Head 66.2, breech 1.8, footling 8, and transverse 24. Of the total 133 mothers 8 died; 5 from direct effect of loss of blood, and 3 from fever or exhaustion after the first week. Twenty-seven per cent. of the children were born alive. As for management, the tampon, with expectant treatment, was applied in 7 cases, rupture of the membranes with forceps in 9, forced labour in 1, and combined version in 116; in this latter category all the maternal deaths occurred. The cases, however, in which combined version was employed, were all severe. One patient died from air in the veins nine hours after labour.

THERAPEUTICS.

(312) *The Use of Vinegar for the Arrest of Vomiting after the Administration of Chloroform.*

LEWIN (Rev. de Chir., September, 1895) has obtained very good results with regard to the prevention of sickness after the administration of chloroform by immediately replacing the inhaler by a linen cloth steeped in vinegar, and allowing this to remain over the patient's face for at least three hours after the completion of the operation. He points out that chloroform, which is eliminated almost exclusively by the

lungs, is decomposed in the presence of the inspiration into formic acid and chlorine. The latter agent when set free irritates the larynx and trachea, and thus is one of the chief causes of the vomiting induced by chloroform. On the application of vinegar in the above-described manner the chlorine is taken up by acetic acid, and thus rendered harmless. The author further points out that in order to prevent the demerolizing action of chloroform on the tissues it is necessary for the patient to inspire after the operation air that has been rendered humid. Acetic acid, both from the water it contains and from its energetic capacity of dissolving fibrine, serves to prevent coagulation of the blood. The beneficial action of vinegar in cases of anaesthesia by chloroform may also be explained by the fact that acids in general stimulate the respiratory passages. It is very unnecessary, the author thinks to attempt to explain this favourable influence of vinegar by a hypothetical action of acetic and other acids on the vomiting nerve centre through the vagus motor nerves.

(313) *Subcutaneous Camphor Injections.*

SCHILLING (Münch. med. Woch., September 17th, 1895) refers to the means of overcoming collapse by ether, musk, and camphor administered subcutaneously. Ether has a markedly evanescent effect. The tincture of musk, although a valuable cardiac stimulant, is not constant in its composition. Hence camphor is very generally employed. The author maintains, however, that the doses of camphor used are not large enough. He says that as much as 1 g. of camphor may be employed. The effect of 0.5 g. on a thready and almost imperceptible pulse is well marked, but that of 1 g. is often astonishing. The solution of camphor used is camphor 1, olive oil 10. He gives one ordinary syringe-full to children, seldom three, and mostly five to ten to adults. These large doses of camphor are well borne. No ill effects on the skin, brain, or lungs have occurred. Fear of fat embolism should scarcely exist, since hardly a case of the kind has been put on record. The author then refers to the small doses recommended in the recognised textbooks. Probably large doses of camphor act differently in animals than in man. Even in cases with cerebral symptoms the author has used these large doses without any increase in these symptoms. Camphor leaves the body within a couple of hours, and has no cumulative action.

(314) *Hymenodietionia.*

CORONDI (Gazz. degli Osped., July 27th, 1895) has experimented on the frog with this a-kain which is derived from the bark of *Hymenodietion exaltatum*. Solutions of the drug—0.02 g. in 100 c.cm. of nutritive fluid—exercise a marked effect on the heart. First there is a short phase of irregular movements, and then a true diastolic arrest. The

heart can easily be made to resume its natural movements by passing simple nutritive fluid through its cavities. Finally, however, the heart ceases to beat, generally in systole as regards the ventricles, whilst the auricles remain flaccid. During the phase of diastole arrest the heart, especially in the auricles, is enormously distended, and may reach double its size. Ventricular movements observed at this phase in the ventricles. The author thinks the drug is a nerve poison rather than a muscle poison. There seems to be a certain analogy between its action and that of digitalis. Hymenodietonin does not appear to be a very powerful drug, as its effects could easily be removed by passing simple solutions through the heart.

(313) *The Treatment of Actinomycosis.* EYDORFF (*Wien. klin. Woch.*, September 12th, 1895) first refers to the difficulty of getting all the diseased tissue away, and the liability to relapse which is thus produced. The discovery of the curative action of potassic iodide, taken internally, was for this reason welcomed. Unfortunately this agent is not always successful, and in the author's first case it had been administered internally for a long time without effect. Case I: A patient, aged 26, came with a swelling along the sterno-mastoid muscle, with a sinus and scars of a previous operation. Owing to the depth and extent of the infiltration brought about here by the actinomycetes, the author abstained from further operation, but, in addition to its internal administration, potassic iodide in 1 per cent. solution was injected subcutaneously. Every one to two weeks 2 to 4 syringefuls were injected into the infiltration, and in two months the patient was cured, the infiltration having entirely disappeared. Case II: A man, aged 46, had a tumour in the abdominal wall below the right costal arch. It had opened spontaneously on the surface, and a sinus remained, from which there was excreted pus containing the actinomycetes. There was no evidence of disease in the abdominal organs. Potassic iodide in 1 per cent. solution was injected into the infiltration at intervals of a few days, and the infiltration below the ribs practically disappeared, although that in the neighbourhood of the umbilicus still persisted when the patient was obliged to leave the hospital. The beneficial action of the parenchymatous injections, however, could not be questioned in this case, and no iodide was taken by the mouth. In both cases an increased quantity of pus was discharged from the sinus after the injections.

(314) *Treatment of Diabetes.* ASCOLI (*Il Policlinico*, vi, 14, 1895) reports the case of a man, aged 60, who had suffered from diabetes for two years. The ordinary methods of treatment were tried but without any particular benefit. In the spring of 1895, the symptoms being more acute,

inhalations of oxygen were tried. This mode of treatment was practised from March 7th to June 16th, with one week's interval in May. On an average 180 litres of oxygen were inhaled daily. After a few days the urine began slowly to diminish in quantity, lose its high specific gravity, and the sugar sank to 1 per cent. At the end of April the sugar disappeared entirely. In the early part of June no sugar was found even after a meal rich in carbohydrates. The body weight increased 2,500 g. under treatment. The usual dietetic restrictions were observed.

PATHOLOGY.

(315) *Keratomycosis in an infant the subject of Congenital Hemorrhagic Syphilis.*

ZORIN (*Wien. med. Woch.*, August 29th, 1895) describes the pathological appearances in the cornea of this unusual case. The cornea was of normal size, but almost completely covered with a clear layer approximately circular in form, and surrounded by a narrow ring of normal tissue. The centre of the superposed disc was occupied by about 20 rounded spots about the size of poppy seeds, resembling in appearance the colonies which Eberth and Lieber grew in the cornea by the inoculation of cocci with needles. In section this disc appeared as a clear yellow plateau on the anterior margin of the cornea. The sclerotic conjunctiva was oedematous with widened vessels and numerous extravasations. The corneal conjunctiva was attached to the cornea for a brief distance peripherally; towards the centre there was progressive disorganisation beginning in the superficial layers, and eventually extending right down to Bowman's layer, all the tissues external to which were replaced by masses of detritus and colonies of fungi. In the centre, where the plateau of new formation was observed, there was a still greater bacterial invasion. Bowman's layer, as well as the epithelium, having disappeared, and the interfibrillary spaces being infiltrated with micro-organisms. The condition of the cornea was to be attributed to changes during life and not to post-mortem softening. The peripheral and central ingrowths of cocci had spread themselves under Bowman's layer, where they took a darker stain than in more superficial parts. Between the colonies there were no leucocytes, which, however, formed a ring round the necrotic portions extending right down to Descemet's membrane. The cocci were round in form, but no pure culture was obtained, so that their actual nature remains uncertain. There was marked cell infiltration of the canal of Sehlerrn, the preparation showing that some of the leucocytes of the posterior part of the cornea arise from that channel, whence they pass outwards in tracks which can be followed along Descemet's membrane. The eyelid showed a superficial ulceration of the epidermis, the ulcers being covered with detritus and heaps of cocci. Zorin considers the pathology of the case

clear. The debility of the child led to impaired action of the lids with drying and pathological affection of the corneal epithelium. The necrosis of the conjunctiva allowed the growth of micro-organisms, which took advantage of the diminished resistance to penetrate into the parenchyma. By their distant action these caused inflammatory reaction, the leucocytes swarming in from the vessels on all sides in the manner laid down by Cohnheim. Zorin further holds that the changes described in his case would have gone on to keratomalacia had they not been interrupted by the child's death and that keratomalacia has its origin in diminished resistance, from general debility, or otherwise of the cornea to the attacks of micro-organisms.

(316) *Pathological Anatomy of Progressive Muscular Atrophy.*

CRAMER (*Centralbl. f. allg. Path. u. path. Anat.*, 1895, Bd. vi, p. 552) gives a summary of the published cases in an exhaustive paper, and draws the following deductions from the data: (1) Some forms of muscular atrophy which have lasted even for as long as ten years show by our present methods no changes either in the central or in the peripheral nervous system. These forms of muscular atrophy come under the heading of those cases which Erb has included under the name of "dystrophy." (2) The atrophies which occur with recognisable spinal lesions present very different clinical pictures. With the same spinal lesion there may be either the symptoms of dystrophy or of spinal muscular atrophy. Even an isolated disease of the cells of the anterior cornu may give rise to the most different clinical signs. Dystrophy may therefore occur with a spinal lesion or the peripheral and central nervous system may remain intact. (3) Cases are to be found intermediate between all forms of muscular atrophy, with and without lesions in the nervous system. (4) The appearances in the muscles are the same whether the central nervous system partake in the disease or no. (5) The pathogenesis of muscular atrophy is still obscure, but an embryonic condition which may also be hereditary appears to be a predisposing cause. Whether this hypothetical embryonic cause affects the nervous system or the muscular system directly is uncertain. (6) There are cases of muscular atrophy with isolated disease of the peripheral nervous system which seem to form a definite group (Hoffmann's neural variety). The appearances in the muscles, however, are not different from those found in other cases. (7) Cases of muscular atrophy in tabes show identical appearances. (8) Some forms of muscular atrophy are of cerebral origin, and as a rule depend upon local disease in the neighbourhood of the convolutions. These muscular atrophies may occur without any obvious affection of the pyramids or the anterior horns of the spinal cord.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(319) Pemphigus.

Kaposi introduced a discussion on this subject at the German Dermatological Congress, September 23rd, 1895. His conclusions, based on about 420 cases, are as follows: (1) Pemphigus is a purely clinical idea, dependent neither on morphological peculiarities nor on histological characters, but on the combination of these with the clinical history. (2) Our limited knowledge of the causes of this disease and our complete ignorance of its etiology are no reason for giving up the clinical idea of pemphigus. (3) In the course of months and years one may see in the same patient every shape and form of pemphigus; hence (4) the various types of pemphigus represent one and the same disease. (5) The chronic, relapsing, more or less benign, malignant, or fatal forms described as dermatitis herpetiformis correspond in clinical and histological signs, and are thus identical with pemphigus. (6) There is thus not the slightest reason to abandon the classical name of pemphigus in favour of the modern dermatitis herpetiformis. (7) The processes called by authors acute and benign forms of the putative dermatitis herpetiformis (Dühring) are only well known and long described complaints such as urticaria papulo-bullosa, annularis, and gyrata, lichen urticatus, and especially erythema multiforme (Hutchinson) in its vesico-bullous form. (8) The name dermatitis herpetiformis has thus no right to be applied to the acute erythema-papulo-vesiculo-bullous forms. (9) Whether there were any forms beyond the ranks of pemphigus to which the name dermatitis herpetiformis might be applied Kaposi did not know. He had never yet been reduced to labelling a disease with that name. Rosenthal, who had been selected to continue the debate, entirely opposed Kaposi's views, and maintained the following propositions: (1) Pemphigus cannot, according to our present knowledge, be considered a disease entity; it is merely a definite elementary form of skin eruption. (2) The following groups, which are or might be brought under this designation, are to be distinguished: (A) Those diseases which, for reasons not always obvious, assume a vesicular form, for example, large vesicled eczema, urticaria bullosa, etc. (B) Those affections in which the formation of vesicles is a secondary symptom; to this group the name dermatitis bullosa should be given. They are found (a) in acute and chronic infectious diseases, for example erysipelas, scarlet fever, (b) in injuries and inflammations of nerves, so-called pemphigus tra-

matus, neurotic-traumaticus, neuriticus, and in central affections, chronic myelitis, tabes, spinal cord sclerosis, and syringomyelia. (c) After the administration of drugs, the bullous form following particularly antipyrin iodides. Rosenthal then enumerated eleven other groups of skin affections which were, or might be, included under the old name of pemphigus. In addition to these there are a number of cases distinguished clinically by a continuous or intermittent eruption of bullae containing at first serum, and having their bases reddened slightly or not at all. These are to be called pemphigus acutus, pemphigus vulgaris, pemphigus foliaceus, and pemphigus vegetans, according to their characters. Pemphigus vulgaris is further subdivided into the subacute and chronic forms. Rosenthal concluded by stating that eruptions existed, having characters intermediate between those of the various groups enumerated, and so leading on continuously from one to another.

(320) Objective Signs in Gastric Disease.

LION AND HAYDEN, in continuing this subject (*Arch. gén. de Méd.*, September, 1895), make some remarks on the shape of the abdomen under the heading of inspection. (1) Prominence of the abdomen in the upper part is seen in large eaters, such as diabetics. (2) Prominence below may occur in many conditions, as in women who have borne many children, gastroptosis, etc. (3) A central prominence extending from the lower part of the sternum to below the umbilicus is seen after a full meal in patients with pronounced dilatation without ptosis of the stomach. (4) Flattening of the abdomen with hypogastric prominence occurs in those having dilated stomachs with ptosis. A slight transverse ridge may often be seen corresponding to the lesser curvature of the stomach. The abdomen observed in profile may show: (a) A sub-sternal hollow; this occurs in inanition, frequent vomiting, etc. (b) An abnormal prominence, mostly sub-sternal or epigastric, due to distension of the stomach. (c) A flattening of the epigastric region with hypogastric prominence seen in gastric dilatation with ptosis.

(321) Hydrothorax Nihil.

POTAIN AND VAQUES (*Sem. Méd.*, September 25th, 1895) report a case of nervous origin. The patient, a man aged 30, had had recurring attacks about three or four times in the year ever since he was 12. The profuse secretion was accompanied by great irritation in the nose, and was preceded by an injection of the conjunctive and tear secretion. His general health was good, even during the attacks. The attacks became more frequent as he grew older, and the secretion more watery and profuse. At the time of observation the attacks occurred every fortnight, and lasted one to two days. The attack came on, as a rule, in the

morning, and ceased quite suddenly in the afternoon of the second day. Within a quarter of an hour the nose was quite dry. The quantity secreted during an attack averaged 1 litre. It was an alkaline, opalescent fluid of low specific gravity, and contained some albumen and salts, chiefly NaCl and Fe. Also small quantities of a fatty substance. The nasal mucous membrane was normal, with the exception of some injection and swelling of the right concha media. Local treatment caused no improvement, but atropine controlled even the most violent attacks within half to one hour. A year after the first observation the attacks had not changed character, but the atropine had not the same effect, and the patient, by watching the prodromal symptoms, was able to regulate the strength of the dose needed. Trouseau found constantly that these nervous hydrothorax in course of time changed character and became transformed into a nervous asthma.

(322) Cardiac Hypertrophy and Normal Growth.

POTAIN AND VAQUES (*Sem. Méd.*, September 25th, 1895) deny the pathogenic part said by some authorities to be played by ordinary development in the production of various cardiac conditions, notably hypertrophy. Although rapid growth favours unmistakably the appearance of functional cardiac troubles, especially cardiac irritability, a definite idiopathic hypertrophy cannot be demonstrated. Ordinary estimates of the normal cardiac volume in children have been mainly founded on anatomical researches, without accurate clinical investigation. The flexibility of the thoracic walls and their muscular covering renders the heart impulse in children very apparent, and often so diffused as to make the exact position of the apex a difficult problem. A displaced apex beat is not in itself of diagnostic value; in many normal hearts it extends to the lower margin of the fifth interspace. The nipple, being situated in most diverse positions with reference both to its height and to the middle line of the body, is of little value. In a small heart the apex beat is often found 3 or 4 centimetres below and external to the lower demarcation of precordial dulness by percussion is the only certain guide. Examination of 100 apparently healthy subjects gave very interesting results. Neither body weight nor the general figure of the subject were found to bear constant relation to the size of the heart. Neither arterial tension nor pulse-rate afforded any explanation of the variations from the normal observed. A much more exact relation was found to exist between the heart volume and the length and circumference of the trunk. The pathological conditions such as cardiac hypertrophy must be distinguished from exceptional variations in size were found in three leaders of gymnastic exercises, these being evidently due to muscular exercise, and varying in proportion to the time such exercises had been in-

duled in. In no cases of abnormal-sized hearts did the subjects complain of, nor were there any signs of, functional or organic disease. Any acute illness in growing children, especially if accompanied by rheumatism, may be the origin of a temporary hypertrophy, which does not however persist after the re-establishment of compensation. It is concluded that all such symptoms as exaggerated impulse, murmurs at the apex, irregular pulse, or tachycardia, are mainly due to over-fatigue or neurasthenia, but that they afford no real indication of true hypertrophy.

SURGERY.

(321) Castration for Hypertrophied Prostate Gland.

WOSIDLO (*Centralbl. f. d. Krankheiten der Harn-u. Sexualorgane*, Band vi, Heft 5, 1895) has collected statistics on this subject, and finds 43 cases successfully operated on, the ages of the patients ranging from 60 to 81 years. Before operation in all there was great difficulty in emptying the bladder, and more or less severe cystitis. In all the 43 cases castration was performed on both sides, and an improvement in the cystitis and micturition always resulted, mostly immediately after the operation. In a great number of cases the patients could discard the catheter entirely, and hold their water for some time. In all there was a shrinking of the enlarged gland. Comparing this with other radical methods he finds it has the advantage of being less dangerous and more easily carried out, though several fatal cases show that the operation is by no means devoid of danger. Still up till now such cases are few compared with the successes, and time alone can show whether bad results occur often enough to discredit the procedure. As regards the results of castration on one side only, the reported cases are up to now too few and contradictory for any conclusions to be drawn from them.

(322) Infection of the Urinary Tract.

BASTIANELLI (*Boll. dell' Ac. Med. di Roma*, An. 21, Fasc. 2-6) has made a clinical and experimental study of this subject. He first gives a short clinical report of 37 cases of cystitis observed by him, adding in each case the result of bacteriological examination of the urine collected by catheter with all antiseptic precautions. Micro-organisms were present in every case. In 25 out of the 37 only one organism could be cultivated. The organisms most frequently met with (21 times) were microbes belonging to the coli bacillus group (including Eberth's). In 19 cases there had been no previous surgical interference (no catheterism, etc.) whatever, before the onset of the cystitis. The author then discusses the morphology and biology of the various micro-organisms found by him in the urine, and details the results of experimental infec-

tion of cultures into the bladder of rabbits. Unless there was previous retention (partial or complete) of urine or some morbid condition of the mucosa, the injection of micro-organisms never caused cystitis. If they were injected into the veins they were constantly found again in the urine, but did not set up cystitis unless there were predisposing local conditions. Unless pus and micro-organisms are to be found in the urine, cystitis is not present. Applying these results to the pathogenesis of vesical infection in man, the author concludes that micro-organisms, by whatever pathway they may reach the bladder, can only induce cystitis when there is some pre-existing morbid condition of the mucosa, or when there is some impediment to the free flow of urine. Under such conditions the germs multiply, and insinuating themselves between the epithelial cells cause diapedesis, suppuration, and local necrosis, finally passing, *via* the lymphatics, etc., into the circulation and system generally. Neither micro-organisms nor the aforesaid predisposing conditions can set up cystitis if acting alone, but in combination they are efficient causes of the same. The various possible pathways of infection receive full consideration at the author's hands, and a bibliography and photographs of the inoculated bacilli are attached to the monograph.

(323) Juxta-articular Osseous Tuberculosis.

MÉNARD (*Rev. d'Orthop.*, No. 5, 1895) publishes a group of cases of tuberculosis affecting an epiphysis of a long bone without involving the adjacent articulation, but extending directly to the surface of the limb. In such cases, the author points out, the tuberculous deposit should be exposed and removed as soon as the diagnosis has been made, with the object of preventing extension of the disease to the nearest articular cavity. This danger is especially active in tuberculosis of the lower end of the femur and the head of the tibia. Although articular tuberculosis usually originates in a tuberculous deposit in one of the osseous extremities constituting the joint, such morbid deposit in bone does not habitually give rise to tuberculous disease of the adjacent articular cavity. In this sequence the anatomical arrangement of the articular surfaces plays an important part. As the synovial membrane of the hip-joint surrounds the neck of the femur, tuberculosis of this portion of bone as a rule extends rapidly to the articular cavity. In tuberculosis of the lower extremity of the radius or ulna the wrist is seldom involved, as the disease extends to the superficial posterior surface of the affected long bone more readily than it does to the joint. Radio-carpal tuberculosis, it is held, is more frequently due to primary disease of the carpal bones. In the region of the elbow the olecranon is the osseous extremity in which the conditions are most favourable to the extra-articular evolution of a tuberculous deposit.

MIDWIFERY AND DISEASES OF WOMEN.

(324) Puerperal Tetanus.

WALKO (*Deut. med. Woch.*, September 5th, 1895) relates a kind of epidemic of tetanus which raged in the Prague University maternity last spring. In two cases the uterus was extirpated directly symptoms set in, with the view of removing a focus of infection. The bacillus of tetanus was found in the lochia in both instances. The convulsions became more acute after the operation, and neither patient recovered. In the third case the bacillus could not be found, but the objective symptoms were very severe. The patient was 23. On April 11th she was delivered in her home, labour being hastened on account of placenta previa. The child died in two hours. The practitioner was obliged to apply a tampon as flooding continued; he then sent the woman to the Maternity. On April 19th she was discharged well; but severe trismus set in a day or two later, and she was readmitted with very marked opisthotonos and other symptoms of acute tetanus. The least disturbance by sound or touch set up the spasms, and caused intense pain. The patient died on April 28th. Eighteen injections of 0.2 gramme of Tizzoni's antitoxin had been injected, with antiseptic precautions, at intervals of about five hours. For the first few days the injections seemed to do good, but though the opisthotonos at least abated for a while, the trismus and spasm of the muscles of deglutition steadily increased. The tendency to fresh convulsions on the slightest mechanical or psychical disturbance also became more marked till death. Walko's memoir on these obstetrical disasters includes scientific and statistical matter of high value.

(325) Dilatation not a "Conservative" Operation.

FOURNEL (*Nouv. Archiv. d'Obstét. et de Gynéc.*, August 25th, 1895) not only condemns "mutilating" operations, such as removal of the uterine appendages, without due deliberation, but maintains that dilatation of the uterus is in no sense conservative. In mild cases of perimetritis, with little or no pain, dilatation has merely a negative effect, and deludes the operator, who fancies that it is the cause of ultimate recovery. In very severe and acute cases nobody thinks of dilatation. In cases of distinct suppuration, surgical—that is truly surgical—treatment is demanded at once. Expectant treatment in these instances is unsurgical, dilatation even more so. Dilatation itself often involves sterility, not rarely death, and very frequently aggravation of the perimetritic inflammation which it is supposed to cure. Diagnosis of perimetritis is by no means easy, whilst experience abundantly proves that very bad cases recover without loss of function. True surgery teaches us to preserve all that can be preserved. The whole of the internal organs must be

saved if possible. If not, fecundity must be preserved; in other words, we must not be over dogmatic about removing the appendages on both sides. Should the case be desperate, the hopelessly diseased structures, and nothing besides, must be removed, in order to preserve life and health.

(328) Tetanus from Tongue-Bites in Eclampsia of Pregnancy.

ARELIN (*Revue Méd. d'Obstét. et de Gynéc.*, August 25th, 1895) states that a woman was seized one day last spring with severe eclampsia, and was hurried off to the Rochefort Maternity. In the cab a very severe fit occurred. On her arrival the tongue was found very severely wounded in several places. A chloral enema was given, the fits became less frequent and violent, and the forceps was applied. A live child was delivered. The eclampsia disappeared. The patient did well till the end of a week when violent pain in the tongue came on, followed by forty hours of acute tetanus, ending in death. Infection by the tetanic bacillus through the tongue wounds evidently occurred, most likely during the ride to the maternity. As eclampsia specially interferes with the functions of the liver, so that blood poisons are no longer arrested and destroyed, the prognosis of tetanic infection after convulsions must be unusually grave.

(329) Hyperemesis Due to Local Cancer.

LA TORRE (*Rép. Univ. d'Obstét. et de Gynéc.*, August 25th, 1895) maintains that the primary cause of uncontrollable vomiting in pregnancy is a complex lesion in the cervix determined by pregnancy itself. The cervix is congested; there is venous stasis, with oedema, compression of the nerves of the cervix, and irritability of the muscular fibre. This morbid condition gives rise to vomiting as a reflex symptom. The stomach must be kept at rest, hence rectal alimentation is imperative. But, in accordance with the evidence of local disease, the cervix must be attended to. La Torre uses glycerolate of ichthyol applied on tampons. When the sickness has continued for some time, the congestion is extreme and mere dressings will not suffice. Mechanical dilatation will then be needed. In extreme cases, of course, nothing avails as long as the pregnancy continues. According to La Torre's principles, local must precede general treatment.

(330) Ovariectomy in a Patient over 40.

KRAFT (*Centralbl. f. Gynäk.*, No. 33, 1895) has published notes of this case, which was under the care of Sundgaard. The patient had observed the tumour for seven years, and had been repeatedly tapped. For six months she had been confined to her bed on account of the size of the tumour. The operation lasted twenty minutes. The tumour was unilocular and contained 9 pints of fluid. The temperature during convalescence never exceeded 101°. At the end of a week the patient got up. When

the report was published by Kraft eleven months after the operation the patient was well and took long walks.

(331) Induction of Premature Labour.

HUCKENBROICH (*Deut. med. Woch.*, 1895, No. 11) publishes a series of 50 obstetric cases of this class. The condition demanding help was in 48 cases pelvic deformity, in 1 uncontrollable vomiting from cancer of the stomach, and in the remaining case advanced morbus cordis. Only 1 patient was lost: in that case there was placenta prævia and transverse presentation. Turning was required, and a tetanic spasm followed. This was complicated by peritonitis and the patient died on the fifth day. Nine children were stillborn, and 20 died before the tenth day, including most where turning was needed. Twenty-one were reared. Labour was not induced in any case before the thirty-fifth week. A bougie as stout as possible was passed into the uterus. The effect was very varied, labour ending from eighteen hours to eight days after the passage of the bougie. Uterine cramp was frequent; opium was used for its relief. In one instance division of the cervix was found necessary.

THERAPEUTICS.

(332) The Antitoxin Treatment of Diphtheria.

WELCH (*Trans. of Assoc. of American Physicians*, x, 1895) has collected statistics of 7,166 cases treated by antitoxin up to July, 1895. There can be no doubt as to its efficacy in curing inoculated diphtheria in animals. The problem for solution is the possibility of rendering the conditions in human diphtheria similar to those in experimental. Dosage and timely administration are essential factors in the antitoxic treatment. In these respects diphtheria compares very favourably with tetanus, in which the dose of serum required increases enormously with the weight of the animal and the lapse of time after infection. Welch considers it proved that antitoxin has no bactericidal action on the diphtheria bacillus, but renders certain cells of the body (nerve cells perhaps less than others) tolerant of the toxin. The most important difference between experimental and human diphtheria is that the latter is very often a mixed infection, the most dangerous complicating micro-organism being the streptococcus pyogenes. The failure of a case of diphtheria to respond to injections of antitoxin is an indication of mixed infection and complications, such as broncho-pneumonia, which might be obviated by better hygienic conditions. The evidence as to the value of antitoxin is twofold: (1) The clinical observations of those who have had extensive experience of diphtheria; (2) mortality statistics. The former, which are almost unanimously favourable to the new remedy, are most valuable; the latter are subject to sources of error which can only be obviated by the collection of a very

large number of cases. The mortality in the 7,166 cases referred to was 1,129, or 17.3 per cent. Welch estimates the previous mortality (before the introduction of antitoxin) as 42.1 per cent. Hospital reports show for 5,777 cases a mortality of 18.7 per cent., as against a previous mortality estimated at 43.5 per cent. In 633 cases in private practice treated by antitoxin the mortality was only 6.9 per cent. The magnitude of the type of diphtheria recently encountered is sufficient to explain the reduced mortality; the same applies to the undoubted fact that since the introduction of antitoxin cases have been brought to hospital at an earlier stage of the disease than formerly. The relative value of the treatment in operated and unoperated cases is a question of great importance. Welch finds that the mortality after tracheotomy has been reduced from 61.5 per cent. to 42.5 per cent., that after intubation from 62.4 per cent. to 31.6 per cent. The fatality in 3,127 unoperated cases was only 11.4 per cent. against a previous mortality of 26 per cent. Furthermore, many cases of laryngeal stenosis are relieved by antitoxin without operation being necessary, and cases free from laryngeal involvement at the time of injection rarely develop it later. Hence tracheotomy has become rarer since the introduction of antitoxin, and should in the near future give place entirely to intubation. In this latter operation serum therapy will lead to a reduction of the time during which the tube is to be kept in the air passage. The curative effects of the new treatment are most strikingly shown in the reduction of mortality among children under 2 years old from over 60 per cent. to 33.3 per cent. Behring claims that if antitoxin treatment is properly begun before the third day of the disease the mortality will fall below 5 per cent., and this is borne out by statistics. Thus out of 322 cases so treated on the first day of the disease only 5, or 2.2 per cent., died, while out of 341 first-day cases treated without antitoxin 44, or 13.3 per cent., succumbed. The percentage of deaths in 814 cases to which antitoxin was administered on the first or second day was only 5.5; the mortality in cases untreated till the third or fourth day is nearly three times as great (16.2 per cent.). The most striking confirmation of the value of antitoxin has been afforded where the supply ran short during an epidemic. In Haginsky's clinic the interruption of the serum treatment promptly raised the mortality from 13.6 to 48.4 per cent.

(333) The Action of Vaccinia Serum.

HLAVA AND HOUL (*Wim. Abh. Rundschau*, October 6th and 13th, 1895) have investigated the immunising and curative properties of vaccinia serum with a view to substituting its subcutaneous injection for inoculation with animal lymph, which has the disadvantages of uncertainty in action, rapid loss of protective power, and occasional serious complications. They used

three different methods of preparing the serum from calves: (A) The animals were inoculated with vaccinia; in four days the resulting pustules were pricked and the lymph collected; subsequently a second and third injection of stronger lymph were made, without causing any pœmulation or rise of temperature; the serum was collected about a fortnight after the last injection. (B) Inoculation as in A; no lymph collected; first re-inoculation caused a rise of temperature, second none; serum collected fifteen days after the latter. (C) Serum, plasma, and blood—the latter two mixed with 2 per cent. sodium citrate—taken from the calf four days after inoculation. Experiments were made with all these upon calves, and then, no ill effects having been observed, upon children. The serum was injected, and at the same time or subsequently the children were inoculated with vaccinia. Serum B was found too weak to produce much effect, though the vaccine vesicles were not so well developed as if it had not been used; 3 to 10 ccm. of serum A prevented the development of vaccine vesicles in 6 children out of 13 on whom it was tried; the injection of serum C to the extent of 0.6 to 1.0 ccm. per kilo of body weight entirely prevented the action of vaccine lymph inoculated four days later. (The experiments with blood and plasma are not yet published.) Experiments have not yet been tried in variola; if they succeed, Hlava and Houk claim to have prepared a serum which will replace inoculation with vaccine lymph. It is immaterial whether the serum contains an antitoxin or the "vaccinia germ;" if the latter is the case, the method approaches that of vaccination with an impoverished pure cultivation.

(334) Thyroid Feeding.

ELENSBURG (*Deut. med. Woch.*, August 16th, 1895) draws attention to the abuse of this treatment owing to the unrestricted sale of thyroid preparations and especially tablets. Since the investigations into the use of this agent in the reduction of obesity it has been adopted by many of the public, and especially women, without medical supervision. The author relates such a case in which a well-known artist had taken as many as six tablets in the day, whereas two tablets only should be administered, unless in exceptional cases, when the results should be carefully watched. Very severe nervous and cardiac symptoms ensued, and a loss of 19 lbs. in weight within two months. These symptoms were apparently due to a hydremic condition of the blood without visceral lesions. Restrictions should be placed upon the sale of these thyroid preparations as well as upon some other of the newer drugs.

PATHOLOGY.

(335) Contagious Myxoma.

CARRI (*Prose Medica*, September 28th, 1895) describes a form of contagious and inoculable myxoma, which is produced

apparently by the proliferation of a micro-organism resembling the yeast fungus in the connective tissue. The tumour on which the observation is based was removed from Scarpa's triangle (right side) of a healthy young man, a locksmith, where it had been growing for about two months, and had attained the size of two fists. As it fluctuated, it was incised, on the supposition that it contained pus, a diagnosis favoured by the coexistence of a large fistulous abscess in the lumbar region of the same side. On incision the swelling was found to consist of a soft gelatinous tissue. It and the abscess sac in the lumbar region were dissected out; the morbid growth did not extend to the deeper structures, but lay between the skin and the muscles. Under the microscope the growth showed a few connective tissue fibres and an enormous crowd of large, yeast-like cells, each cell being surrounded by a thick, gelatinous, hyaline capsule. The cells for the most part were spherical; some of them showed buds; all of them exhibited the micro-chemical reactions of cellulose. The cells grew rapidly on potato and gelatine, losing their gelatinous envelope and multiplying by gemination. A fragment of the tumour implanted in a rabbit gave rise in the course of twelve days to a tumour the size of a small orange; this experimental tumour contained the yeast-like fungus in abundance, though not in a state of absolute purity.

(336) The Relations between Coagulation and the Action of Antitoxin.

FREUND AND GROSZ, in a preliminary communication (*Centralbl. f. inn. Med.*, September 21st and 28th, 1895) say that the general view which seems to obtain is that antitoxin is produced by cellular action. The bactericidal action of nuclein acid has been pointed out in this relation (Kossel), but it has not been shown whether it is really a bactericide or chemically neutralises the toxin. The authors say that the development of this question is very like that of coagulation. The importance of serum and of soluble salts in both cases is obvious, and a temperature of 56° has a destroying action in both instances. It seems probable that some inactive body splits up under certain circumstances into two bodies with different properties, which, either alone or combined, may in one case produce or hinder coagulation, and in another act as a toxin or an antitoxin. The specificity of the toxin and antitoxin is only an apparent difficulty. The authors have studied the relation between coagulation processes and immunisation. They have investigated such bodies as induce or prevent coagulation as regards their behaviour to immunity and their antitoxic action. Lillienfeld has obtained a body from leucocytes called nucleo-histon, which can split up into nuclein and a basic body, histon. Nuclein produces coagulation and histon prevents it, whereas nucleo-histon is without action.

From a series of experiments they conclude (1) that both nucleo-histon and nuclein acid (obtained from nuclein) quantitatively precipitate diphtheria toxin from its solution; (2) that histon does not precipitate it; and (3) that nucleo-histon also precipitates the active body from curative serum. The authors have also succeeded in obtaining other bodies preventing coagulation. Both from a solution of nucleo-histon, precipitated by acetic acid, as well as from the filtrate of a nuclein solution, precipitated by hydrochloric acid, bodies may be isolated which prevent coagulation. The authors continued their investigation with the help of Jelinek. They have experimented with these bodies to find out whether they have an immunising effect, especially in regard to the diphtheria toxin. From a series of experiments they conclude that nuclein acid and nuclein are not able to antagonise the action of the diphtheria toxin. In another series of experiments they were able by injecting histon and other coagulation preventing bodies to keep animals infected with diphtheria alive. It would appear that these bodies have an action analogous to the curative serum, and further investigation must show whether it is equally complete. At any rate a close relation appears to exist between the process of coagulation and passive immunisation.

(337) The Lungs of one of Koch's Earliest Tuberculin Patients.

ADAMI (*Montreal Med. Jour.*, Sept., 1895) relates the history and post-mortem appearances of a Finnish patient who came under Koch's care in 1890 suffering from hæmoptysis, cough, night sweats, and progressive emaciation. After fifty-two weeks of repeated tuberculin inoculations his health appeared to be entirely restored. In June, 1893, he went to Canada, and was employed as a skilled mechanic at the McGill University. In January, 1895, the old symptoms all returned, and on April 28th he died of hæmoptysis. At the necropsy firm adhesions were found at both apices, which showed well-marked fibroid changes, and contained well-encapsuled caseous masses and small contracted cavities. In these parts the tuberculous process had evidently been arrested, but the rest of the lung tissue contained numerous miliary tubercles distributed along the course of sundry bronchi. The tubercles were most numerous in the neighbourhood of the old mischief; they were surrounded by very little pneumonic disturbance, and were rather of the fibroid than the rapidly advancing type. The second attack was thus not the result of fresh infection, but of the recrudescence of the old process starting from the incompletely-healed disease foci. Their nature indicated either relative attenuation of the bacilli, or increased resistance on the part of the tissues. In any case a year's treatment by Koch's method had succeeded in arresting for four years an active and extensive tuberculous process in both lungs.

MEDICINE.

(332) Abscess of the Lung in Infants.
 Tu. Hirsch, of Eichhorst's Clinic (Münch. med. Woch., August 27th, 1898). Abscesses that occasionally abscess of the lung has been known to complicate influenza, and he refers to recorded cases. He relates a case in which influenza bacilli were found in pure culture in the pus spat up from such an abscess. The bacteriology of pulmonary abscess has been but little investigated. A woman, aged 55, had suffered from two previous attacks of influenza, and after the second she had a right pleurisy and acute laryngitis. The present attack began with pain in the limbs, weakness, fever, and cough. Three months later she became worse, with pain in the right chest, increased cough, and mucovulent expectoration. On admission there was great prostration, rapid breathing, and a pulse of 150. There was cough with yellowish brown, more or less tenacious, but not rusty sputum. There was impaired percussion behind from the fifth rib downwards. Moist sounds were present. The dulness became more marked and the vocal fremitus less distinct. Later a tympanic note could be made out with amphoric and occasionally metallic breathing. Elastic fibres in alveolar arrangement were found by Eichhorst in the sputum. The latter, amounting to 100-200 c.c.m. in the day, was never offensive and never contained tubercle bacilli. The sputum steadily became less as well as the cough, and the tympanic resonance with the metallic phenomena disappeared. No more elastic fibrils were found in the sputum, and the patient was ultimately discharged perfectly well, having gained 10 kilo. in weight. The clinical diagnosis of abscess in the right lower lobe could not be doubted, and the preceding pneumonia had all the characteristics of influenza pneumonia. A bacteriological examination was made after the first symptoms of abscess and frequently repeated. The sputum was obtained with all the usual bacteriological precautions, and both morphologically and by cultivation the presence of the influenza bacillus in pure culture was established. The diagnosis was further confirmed by a bacteriological examination in Pfeiffer's laboratory. Strepto- and staphylococci were quite absent. After the clinical evidence of the abscess had disappeared, Pfeiffer's bacillus also disappeared from the sputum. Pfeiffer's bacillus is the recognised cause of influenza and influenza pneumonia. The absence of the usual pyogenic microbes as well as of Fraenkel's diplococcus, and the presence of the influenza bacillus, as proved morphologically and by culture, show that this bacillus must be looked upon as the cause of the pulmonary abscess.

(333) Diphtheria.

LAUSTENS (Dent. med. Woch., August 29th, 1898) discusses the question of incubation, and relates a case in which it was possible to determine the period of incubation. In a family of three children, aged 12, 10, and 8 years respectively, one presented herself on July 1st with diphtheria, which was proved bacteriologically. Fourteen days later her brother was seized with vomiting, diarrhoea, delirium, and fever. Membrane appeared in the throat, and the diphtheria bacillus was found. As it was possible that the remaining child might develop the disease, the throat was inspected daily, and blood-serum cultures were made from the mouth beginning with July 15th. On the 19th, the diphtheria bacillus was found. On the same day headache was complained of, and on the following day there was redness of the left tonsil, slight glandular swelling, and enlargement of the spleen. The presence of the diphtheria bacillus was again proved, and the child passed through a severe attack of the disease. On the 26th the child was practically well, but the bacillus was still present in the mouth. With almost absolute certainty it may be said that the 19th was the first day of the infection—that is, on the first day the bacillus was found the symptoms of the disease appeared. Here the incubation period was at most twenty-four hours. The case accords with the view that the more severe the infection the shorter the incubation period. The author also refers to another family of five children, one of whom developed diphtheria. Isolation, although recommended, was not adopted. Cultivation experiments were frequently made from the mouths of the remaining children, but always with negative results, and none of them developed the disease.

(334) Cerebellar Disease.

FRÄNDRERG (Berl. klin. Woch., August 19th, 1898) discusses the symptomatology based chiefly on Luciani's experiments, and the observation of 9 cases occurring in Aufrecht's clinic. These 9 cases included 1 of glioma, 1 of angiosarcoma, 1 of cysticercus, 1 of massive tubercle, 1 of hemorrhage, and 3 of abscess. The details of the cases are shown in a very instructive table. Etiologically, the disease could in no case be assigned to injury. In the 3 cases of cerebellar abscess there was middle ear suppuration. The cerebellum is less frequently the site of abscess than the temporal lobe. In the case of hemorrhage there was arterio-sclerosis of the cerebral vessels. The comparatively short duration of the disease was remarkable, the longest being one year and a half, whereas the average was only a few months. The analysis of symptoms presented considerable agreement with Luciani's observations. In 4 cases occipital headache was present, and in the remaining case of a child, aged 3 years, its presence could not be proved. It was mostly severe, and usually the first symptom. In 5 out of these 9 cases there was marked rigidity

of the neck and this became more accentuated as the disease advanced. It was probably due to pressure on the medulla. Vomiting was present in 8 cases and vertigo in 4. In 8 cases long under observation there was more or less wasting in 5. Nystagmus during this dystrophy there were never any bed sores. Hemiplegic symptoms were never present. In cerebellar disease such symptoms hardly ever exist—at any rate, in tumour. The brachial monoplegia seen in 1 case and the facial paralysis in 2 cases were probably the result of pressure and not true cerebellar symptoms. Cerebellar ataxia was seen in 2 cases only. According to Luciani, this ataxia is not the most characteristic symptom of cerebellar disease as believed by many. Forced posture was present in 1 case only. Here the patient lay with the body bent forwards and the head backwards. Forced movements were never present. Irritative symptoms such as spasm were seen in 4 cases, and were, perhaps, due to irritation of the mid-cerebellar peduncles. In 1 case the position of the hand was very like that seen in cervical hypertrophic pachymeningitis. In addition to the vomiting, probably due to pressure, the following symptoms were noted—loss of weight, occipital headache, vertigo, especially on standing and walking, ataxia, ultimate inability to stand or walk, spasm, etc. The rigidity of the neck was remarkable; it appears not to have been often noted. Of diagnostic value in abscess is the pain in the ear and tenderness over the mastoid process. A negative result of the tuning fork experiment, namely, where the cranio-tympanic conduction prevails over the air conduction, has recently been said to point to cerebellar abscess (McBride).

SURGERY.

(335) Craniectomy.

SPANROCK (Neural. Centralblatt, September 18th, 1898) records a case of imbecility improved by craniotomy. The patient was a boy, aged 14, of exceedingly weak intellect. When questioned he either repeated the words of the question or answered in an altogether meaningless way; he was restless both in his ideas and in his bodily movements; he was unable to remember events of the past few hours. Morally he was equally weak; he was addicted to abusive language, and often tried to strike and injure others, sometimes throwing stones at them; he was given to stealing, dirty in his habits, and always suspicious. The body is well formed, with the exception of the head, which shows low forehead, large projecting ears, and high palate with widely separated teeth. Craniotomy was performed, portions of both parietal bones being removed; at the operation the dura mater was opened, and the brain substance seen to be unaltered, protruding in appearance; connection with fasciation of the motor cortex gave corresponding muscular contractions. The patient made a

good recovery from the operation, and there was at first no change in his condition. After two months improvement began, with occasional relapses, until at the end of a year there is distinct permanent improvement both intellectually and morally. The moral change is most striking and complete; the tendency to stealing, lying, abusive language, etc., has disappeared, and the patient is now an industrious trustworthy person, grateful for the operation and particularly anxious to have a weak-minded acquaintance improved similarly. The good result of the craniotomy is difficult to explain; suggestions are made that it is due to the greater space allowed for the development of the brain; that the oedema of the brain mentioned disappeared owing to the increase of space; that some external factor perhaps the faradic current used, affected the brain when exposed.

(312) The Effect of Trephining in Thinned Disc.

ANGELUCCI (*Archiv. di Oftalmol.*, Fasc. 12, 1895) reports three cases of cerebral lesions causing oedema of the optic disc, in which trephining was followed by considerable improvement of vision. The first case was one of hemiplegic epilepsy. After trephining the papillary oedema disappeared; vision was so far regained as to allow the patient to perform the grosser offices of a housewife; the fits and the headache also ceased. In the second case of cerebellar lesion (unsteady gait, vertigo, acoustic symptoms, etc.), with double bilateral oedema of the discs, improvement of vision followed almost immediately after the operation. In the third case, in which the symptoms were more severe and in which a cerebellar tumour was diagnosed, improvement also followed, but to a slighter extent.

(313) Cysticercus Celluloseus in Man.

BERGH (*Norsk Magazin for Lægevidenskab*, June, 1895) publishes the first case observed in Norway. The patient, a healthy young man, had two years and a half previously developed a tumour in the right posterior axillary line, which had become larger and tender for the last four months. At the time of observation it was inflamed and fluctuating, and 7 cm. to 8 cm. in diameter. On incision an elastic bladder, 2 cm. in diameter, was discharged with the pus. On examination by Heiberg this was found to be the cysticercus of the tenia solium.

(314) Muscular Kidney.

ABDARRAN (*Ann. des Mal. des Organ. Gén.-urin.*, August, 1895) asserts that a good nephrorrhaphy should be: (1) a benign operation; (2) should assure fixation of the whole kidney, allow free flow of urine; and (3) alter as little as possible the renal substance. It is important to ascertain the length of the last two ribs, as there is danger of wounding the pleura if the twelfth rib does not extend beyond the edge of the sacro-lumbar mass. The author advises

removal of the adipose capsule, so as to allow the kidney to be brought in direct apposition to the parietes, as this gives a firmer coatrix. It is good practice to bathe the surface of the capsule with strong phenol solution or AgNO_3 (4 per cent.). Parenchymatous nephrorrhaphy, without decortication of the kidney, appears to give the best results. Catgut sutures seem on the whole to produce less irritation than silk. Out of 374 published operations there were only 7 deaths, and of these only 4 attributable to the operation. Fourteen per cent. of the cases were improved by the operation; 36 per cent. derived no advantage. In 88 per cent., however, the pain was lessened by the operation.

(315) Treatment of Chronic Urethritis.

HODARA (*Annales des Mal. des Org. Gén.-urin.*, August, 1895) advocates the use of the Nitze-Oberlander urethroscope in the diagnosis and treatment of chronic urethritis. He summarises Oberlander and Kollmann's treatment of gleet as follows: (1) Dilatation of narrowed parts of the urethra should be commenced as soon as all acute symptoms of gonorrhoea have subsided. (2) It is important to differentiate between anterior and posterior urethritis and to heal the latter with deep instillations of nitrate of silver (1 per cent.) (3) If there is any infiltration of the verumontanum, dilatation of this part of the canal with Oberlander's dilators is advised. (4) Catarrh of the glands, crypts, or glands of Morgagni need electrolytic needles thrust into them and a current passed through their walls. Section of the mouth of each crypt under control of the eye by means of a sharp-pointed urethral knife is also of value.

MIDWIFERY AND DISEASES OF WOMEN.

(316) Hematoma and Myositis of the Sternomastoid Muscle in Newborn Children.

LUDWIG PINCUS (*Zeitschr. für Geburtsh. und Gynäk.*, Bd. xxxi.) deals with the subject of hematoma of the sternomastoid muscle in an exhaustive manner. In the introduction he mentions the work done in this direction by Bohn, Skrzeczka, Küstner, O. Ruge, Köster, Vollert, Witzel, Taylor, and Spencer, and gives the history of a case of his own which he observed for six years and which was followed by wryneck. Historically Dieffenbach (1850) was the first to describe this injury. Tulpius gave as the cause of wryneck "induratus corrugatusque musculus." Minnius (1652) and Florianus (1688) treated it by tenotomy, and van Roonhuyzen (1674) recognised that the affection existed "from the mother's womb." Since the appearance of Dieffenbach's monograph, many works have been published, of which a complete bibliography comprising 220 papers is appended to Pincus's paper. Observations upon the pathological anatomy of hematoma of the sternomastoid muscle have been made in newborn children by

Skrzeczka, Fashender, von Sassen, Ruge, von Huttenberger, and Spencer, and histological observations by Taylor, Ruge, von Huttenberger, Vollert, Köster and Spencer. Spencer's description is quoted in full, as being the only known observation upon the injury in a stillborn child, and it is shown that this description resembles that of specimens obtained from young infants and from the contracted muscle in torticollis, except that in the former the material between the fibres is blood, in the latter fibrous tissue. Pincus therefore regards the sterno-mastoid tumour as myositis following hematoma of the muscle. The differential diagnosis has to be made from myositis syphilitica, from abscess within the sheath of the muscle, and from myositis ossificans commencing in the sterno-mastoid muscle. "Sarcoma" of the muscle in infants he suggests is possibly hematoma. Syphilis is considered to play no part in the production of hematoma, and the effect of manipulation during the birth of the child is well described. The percentage of cases in which the head presented was 34.97, a larger figure than usually admitted. In 12.14 per cent. spontaneous labour occurred. The greatest danger to the muscle occurs from manual extraction in breech presentation. In head presentations the injury was on the right side in 52.94 per cent., on the left side in 47.06 per cent., and never on both sides; in breech presentations on the right side in 64.15 per cent., on the left side in 35.85 per cent., on both sides in 18.57 per cent. As regards prognosis, on an average the tumour disappears in two to three months; suppuration rarely occurs. The injury to the sternomastoid muscle is rarely followed by persistent torticollis. The prophylaxis consists in the use of properly constructed forceps, avoidance of torsion, Winkel's method of delivery in breech presentation, and it is of importance that every textbook of midwifery should contain a chapter upon the injuries to the child's body which occur during the act of birth.

(317) Danger of Amateur Massage in Gynaecology.

ZIEGELROTH (*Der Frauenarzt*, September, 1895) points out that doctors are often to blame for handing over a case for massage without knowing anything definite about either the principles or practice of that now fashionable therapeutic agent. Whilst most practitioners transfer their cases to a specialist of the highest skill, and never ascertain if the subsequent cure or failure be in direct relation to the treatment, others, also overconfident in the very name of massage, commit patients to persons of deficient training. Ziegelroth relates a curious case of the latter mistake. A young, recently-married lady suffered after abortion, and, distrusting her village doctor, consulted another in a neighbouring town. The latter gentleman had a great belief in massage, and, quite ignorant of how it should be done, he directed the patient's midwife

to employ internal massage in this case for the remedy of a displacement. This midwife went boldly to work, but as after several "sittings," which gave great pain, the patient was no better she gave up the treatment on the score that she could not properly work with the whole hand in the vagina. It then transpired that the midwife had been accustomed to work at a leg or muscle by rubbing it with the flat well doubled up. The physician was not aware that she was ignorant of the most elementary manipulations in massage.

(340) Fibroids Cured by Extract of
Thyroid Gland.

JOUIN (*Revue et Mémoires de la Soc. Obst. et Gynéc. de Paris*, No. 8, 1895) states that he has successfully treated several cases of myoma of the uterus by doses of Nielsen's dry extract of sheep's thyroid gland. He gives 4 to 8 tablets daily, equivalent to half a thyroid gland. Out of 5 cases, the 2 which have been fairly long under treatment have distinctly improved in health. In the first case the tumour has distinctly diminished in size. Menorrhagia is much diminished by this treatment. As in other cases of patient, hemorrhoids present in at least one case were greatly relieved.

(341) Asafoetida in Obstetrics.

WARMAN (*Der Frauenarzt*, August, 1895) finds that this drug is a most valuable therapeutic agent in midwifery. It is a direct sedative to the pregnant uterus and exercises no evil influence over the general system. It is of particular value when abortion is imminent, as it controls uterine irritability. On the other hand, it is of no use as a prophylactic agent in such cases, and must not be relied upon when the abortion has proceeded so far as to require manual interference. In habitual constipation and also in nervous conditions during pregnancy, asafoetida is highly beneficial.

(342) Ectopic Gestation: Morphine
Injections.

PROCHOWNICK (*Frank's Berliner Klinik*, October, 1895) supports this practice, which was also advocated by Winckel so recently as 1889. He considers that the injection should be practised in any case of extrauterine pregnancy during the first three months, provided that it is fairly evident that the ovum is yet intact and the embryo alive. After the twelfth week injections are not justifiable, and if abortion has clearly set in, if hæmatocoele or hæmatoma be present, or if the uterine decidua has come away, this practice is useless, as its object, according to the light of recent experience, should be solely the destruction of the embryo. A single injection of about half a grain in half a drachm of water will usually suffice. It must be administered from the vagina, with a short straight or curved needle, which must be fitted on to the syringe direct without any intermediate rubber tubing. Antiseptics must be practised, and an iodoform tampon must be applied to

the vagina after injection and left there for twenty-four hours. Evidence of perimetritis or gonorrhoea contra-indicates this treatment. An anaesthetic is only needed in very sensitive excitable subjects.

(351) Hysterectomy: "Collarette"
Operation.

DELAGÉNIÈRE, of Le Mans (*Archives Provinciales de Chirurgie*, August, 1895), strongly supports this practice, which, roughly speaking, consists of amputating or enucleating a fibroid and leaving behind as little of the tissue of the stump as possible, the muscular part of the cervix and portion of the body of the uterus being dissected away. The "collarette" thus left behind is sewn up so that its edges are turned downwards into the vagina, which is exposed. As much oozing follows, Delagénière has always hitherto drained the abdominal cavity. The difficulty in securing the broad ligaments and in getting at the uterine arteries is not great. The ureters and adjacent structures cannot be damaged. At the same time the uterus is removed as far as the vagina without any manipulations from the vulva. When the fibroid has invaded the broad ligament it must first be enucleated, then the broad ligament is cut away and the cervix treated as in a simple case. Delagénière has lost only 1 in 20 cases.

THERAPEUTICS.

(352) Typhoid Antitoxin.

BEUMER AND PRIPER (*Zeitschr. f. Klin. Med.*, Bd. xxviii, Heft 3 and 4) had already shown (see *Epitome*, July 13th, 1895, Par. 37) the reaction of the human organism to the subcutaneous injection of broth cultures of typhoid bacilli sterilised by heating to 55° to 60° C. It consists in a slight febrile condition with transient enlargement of the spleen. In patients with typhoid fever small doses (at most 0.05 c.c.m.) of such a culture show a marked influence upon the course of the disease. In 8 cases treated in this way, after a few injections the further progress of the disease was cut short and the fever completely subsided. The authors then instituted a long series of experiments on white mice, guinea-pigs, and sheep to see whether an antitoxin could be obtained similar to those of diphtheria and tetanus. They obtained by injecting sheep for three months with sterile broth cultures of the typhoid bacillus, a serum which had marked antitoxic properties, though it had no direct power of destroying the bacilli. For immunising white mice $\frac{1}{2}$ to 1 drop was sufficient to protect against the fatal dose. For guinea-pigs 0.07 c.c.m. to 0.08 c.c.m. serum completely protected 100 grammes of animal against four times the fatal dose. The serum has curative powers, since of 5 guinea-pigs treated one hour after injection none died; of 5 treated two hours after injection none died; of 5 treated three hours after injection three died; and of

5 treated four hours after injection 1 died. The results are very noteworthy, since the effects of injection with typhoid toxin are definitely seen one to two hours after injection, and as a rule the animal dies in twelve to twenty-four hours after a fatal dose has been administered. In every case animals treated for a long time with typhoid toxin yielded a serum which had immunising and curative powers. How far these results may be applied to patients one cannot as yet say with certainty. The harmlessness of the serum to human beings has already been proved.

(353) Sublimato Injections in Syphilis.

SCHRECHER AND ALLOXYER (*Ref. Med.*, September 7th, 1895) give the results of the above treatment in 128 cases—53 men and 75 women; 115 had secondary syphilis, and 11 tertiary. The sublimate was dissolved in water containing five or six times as much salt as sublimate, and of this solution about 1 c.c.m. was injected. The injection was usually made in the notes, etc., followed by local massage. In men from 2 to 5 cgr. were injected, in women smaller doses. The injections were repeated once a week, in some cases up to twelve weeks. The men bore the treatment much better than the women. No abscesses ever followed, but local urticaria, redness, stiffness were not uncommon, especially in the women. Forty-seven were mercurialised, that is, suffered headache, nausea, epistaxis, fever, stomatitis (20 cases), intestinal disturbances (14), nephritis (1 woman). Some had curious dyspnoea. Severe mercurialism occurred in 5 women—four or five hours after injection stomatitis, colic, diarrhoea, fever, and albuminuria appeared, and lasted off and on for ten days. The syphilitic manifestations disappeared after treatment in 108 cases, and generally after three or four injections. Women can rarely stand more than 3 cgr., and 5 cgr. is liable to cause severe symptoms of mercurialism. On the whole the authors are not enthusiastic about the new treatment.

(354) Best Results of Nasal Applications.

RISNOR (*Therapeut. Monatsheft*, September, 1895) summarises the occasional evil results of local applications to the nose. Otitis media following the nasal douche may be avoided by attention to the following points: The douche must not be at too high pressure, nor too prolonged; no swallowing or coughing to be allowed during douche; head to be slightly inclined forward; douche to be administered through the narrower of the two nostrils; nose not to be blown in the ordinary manner just after douche, but patient to close one nostril while he blows out through the other; fluid used, to be at first lukewarm, then gradually cooler; nozzle of douche not to fit the nostril tightly; cotton-wool to be worn in the ears after the douche. Neuritis results sometimes from allowing the stream of a douche to impinge on the roof of the nasal cavity; the nozzle of the douche should therefore be either horizontal or pointing down-

wards. Impairment or even permanent loss of smell may result from the use of too strong solutions of zinc salts or alum. Nasal insufflations less often give rise to trouble, but powders should be used as weak as possible, for the mucous membrane is sometimes very sensitive to the stronger powders; prolonged lachrymation with swelling of the whole nose, neuralgia of the fifth nerve, and sometimes even membranous rhinitis following their use. Where chromic acid is applied to the nose, an alkaline douche should be used after the patient has blown the nose thoroughly; neglect of this has led to severe toxic symptoms due to swallowing of chromic acid. Adhesions between adjoining surfaces after use of caustics or galvanocautery are to be avoided by application of ointments, and daily breaking down of adhesions. Many nervous disturbances have followed the use of the galvanocautery, for example, headache, neuralgia, asthma, and in several cases more serious and even fatal results, especially pyæmia and thrombosis of cerebral sinuses. The danger of septic processes is still greater in operations on the nose associated with much bleeding, for example, removal of polypus or growth, correction of septal deviation, etc. In view of such cases all instruments used for nasal operations should be sterilised, and the nasal cavities should be irrigated with antiseptic fluids after all such operations.

(333) Topical Action of Salol.

COLOMBINI (*Rif. Med.*, September 14th, 1895) has been experimenting with regard to the local effects of salol dissolved in liquid vaseline. In the presence of alkaline fluids or living tissues salol appears to break up into salicylic acid and phenol in the nascent state. When split up in this way the author found that, whilst the good antiseptic action of each of the acids was maintained, their irritant action was absent either from the way in which they were set free or from the small quantities of the acids evolved. Clinically it was found that salol in vaseline solution—the best solvent—did not irritate the skin nor inflame ulcerated surfaces which healed under the treatment without pain or local reaction. The author thinks there may be a useful field opened up in the local application of salol as a non irritating and sufficiently powerful antiseptic.

(334) The Action of Anemonin.

NOLA (*Gazz. degli Osped.*, September 28th, 1895) has been experimenting with anemonin, on frogs, rabbits, dogs, and guinea-pigs, and concludes that it is a poison of slow action, producing first drowsiness, then paralysis, and finally convulsions. In the paralytic period the sensibility and the reflexes are at first preserved, to be, however, finally abolished or much diminished. The convulsions vary in intensity and form from simple isolated spasms up to clonic and tonic convulsions. The sleep is probably owing to

the physico-chemical action of the drug on the cerebral cortex. The paralysis is of central origin, affecting the brain first and then the spinal cord. The convulsions are of bulbar origin. Death occurs through asphyxia from arrest of the respiratory mechanism, the muscles being completely flaccid. The drug is very slightly soluble in water, alcohol, or ether. It is generally in the form of white ortho-rhombic crystals, and has a peculiar odour.

PATHOLOGY.

(335) Thyroidism and Thyroproteinidism and their Connection with other Internal Secretions.

REVELLION (*Rev. méd. de la Suisse Romande*, August 20th, 1895) describes the effects of thyroproteinid and thyroidin discovered by Notkine (*vide Epitome*, September 14th, 1895). The function of thyroidin is to neutralise and eliminate the thyroproteinid. "Thyroproteinidism" (corresponding to myxœdema) may result from (1) excess of thyroproteinid; (2) deficiency of thyroidin. Hyperthyroidism or "thyroidism" (corresponding to exophthalmic goitre) from (1) deficiency of thyroproteinid; (2) excess of internal secretion of thyroidin. This explains why an enormous goitre may be compatible with health if the two substances are in proportion to maintain physiological equilibrium. The conception, however, of the influence such a gland as the thyroid exerts on metabolism must be enlarged when we consider that other hemopoietic glands act together with it, and possibly to some extent vicariously. In fact, for nutrition to be in equilibrium, it is necessary for a certain combination of humours to circulate in the system. Thus while the thyroid has to do with growth, stature, quality of the skin, the expression, etc., the pituitary body directs the formation of the skeleton and extremities. Experimentally extirpation of the thyroid gland is followed by hypertrophy of the hypophysis (Rogowitch, *Arch. de Physiol.*, 1892). Extirpation of the spleen is followed not only by hypertrophy of the lymphatic glands, but sometimes by goitre, which in one recorded case was accompanied by some symptoms of Graves's disease. Again, the thyroid is related to sexual power, which is lost in myxœdema; it enlarges at puberty, and sometimes diminishes at the climacteric. The relation of osteomalacia to the function of the ovary is well known. If ablation of the ovaries cures osteomalacia, the latter must be due to their morbid activity (? overproduction of their internal secretion). Hoffmeister found, after thyroidectomy in rabbits, anatomical changes in the hypophysis, ovaries, kidneys, and osseous system, and the author has had several cases of more or less pronounced Graves's disease combined with a certain type of osteomalacia, consisting of an exaggerated flexibility of the finger and wrist joints, or great brittleness of the bones. Deformities of the skeleton are common also in goitrous subjects. This

raises the question of how many morbid changes in the bones and joints, commonly called rheumatic, may be really due to perverted glandular function. Trachewski has even produced rickets in the foetus of animals by performing thyroidectomy. The existence of a thyroid "osteopathy" is also supported by the frequent presence of phosphaturia in Graves's disease (7 in 40 of author's cases). This leads us by Telsier's law to glycosuria (1 case had both phosphaturia and glycosuria, 2 had polyuria plus characteristic fingers). Spontaneous hæmorrhages from all parts are common in subjects of goitre; this is connected to osteomalacia by Barlow's scurvy rickets. As regards the numerous nervous manifestations of thyroid intoxication, one case of old paraplegia with abolition of reflexes in a woman with goitre and incomplete myxœdema was rapidly improved by the administration of thyroid tablets. The skin also seems to be influenced by the thyroid function, as, besides the classical myxœdematous pachydermia, some cases of psoriasis are cured by thyroid extract. Lastly, idiopathic emaciation is related to that occurring in Graves's disease by the nervous irritability and intestinal and vascular spasms of neurasthenia; and loss of weight is the most marked effect of the absorption of thyroid juices. Both are improved by the administration of cod-liver oil, which may be looked on as an internal secretion of the liver, to some extent equivalent to and capable of replacing the colloid substance of goitre (thyroproteinid), which has not yet been prepared as a medicine.

(336) Intrauterine Infection with Enteric Fever.

FREUND AND LEVY (*Berl. klin. Woch.*, 1895, p. 539) give the history of a case in which a woman, five months pregnant, was attacked by enteric fever. In the fourth week she suddenly miscarried; the foetus was alive but died immediately after section of the umbilical cord. Foetus and placenta were forthwith placed in sterile vessels, and a bacteriological examination made. Plate cultures made with spleen pulp, and with placental blood showed colonies of micro-organisms which were clearly *B. typhosus*. The cultures caused no coagulation of milk, led to no fermentation, did not form gas or indol, and grew on potato as an imperceptible layer. Examination of the foetus discovered nothing beyond a somewhat enlarged whitish spleen; in the placenta the decidua was very thick; no typhoid bacilli were recognised in sections. The case clearly shows that typhoid bacilli may pass from the maternal to the foetal organism without any modification of the placenta; neither hæmorrhages nor lesions of the villi or of their epithelium were to be found.

ERRATUM.—In the abstract of Prof. Welch's paper on the Antitoxin Treatment of Diphtheria, published in the *Epitome* of October 20th (par. 332), the word "sufficient" in column 3, line 13, should be *insufficient*.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(329) Gout.

G. KLEMPERER (*Deut. med. Woch.*, October 3rd, 1895) discusses the pathology and treatment of gout. He first refers to the failure of uric acid solvents such as piperazin, lysidin, to cope with the disease. As regards the origin of the uric acid deposits, Garrod has attributed them to increased formation and diminished excretion of uric acid. The uric acid in the blood, according to Ebstein, irritates the tissues, which become inflamed and necrotic, and the uric acid crystallises out in the necrosed tissues. Ebstein maintains that this necrosis is primary. The author thinks this view open to question because the blood does not contain so large an excess of uric acid as to induce the necrosis in the tissues. Von Noorden disputes the causal relation between uric acid and necrosis. He thinks the primary necrosis is due to a ferment, and that in the necrotic tissues the uric acid crystallises out. The author confirms by his experiments Garrod's view that the blood contains an excess of uric acid. He also concludes by estimating the amount of uric acid in the urine that a uric acid retention does not exist. Weintraud has shown that the amount of uric acid in the urine is increased by the administration of calves' thymus. The author found that by administering thymus to gouty patients the excretion of uric acid is also increased as in the healthy. Thus as long as the kidneys are intact, uric acid retention does not occur. The increased quantity in the blood is due to increased formation. The author would not attribute all the symptoms of gout to the increased amount of uric acid in the blood because the same thing exists in other diseases, as he shows in cases of leukaemia, Bright's disease, etc. He has also estimated the solvent power of the blood for uric acid in gout, and finds that it still has a considerable solvent power left. As regards the alkalinity of the blood, the author finds that it is slightly lessened in gout, but not so much so as it often is in other diseases. The author thus sums up his views upon gout: Unknown products lead in gout to inflammatory and necrotic processes in certain tissues; these necrotic foci attract the uric acid from the blood, and the chemical affinity of the gouty necrosis for uric acid is occasionally so great that the blood is unable to bring the acid again into solution. The author discusses the relation of these products to heredity, alcohol, and lead. In a dog fed with lead to such a degree as to produce epilepsy there was no diminished excretion of uric acid. The author thinks that lead predisposes to the necrotic action of the above-named products. The object of treatment is to

counteract these necrotic processes by oxidation and excretion. Agents and means by which metabolism is increased should be employed, such as exercise, baths, etc.; abundant fluids and frequent sweating have the object of hastening excretion. The author concludes by discussing the question of diet.

(330) A New Type of Crossed Hemiplegia.

MADAME GOUKOVSKY (*Nouvelle Iconographie de la Salpêtrière*, No. 3, 1895) describes a case presenting a new type of crossed hemiplegia—namely, paralysis of the limbs on one side and of the muscles of the tongue on the opposite side. In the case reported there was (1) paralysis of the arm and leg on the right side, without paralysis of the face and without aphasia; (2) complete paralysis and atrophy of the left half of the tongue, with deviation to the left on protrusion. The absence of facial paralysis indicated a lesion of the motor tract below the separation of the facial fibres (that is, below the pons). The atrophy of the left half of the tongue indicated a lesion at the hypoglossal nucleus, or on the peripheral side thereof—that is, a lesion in the medulla. A single lesion in the upper part of the fissure between the pyramid and the olivary body of the medulla, above the pyramidal decussation, was diagnosed. Such a lesion would involve the left hypoglossal nerve and the motor tract for the right arm and leg, before the fibres decussated. *Post-mortem* examination confirmed this diagnosis, and revealed a patch of softening, limited to the left olivary body and the left pyramid of the medulla. The greater part of the roots of the left hypoglossal nerve had been destroyed. The softening was due to chronic endarteritis obliterans.

(331) Edema without Albuminuria.

TECHERKOFF (*Rev. de Méd.*, August, 1895) has observed considerable edema in several cases without albuminuria. The patients' ages varied from 26 to 60. In some the general appearance resembled that of renal disease; in others, and especially the anemic, the anasarca developed rapidly, the peritoneal cavity filling with fluid very much, as in cases of cirrhosis of the liver. Renal disease was in all cases carefully excluded. A general loss of hair was noted. The blood was normal, except that in most cases there was a quantity of reduced hemoglobin present. There was no evidence of cardiac lesions or of general stasis of the blood. The author then refers to a possible nervous origin in the shape of a lesion of the vasomotor centres or nerves. There was a profound alteration in nutrition. In those recovering there was great wasting and exhaustion. The above alteration in the blood serves to distinguish the edema from that of chlorosis or pernicious anemia. The author gives details of some of the seven cases of generalised edema without albuminuria, observed by him. In one case of a man, aged 48, there was

a rapid development of edema, with effusions into the peritoneal, pleural, and pericardial sacs. None of the ordinary causes of general dropsy were present. The author comes to the conclusion that the most probable cause lay in a lesion in the vasomotor system rather than that the disease was due to any profound alteration in the heart, or to a lesion in the vessel walls. In other cases the edema of the extremities is never great, but the effusion into the serous cavities and dilatation of the right heart are most constant. The author then refers to the possible syphilitic origin of the affection, and gives details of two cases in which recovery ensued after treatment with potassium iodide. The author recognises two groups of cases: (1) acute, with rapid edema and dropsy of the serous cavities; and (2) chronic, with slow development and with trophic disturbance and venous paralysis. In five out of seven cases there was previous syphilis, and antisyphilitic treatment gave brilliant results. The author could not but conclude that such cases were syphilitic in nature; they are certainly due to an affection of the vasomotor centre, whatever the exact nature of that lesion may be. Apart from syphilis, the infective diseases seem to be the most frequent cause, the toxins, in all probability, producing an alteration in the vasomotor centres. The author does not think that these cases can be of lymphatic origin. He concludes that (1) generalised dropsy may occur without albuminuria, and in the absence of disease of the heart, lungs, liver, or other organs; (2) it may be called general vasomotor edema; (3) it may be accompanied by cardiac dilatation and moderate arterio-sclerosis; (4) the blood presents certain alterations in the shape of reduced hemoglobin; there may be trophic changes and paralysis of the cutaneous vessels; and (5) the disease is mostly syphilitic, and yields to appropriate treatment.

SURGERY.

(332) The Surgical Treatment of Movable Spleen.

PETESKAN (*Central. für Chir.*, No. 40, 1895) reports a case in which a movable spleen was first exposed by laparotomy, and afterwards securely fixed in the lumbar region by sutures. The patient—a woman 23 years of age—who had suffered constantly during 3 years from pains in the stomach and over the epigastrium, came under the care of Hildebrandt with a firm and smooth tumour, which occupied almost the whole of the anterior pelvis on the left side. After the abdomen had been opened in the median line this tumour was found to be the spleen enlarged to about double its normal size, of firm consistence, and of a dark red colour. The wound in the anterior abdominal wall having been closed, the patient was turned over on to her right side, and a second incision was made in the mid-axillary line from the costal arch

to the crest of the ilium. The peritoneum having been exposed, an incision was made in this membrane through which the movable spleen could be pressed through from the abdominal cavity. In this new and retro-peritoneal situation the displaced organ was fixed by sutures to the lumbar fascia, to the retroperitoneal connective tissue and fat, and to the tenth rib. The edges of the peritoneal wound were very carefully stitched around the elongated pedicle of the spleen. The patient made a speedy recovery from this operation, the object of which, it is stated, seemed to have been secured. In comparing this procedure with that advocated by Rydgyler, in which anterior laparotomy is performed, and the wandering spleen fixed by sutures to the parietal peritoneum, the author points out that the former presents the following advantages: it is, he holds, less dangerous and can be more readily performed; there is no prolonged exposure of the peritoneal cavity, and the necessity of exposing and handling intestine is prevented; the spleen is secured to unyielding and fixed structures, and finally there is much less risk of any subsequent tendency to hernia at the seat of operation.

(342) Compression of the Brain.

GIANNELLI (*Riv. Sper. di Freniatria*, vol. 21, fasc. 23) gives the results of some pressure experiments on the brain of a woman, aged 33, who had been trephined over the middle of the ascending parietal convolution. In one set of experiments the pressure was increased gradually up to 20 cm. Hg., in the others, rapidly up to 18 cm. Similar symptoms were observed in each case except that they occurred at once when the pressure was rapidly increased and gradually in the other class. The pupils contracted in the first series and dilated clearly in the second. It was not noticed which pupil altered first; the changes were equal. The pulse was at first slightly increased in frequency, but ultimately lessened, and the height of the pulse tracing tended to get lower. The respiration, which was at first increased, speedily diminished, and it appeared that stimulation of the part of the cerebral cortex under observation exercised an inhibitory influence on expiration. No Cheyne-Stokes breathing was observed, perhaps because the pressure was not high enough. Pain in the head became intense at 14 cm. pressure, unbearable at 18. Temperature in the rectum fell slightly under pressure, but rose to normal in a few minutes after the pressure was relieved. Salivation was often noticed. Drowsiness up to loss of consciousness observed when the pressure was high. It was not possible to observe the optic discs during the course of the experiments.

(344) Surgical Interference in Traumatic Rupture of the Abdominal Viscera.

THOMSON (Reprint from *Edin. Hosp. Rep.*, vol. iii.) reports four cases of severe abdominal injury treated by

surgical operation, in three of which the treatment proved successful. From a careful consideration of the indications and contra-indications for operative interference in such cases, the author concludes that it would appear to be the duty of the practitioner when called to a patient who has met with an injury to the anterior abdominal wall, and especially if the violence has been sustained over a limited area, to exclude, in the first instance, rupture of the bladder, then to search for evidences of internal hæmorrhage or escape of gas. If either of these be suspected, and if the facts elicited with regard to the injury are such as to corroborate the inferences made from physical examination, he should not delay to afford the patient the chance of relief by surgical interference. An exploratory median laparotomy should then be the proper procedure, either above or below the umbilicus, according to the indications presented in each individual case. In considering the pros and cons of an exploratory operation it should be remembered that a ruptured abdominal viscus, if left to Nature, is almost inevitably fatal. It is hopeless, also, to delay interference until the shock has passed off, for, should a rupture exist, the phenomena of shock will only yield to those of perforative peritonitis. The injection of a hot saline fluid into the veins, or into the peritoneal cavity, is regarded as a valuable procedure for alleviating shock and tiding the patient over a critical period.

(345) Paralytic Dislocation of the Hip.

APPEL (*Münch. med. Woch.*, October 1st, 1895) remarks that congenital dislocation of the hip can never be attributed to an infantile paralysis occurring in the earliest period of life. He then refers to the few recorded cases of paralytic dislocation, and reports the following exceptional case of it. A boy, aged 8, was well up to the end of his first year, when he had an attack of infantile paralysis involving chiefly the right leg. Some improvement subsequently occurred. When he was seen the right leg was shorter than the left, and the foot was in the clubfoot position. When the patient was lying down with the leg extended little that was unusual could be observed, but if the leg was rotated inwards and adducted, the head of the femur passed out of the acetabulum and rested on the back of the ilium. The head and neck of the bone could be distinctly felt here. The patient could cautiously lean on the right leg and make certain movements, even with the head of the bone in this position. He could both voluntarily put the bone out and restore it to its position. He effected the latter movement by pressing on the trochanter with his hand, and making slight abduction and rotation outwards. The neurological report showed that there was moderate atrophy and loss of power in the glutei and in the flexors and adductors of the thigh as well as in the quadriceps, and especially the vastus internus. There was marked atrophy and paralysis of the

peronei, gastrocnemius, extensor digitorum communis, and hallucis longus. In the thigh muscles there was quantitative diminution in the reaction to the faradic and galvanic currents. There was no reaction to faradism in the affected leg muscles, and only a faint response to galvanism. The right knee-jerk was diminished. To explain the case the following must be supposed: (1) The poliomyelitis had produced a paralysis of all the muscles about the hip; and (2) the joint was brought into use by early restoration of some of the muscles. In the attempts at walking the head of the bone had not the usual support, owing to the change in the muscles and looseness of the capsule. The upper and back part of the capsule became more stretched, and hence the dislocation. That the dislocation was not permanent was due to the restoration of function in some of the muscles, and to the fact that the patient soon learnt to replace the bone. Bramann resected the upper and back part of the capsule, with the hope of keeping the bone in place and thus improving the patient's condition. It is too early yet to say what the result will be.

MIDWIFERY AND DISEASES OF WOMEN.

(346) Puerperal Convulsions.

LEUSDEN (*Virchow's Archiv*, October 3rd, 1895) has made a series of investigations on two cases of eclampsia. His results seem admittedly negative, as he has found that certain conditions held as causative and primary are really secondary. He cannot find any sound basis for the hypothesis that a true bacterial infection is present. The presence of a toxic substance is far more probable. Kidney disease plays a very prominent part in eclampsia. A previous observer, Schmori, laid stress on a remarkable embolic condition in the lung. The capillaries were found plugged with bodies corresponding in every respect to placental giant cells. Leusden found such cells in the lungs in both his cases. He insists that they represent a mere accidental peculiarity. These placental cells decidedly have no fibrinogenous power, nor can he detect any other bodies or compound due to placental disease and possessing the same property of causing coagulation. Schmori believed in such an influence. No liver cell emboli were detected, and, though necrotic changes were observed by Leusden in the parenchyma of the liver, he considers that they could not represent the cause of eclampsia. Hyaline or fibrinous capillary thromboses in the lung and liver were discovered, but Leusden notes that they are not peculiar to eclampsia, and are most likely a result of toxæmia of the anæmic type. In the lungs this condition must be related to the local œdema which occurs in eclampsia. In short, there is much to be seen in the tissues of organs from cases of puerperal eclampsia, but nothing like a primary lesion has yet been determined.

(337) Flooding and Icterus Neonatorum.

HAUMEL (*Revue Obstét. Internationale*, October 11th, 1895), read at the Bordeaux Congress a note on a child which was already eight months old and well nourished. It was born about a month before term, after free flooding from detached placenta. On the third day the skin was bronzed, the conjunctivæ yellow and ecchymosed; the urine stains on the child's linen were wine-red in the middle and nearly black at the border. During the first month the urine varied singularly in colour day by day: red, violet, blue, black and yellow tones were observed. On analysis neither hæmoglobin, methæmoglobin, nor hæmaturia could be detected, but indican was present. There was suppression of urine for a short time, and trismus, yet recovery was complete. The hæmorrhage had altered the foetal blood, which was incompletely oxygenated, so that the liver could not transform the products of the destruction of hæmoglobin into bilirubin. In all cases of icterus neonatorum, abnormal as well as normal, search ought to be made for abnormal pigments as well as for bilirubin, etc. Ictæmia represents a distinct variety of the disease.

(338) Puberty and Disturbed Heart's Action.

KISCH (*Frauenarzt*, October, 1895), distinguishes three forms of cardiac disturbance at the epoch of development of the sexual functions: (1) Nervous palpitations and paroxysmal tachycardia in otherwise healthy subjects. They are frequent before the first period and usually cease soon afterwards. (2) The well-known cardiac symptoms in chlorosis. (3) Hypertrophy of the heart occasioned by the alterations of the circulation associated with the establishment of menstruation and aggravated by insanitary clothing, especially tight lacing.

(339) Large Pelvic Hematoma after Ovariectomy.

SCHRAMM (*Centralbl. f. Gynäk.*, No. 34, 1895) was consulted by a servant maid, aged 27, who suffered from pain in the left iliac fossa during defecation. The left ovary was much enlarged. It was removed and found to be cystic, in size as big as a hen's egg, with a long thin pedicle. For a week after the operation the patient passed urine spontaneously. On the eighth day dysuria set in, with severe pain in the left iliac fossa. A swelling of the size of an apple lay to the left of the uterus. Two days later it was found to be very large and tense. The pain was intense, fever entirely absent, and all physical signs pointed to extravasation of blood in the left broad ligament. The swelling extended to the right of the uterus. A vaginal puncture was made, and a quantity of brownish fluid blood came away. The puncture hole was enlarged and a drainage tube inserted. No fever followed, and the dysuria disappeared. Two days later the swelling increased to beyond its original size. Much frothy blood escaped when a second puncture was made. The cavity left

after the escape of the blood was packed with iodoform gauze. This was removed on the second day, and a glass drainage tube was inserted. The cavity was washed out with a 3 per cent. boracic solution every day. The patient made a good recovery.

(340) Diffuse Hypertrophy of Breasts after Delivery.

ANTHONY (*Boston Med. and Surg. Journ.*, August 22nd, 1895) publishes the sequel to Warren's case (*ibid.*, August 3rd, 1893). Anthony states that the patient became pregnant for the third time, and was under his observation during her pregnancy. The breasts, which had become smaller after her second delivery, again increased till they grew very large and pendulous. A rudimentary nipple formed in the right axilla. An accessory nipple on the under surface of the left breast was surrounded by a dark areola. Labour was normal. The patient insisted on suckling the child, which she had not done after the second labour. The supply of milk was equal to the demand. Two months after delivery the breasts were once more as small as before the pregnancy.

THERAPEUTICS.

(341) Thyroid Feeding.

KNOEPFELMACHER (*Wien. klin. Week.*, October 10th, 1895) has investigated the influence of thyroid feeding upon cases of rickets and goitre. Lawz has asserted a relationship between rickets and cachexia strumipriva, both of which give rise to anæmia, tetanic symptoms, and impaired bone growth. In this last respect Knoepfelmacher points out that the resemblance is a very superficial one, since in rickets there is increase of cartilage cells with but slight ossification, whereas in cretinism and allied affections there is accelerated ossification, with very little cartilaginous overgrowth. Four rachitic infants suffering from tetany were fed on thyroid extract without result, except that their rate of growth (as regards body weight) diminished. The tetany yielded readily to other treatment. The loss of weight which usually results from thyroid feeding is held to be due to increased nitrogenous excretion, and not to loss of fat or water. With regard to goitres, Bruns, Lawz, and others had already established the fact that parenchymatous hypertrophy of the thyroid is amenable to specific treatment, the value of which decreases with the age of the patient. Colloid bronchoceles are less affected, cystic not at all. Knoepfelmacher treated 23 cases of goitre with thyroid tabloids. In 11 patients whose ages varied from 2 to 17 years there was marked diminution in the size of the tumour, but never complete disappearance. Nine of these growths were diagnosed as simple hypertrophy, the other two as adenoma. In 12 cases (one aged 12 years the others from 17 to 21) there was slight but evident improvement; in 5 more (aged respectively 8, 9, 17, 17,

and 27) no result followed. It was found that in these latter treatment by iodine—potassium iodide internally and iodide ointment externally—was also unavailing. In 4 cases which were benefited the improvement had been maintained from three to five months later. This disproves the theory of Kocher and Bruns that hyperplasia is a functional disease of the thyroid, and that if thyroid extract is administered this hypertrophy resolves as long as secondary changes have not been added to it. The author suggests as an explanation of the persistent diminution in size that hypertrophy is due either to the claims on the gland being too great, or to certain parts or the whole of it being in a condition of diminished functional activity. In the latter case, the gland being put out of action by feeding with its extract partly atrophies, while the rest recovers its functional capability.

(342) Serotherapy in Meningitis.

RICH (Rif. Med., August 26th, 1895) reports the case of a healthy child, aged 7, who suffered from cerebrospinal meningitis, from which disease his sister had recovered some two or three weeks previously. The illness began with headache and pains all over, fever, shivering, and vomiting. On the second day there was considerable rigidity of the neck and the headache was worse. Examination of the blood at this date showed the presence of diplococci (Fraenkel's). Strabismus, intermittent delirium, naso-labial herpes, and facial paralysis occurred on the next two or three days, and on the fifth day the child was half unconscious. On the sixth day blood was taken from the arm of the patient's sister—who had had meningitis—and 5 c.c.m. of the colourless, limpid serum injected into the patient. There was no reaction at the point of injection. Five hours afterwards the temperature was lower, the respiration better, and the child had willingly taken nourishment. Ten hours afterwards he sat up in bed and could move his head without pain. Three days after the injection the child was able to get up a little morning and evening, and could walk. There was a slight return of symptoms on the seventh and ninth days, but otherwise recovery was uninterrupted, and after fifteen days there had been no return of the symptoms. Very slight strabismus and facial paralysis may still be detected. There was no adenoma.

(343) Serum Treatment of Diptheria.

SPINOCERUS (*Munch. med. Week.*, 1895, Nos. 31 and 32) has treated 24 cases with the serum. The mortality was 37.5 per cent., whereas in those not so treated it was only 23 per cent. No reactions adverse to the serum treatment can be drawn from these figures owing to the different classes of cases. Treatment was required 10 per cent. less frequently than formerly. The cases are divided up into the following groups: (1) 12 mild cases, all of which recovered. (2)

105 severe cases, with involvement of the nose or larynx, enlargement of the glands, and severe general infection; of these 17 died; (3) 88 very severe cases, with extensive gangrenous deposit of membrane in the mouth, pharynx, and larynx or trachea, and presenting septic manifestations; of these 61 died. The greatest mortality occurred as usual under 1 year. Statistical evidence was in favour of early treatment. No abscess or phlegmon was noted, the injections being made in the pectoral muscles. Usually 1,000 immunity units of Behring's serum were used, never more than 2,000. Improvement in the general condition of the patients was mostly noted after the injection, but there was no apparent effect upon the temperature. A local effect upon the membrane was also observed. In 161 cases the larynx was involved; of these 113 were tracheotomized. Thus 45 were spared tracheotomy, and by far the most of these recovered. There was a slight improvement in the mortality after tracheotomy, and death occurred at a later period than hitherto. No unfavourable action of the serum on the kidneys could be proved, but the author does not think that the serum is an indifferent agent as far as the heart is concerned, as cardiac paralysis was noted more frequently than hitherto. In 23 cases there were skin eruptions. In 5 cases there was a scarlatiniform rash. A pemphigus-like rash was observed once. Twice erythema multiforme occurred, 1 of these cases being fatal. In 3 cases articular pains were noted. One hundred and five cases were injected for the purposes of prevention; among these 14 cases of diphtheria were noted; of these only 1 was fatal, and here death could hardly be attributed to diphtheria. In 2 cases the infection was probably already present at the time of the injection. Absolute conclusions cannot be based on these results in the preventive treatment, yet an immunising effect of the serum can hardly be denied.

(374) Trional Poisoning.

BROGNI (Münch. med. Woch., October 1st, 1895) describes the case of a medical man with marked locomotor ataxia, who had contracted the opium habit in seeking relief from pain. He was admitted for the purpose of overcoming the habit. The morphine was gradually withdrawn. Trional was occasionally given—mostly in 1 g. doses—for sleeplessness. Phenacetin was used for the pains. Once the patient succeeded in getting morphine from outside. One day he became somnolent without obvious reason, and the somnolence increased. The urine on the following day was normal and contained no morphine. On the next day, however, it was burgundy red in colour, but clear and transparent. Ferric chloride and calcium chloride both produced a chocolate-coloured deposit. The presence of hæmato-porphyrin could not be proved. The patient was extremely somnolent, had hallucinations, and could not speak distinctly. The breathing was stertorous and occasionally of

the Cheyne-Stokes character. The extremities were cold and blue. The pulse was 90 to 100. The ataxia in the legs was more marked, and it was also present in the hands. The pupils were moderately dilated. Eight grammes of trional were found in the room. Strong coffee, camphor, and carbonic acid water were given. The next day the symptoms persisted and the anorexia was marked. The somnolence diminished two days later, the breathing improved, and the cyanosis disappeared. Recovery slowly ensued, but the urine did not present its normal appearance for at least sixteen days. Here the comparatively small dose of 4 g. in the twenty-four hours was sufficient to produce poisoning. Nervous symptoms not hitherto described in trional poisoning were present, and the after-effects lasted long. The author then refers to the various symptoms which have hitherto been recorded. There were no gastro-intestinal symptoms in this case, possibly owing to the morphine. As in sulphonal poisoning, hæmato-porphyrinuria has been noted, but such cases were fatal. The colour of the urine was due to disintegration of red blood cells, and was, perhaps, a preliminary stage of the appearance of hæmato-porphyrin. Trional is not a harmless hypnotic, as the above case indisputably shows. The author says that it should not be given in larger single doses than 1 g., and the daily dose should not exceed 2 g.

PATHOLOGY.

(375) A Pathogenic Bacillus in Bronchopneumonia.

WRIGHT AND MALLORY (*Zeitschrift für Hygiene*, August, 1895) describe a pathogenic bacillus found in the lungs of a man who, three weeks after diphtheria, died with severe broncho-pneumonia. The necropsy showed also hepatic abscess, due apparently to old appendicitis. In addition to the Klebs-Loeffler bacillus, which was still present in the bronchi, an encapsuled bacillus was found in the secretion from the bronchi, and in the alveoli of the lungs in great numbers. It was easily cultivated on blood serum, agar-agar, gelatine, and potatoe; the pure cultivation injected into mice subcutaneously, and into the veins of the rabbit caused death from septicæmia in twenty-four hours; injected into the trachea of the rabbit it caused death from septicæmia in five days; no definite pneumonia was produced. The bacillus is two or three times as long as it is thick, has the ends rounded, and is enclosed in a definite capsule, which is seen in cultivations; it is not mobile; shows no tendency to formation of spores; and stains well by Gram's method. The organism belongs to the same group as Friedländer's pneumonia bacillus, though differing in several points from that bacillus. It is probably identical with some already described, perhaps with that described by Fasching in the nasal secretion of influenza.

(376) The Bacillus of Tetanus.

GRISONI (*Riv. Med.*, August 21st, 22nd, 23rd, 1895), experimenting with Nicolaier's bacillus, comes to the conclusion that it is aerobic in the soil, and, further, that as long as it remains aerobic it is atoxic. Its toxicity and virulence are brought about by the presence of other microorganisms which act by depriving the media of oxygen, and so rendering the tetanus bacillus anaerobic. This anaerobiosis, according to the author, is indispensable to the tetanus bacillus for the production of its specific toxins, but mere deprivation of oxygen alone is not sufficient—the presence of other microorganisms is necessary. The comparative frequency of the tetanus bacillus in the earth contrasted with the rarity of tetanus; the beneficial effect of antiseptics (which have little effect on the tetanus bacillus spores, but considerable effect on other microorganisms) in checking tetanus are explained by the author's view of the necessity of a particular microbial association for the full development of virulence in Nicolaier's bacillus. This peculiar microbial association fortunately occurs very exceptionally, hence the rarity of tetanus. The nature of the associated microbes seems somewhat indeterminate.

(377) Leucocytosis in Cancer of the Stomach.

HARTUNG (*Wien. med. Woch.*, October 3rd and 10th, 1895) has investigated the condition of the blood as a means of diagnosis in carcinoma ventriculi. Previous observers had shown that in cancer of the stomach as distinguished from ulcer there is a considerable leucocytosis; others had found that in healthy subjects an albuminous meal led to a marked increase of leucocytes in the blood. Schneyer discovered that this increase did not occur in patients suffering from cancer of the stomach, and pointed out that this fact would be useful in diagnosis where chemical examination of the contents of the organ was inadvisable. Hartung used for a test meal—after a fifteen to sixteen hours' fast—eggs, milk, etc., to which 1 grain of nuclein prepared from calf's spleen by Professor Horbaczewski was added. This mixture produced in healthy subjects an increase of leucocytes sometimes amounting to as much as 96 per cent. in 3½ hours. In 10 patients suffering from cancer of the stomach, no leucocytosis resulted from the meal. In all there was a persistent diminution of red corpuscles (chlorotic condition) with increase of white, particularly of the polynuclear leucocytes, the number of which was directly proportional to the cachexia. In most of the cases there was also a diminution of the eosinophile corpuscles in proportion to the cachexia. Hartung considers the blood changes in cancer to be due to the toxic action of products of the malignant growth upon the hæmatopoietic organs, especially the lymphatic apparatus. He claims that his researches afford a safe criterion in the diagnosis of obscure internal cancer.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(318) Medical Pyæmiæmia.

WERNER (*Arch. ges. de Méd.*, October, 1895) records two cases of general infection with the staphylococcus without definite visceral manifestation or other distinct localisation. He refers especially to cases in which the generalised infection reveals itself by severe general symptoms, profound debility, and a characteristic temperature curve. The disease appears to be rare, the following cases being the only two which the author has seen. (1) A girl, aged 23, in previously good health, began suddenly with pains in the limbs and abdomen, anorexia, vomiting, intense but not persistent headache, violent and repeated shivering, etc. On the fifth day the anorexia was complete. There was no constipation, or diarrhoea, or abdominal distension. There was no rash, and the spleen was not enlarged. No disease could be found in the other organs. About a week later the prostration was more marked. There were repeated and severe rigors and occasionally vomiting. The temperature was irregular, occasionally exceeding 40° C. The condition of the patient became very threatening. About a week later improvement set in, the rigors becoming less intense and the vomiting less frequent. About seven weeks after the onset convalescence was established. Colonies of the staphylococcus aureus and albus were obtained from the blood on several occasions. (2) A man, aged 42, complained a fortnight before admission of lassitude, etc. Ten days later he had a rigor. On admission there was marked prostration, a dry brown tongue, and a temperature of 40° C. The abdomen was a little distended, and the spleen and liver slightly enlarged. The urine contained albumen. There was some cough, with frothy expectoration. A bed sore developed a week later. A general eruption of furuncles appeared, and the prostration became more intense. A week later the condition began to improve. Six weeks after the onset a large phlegmon appeared on the right side of the abdomen. The pus contained the staphylococcus albus and aureus. About three months after the onset convalescence was established. Some four months later there was an infective osteomyelitis of the left femur, which recovered. Numerous colonies of the staphylococcus were obtained from the blood on several occasions. The diagnosis could only be made in these cases by exclusion and bacteriological examination. It was impossible to find the point of entry of the infection. Both cases were due to a general staphylococcus infection, and both recovered in spite of the severity of the disease.

(319) Predisposing Causes in Facial Paralysis.

NEUMANN (*Neurol. Centralbl.*, October, 1895) considers that in most cases where cold is the exciting cause of so-called rheumatic facial paralysis, there is also a predisposition which in many cases is hereditary. Two cases are quoted in which facial paralysis arose from quite trivial causes in patients whose antecedents showed in the one case migraine in the mother, and neurosthenia with facial twitchings in the father, in the other facial paralysis in the father and insanity in one aunt. In such cases hereditary weakness of nerve tissue, particularly of the facial nerve, is supposed to predispose to the molecular changes which interfere with conduction. These changes, although in the severer cases presenting the appearances of parenchymatous neuritis, may show no visible change in the slighter ones. The predisposition may, however, be acquired. The facial paralysis occurring in association with certain constitutional diseases, for example, diabetes, syphilis, tuberculosis, would be thus explained, the general disease weakening the nervous tissue, and thus predisposing to the local condition on exposure to some local cause, however slight. The special liability of the facial nerve to be affected he considers due not so much to its exposed position, else the ulnar should often be affected, but to the large number of lymphatics and lymphatic glands surrounding it at its exit from the stylo-mastoid foramen. Stagnation of lymph would favour morbid changes in the neighbouring nerve, and such stagnation would be particularly likely to occur at night; hence the frequency of nocturnal onset of facial paralysis.

(320) Raynaud's Disease in Children.

MAUGUE (*Journ. de Méd.*, September 25th, 1895), in a recent monograph on Raynaud's disease, has collected a large number of cases occurring at different ages. He finds that whilst the most common age is from 30 to 43, still it may occur practically at any time. Thus he quotes 3 cases in the first year and 3 in the second. From this he concludes that its rarity in childhood is more apparent than real.

(321) Diphtheria in the French Army.

BROUWER (*Arch. de Méd. et de Pharm. Militaires*, October, 1895) first discusses the question of pseudo-diphtheria due to other micro-organisms than the diphtheria bacillus. In two years eight such cases with symptoms of diphtheria were observed in a regiment. The author alludes to a form in man produced by the bacillus of avian diphtheria. Thus without bacteriological examination it is impossible to say positively that the case is one of true diphtheria. In analysing the cases occurring in over two million men, he finds the incidence of the disease (morbidity) to be about 9.5 per 10,000. On an average for twelve years the mortality was nearly 1 per 10,000, but of recent years it has been increasing. The

author discusses the causes of this increase, which he would not attribute solely to larger masses of men being gathered together. Mounted troops are more often attacked by diphtheria than the unmounted, and this is particularly the case in Algeria and Tunis. The mortality varies but little in the infantry. In the cavalry, etc., oscillations are noted in the mortality, but this is more marked among the engineers and those connected with hospitals, etc. The mounted troops lose more by diphtheria than the unmounted. The morbidity varies according to rank. Diphtheria is four times less frequent among the superior officers than among the inferior, and seven times more frequent among the men than among the latter. The same is true also in a general sense of the mortality. The younger the individual the greater the liability to the disease, and the mortality lies principally among young subjects. Both the morbidity and mortality are greater among those who have served less than one year. According to the distribution in army corps there is a great difference in the various regions, the maximum frequency being noted in the north and centre of France. The morbidity is slight on the coast of the Mediterranean. The mortality is more equally distributed than the morbidity. It is greater in the army corps situated in parts through which great rivers, especially the Loire and Garonne, flow. As regards garrisons the morbidity and mortality are larger in the small towns than in the great centres. Soldiers coming from the sea coasts are almost refractory to diphtheria, and marines are wonderfully free from it. The maximum morbidity is in March, the minimum in October, and the mortality follows much the same course. As regards the different regions, the troops in Algeria suffer less from diphtheria than those in France, and those in Tunis suffer most, but the mortality is least in Tunis and most in France.

SURGERY.

(322) The Surgical Treatment of Cancer of the Stomach.

QUINZ (*Revue de Chirurgie*, October, 1895) advocates the following treatment in cases of gastric cancer affecting the pyloric region. He would perform an exploratory laparotomy with the object of making out with precision the seat and nature of the disease, and of determining whether or not the new growth be amenable to a radical operation. If the pyloric cancer could not be directly attacked and removed by operation he would perform gastro-enterostomy. If, on the other hand, there were good prospects of removing the whole of the diseased structures he would also establish an anastomosis between the stomach and jejunum, and, after an interval of from ten to fifteen days, perform pylorostomy. The removal of cancer of the pylorus in two stages presents, it is maintained, important advantages. In the first place, by a

preliminary gastro-enterostomy the duration of the subsequent operation of pylorotomy is much shortened, and, in the second place, when the patient has been much emaciated through inanition, the first operation permits of speedy removal of vigour by nourishment, and consequently favours more resistance against the immediate results of the serious operation of gastrectomy. The author has used Murphy's button, and recommends it to his colleagues. In one of his cases of gastric cancer, although he had had no previous experience of this appliance, he performed gastro-enterostomy in less than twenty minutes, much of the time having been taken up in exploration of the tumour and its connections. The objections that have been made to its use he regards as theoretical rather than real and practical. The button, he has no doubt, can be expelled from the intestinal canal by the normal way, and in his own practice he has had no reason to suspect any subsequent contraction of the gastro-jejunal fistula.

(339) Spontaneous Straightening of Bickety Curvatures of the Leg.

KAMPE (*Bruns' Beitr. z. klin. Chir.* xvi, 1), using the material of the Tübingen Clinic, concludes that (1) the greater number of all cases undergo spontaneous cure. Of the author's, all severe, 75 per cent. were cured, 15.8 per cent. improved, and only 9.7 per cent. remained *in statu quo*. (2) The process of spontaneous straightening lasts usually two to four years. If the curvatures begin in the first or second year of life the legs are quite straight by the fourth or fifth. (3) If the curvatures are unchanged by the sixth year spontaneous cure does not take place at all. There are always cases of most severe general rachitis. (4) The chief aim in treatment is to improve the general health so as to strengthen the muscles. In Kampe's experience as soon as the disease is past the acute stage, being about on the legs is not detrimental, but, on the contrary, helps the cure. Orthopedic treatment by plaster-of-paris, splints, etc., is not necessary. Osteotomy is indicated only when the curvatures persist after the sixth year.

(340) The Treatment of Tuberculous Prostatitis by Perineal Incision and Curettage.

GAUDIER (*Annal. des Maladies des Organ. Gén.-Urin.*, No. 2, 1895) reviews the history of this operation, which became possible after the introduction by Dittel in 1874 of the method of separating the anterior wall of the rectum by the curved perineal incision, and thus exposing the gland. This proceeding, at first undertaken only for opening prostatic abscesses, was later used for treating tuberculous disease, and many successful cases have been reported. Gaudier operated this way in the beginning of 1894, when the diagnosis had been made by the demonstration of tubercle bacilli in the sero-purulent secretion, expressed from the large and painful gland. The patient was 22 years of age; his urine off and on contained

traces of blood, and defecation was painful. At the operation the prostate gland was found changed into a lumpy, cheesy mass. This was entirely scraped out, and the cavity, owing to a violent hæmorrhage, packed with iodoform gauze. The whole wound was healed in fifteen days, without any trace of fistula. Since then the patient has had no morbid symptoms.

(341) The Effects upon the Testis of Ligation of the Spermatic Artery and Veins.

GRIFVITHS (*Journ. of Anat. and Phys.*, October, 1895) gives the results of investigations undertaken with the view of determining the structural changes that supervene in the testes after ligation of the spermatic blood vessels in the dog, in which animal the vascular arrangement of this organ is the same as that in man. Ligation of the spermatic artery in a full-grown dog, the author has found, leads within a few days to great diminution in the bulk of the testis, caused by rapid destruction from degenerative changes in the seminal tubules, but after a time the remaining tubules may recover to such an extent as to be again capable of producing spermatozoa. Ligation of all the spermatic veins leads to great swelling from engorgement of the veins and extravasation of blood into the intertubular connective tissue, and to necrosis of the epithelial cells in the seminal tubules. This condition would ultimately cause almost complete disappearance of the seminal tubules and atrophy of the gland. Ligation of the spermatic artery and veins in puppies leads to great swelling of the testes, followed by gradual diminution and atrophy of the seminal tubules, and to atrophy of the organ altogether. Ligation of the spermatic artery and veins in full-grown dogs may lead, according to conditions not yet known, to (1) sloughing of the testes, (2) complete atrophy, and (3) temporary fatty degeneration of spermatogenic cells in the animal, which may be followed by complete recovery.

(342) Hereditary Syphilis.

KRISOWSKI, of Max Joseph's Clinic (*Berl. klin. Woch.*, October 14th, 1895), draws attention to a manifestation of congenital syphilis which has mostly received but slight attention. He relates the following case in a lad, aged 17, who presented himself with a painless ulcer on the face with sharp, hard and infiltrated edges, and about the size of a mark piece. There were some twenty linear, radially arranged scars about the mouth. The upper incisors and corresponding part of the jaw were absent. There were three large scars on the hard palate. The uvula, tonsils, and pharyngo-palatine arch were entirely absent, and the hard palate was united to the posterior pharyngeal wall by cicatricial tissue. The epiglottis was swollen, and the cartilages of Wrisberg and Santorini seemed to be absent. There was a perforation in the septum of the nose. The ulcer healed under appropriate treatment. The diagnosis

of the nature of the ulcer was obvious. The union of the hard palate with the posterior pharyngeal wall hardly ever occurs except in hereditary syphilis. The malignancy of late hereditary syphilis is well recognised. The linear cicatrices about the mouth result from ulcerative syphilitic processes, and remain throughout life. Such lesions about the mouth heal with difficulty, owing to the frequent movement. No other process can give rise to such scars. The seat of the lesion is here in the cutis, whereas in eczema the epidermis is affected, and hence no scars are left. These linear and radiating scars about the mouth are not only characteristic of congenital syphilis, but also of its early appearance. They may be useful in distinguishing early from late congenital syphilis. Hereditary syphilis may also be thus distinguished from the acquired form. These scars are not so very rare.

MIDWIFERY AND DISEASES OF WOMEN.

(343) Treatment of Abortion.

JACOB (*Monatsschr. f. Geburtsh. u. Gynäk.*, September, 1895) maintains that in threatening abortion the right treatment is rest and opium, with extract of viburnum prunifolium. If free flooding sets in, the os remaining closed, the vagina should be plugged with iodoform gauze or aseptic wool. When the os is dilated so as to allow of the passage of a finger, the ovum should be detached and extracted, and the uterus and vagina syringed out once and for good with any suitable disinfectant in solution. When the dilatation of the os is imperfect, so that the finger cannot be introduced without force, whilst flooding grows severe, it is right to press the finger forcibly through with great care till the cervix is dilated. Then extraction must be practised. In many cases the expulsion of the ovum may be left to Nature. Ergot should be given for a week after abortion, spontaneous or induced. Jacob deprecates the routine employment of the curette and of vaginal irrigation.

(344) Abdominal Section by Cow's Horn.

SKILLING (*Amer. Jour. Obstet.*, July, 1895) records a case in which this accidental operation was performed without a fatal result in a non-pregnant woman. The injury is of interest in relation to well-known instances of successful Cæsarean section carried out in the same manner. Skilling was called in shortly after the accident. The patient lay in bed, her clothing saturated with blood. Her countenance was anxious and pale, but there was only slight evidence of impending shock. The cow's horn had entered the abdomen just above the symphysis, a little to the right of the median line, and ran obliquely to the right, making a rent six inches long. The peritoneum was involved; the intestines protruded; loss of blood was relatively trifling. The intestines were replaced, the peritoneum

closed by a continuous suture of fine silk, and the remaining layers of the parietes by interrupted silk sutures. The wound healed almost throughout by first intention except at the lower angle, where slight suppuration took place, probably from unavoidable contamination with dirt during or after the accident. Recovery was rapid and complete.

(329) Disappearance of Tubercles of the Peritoneum after Oophorectomy.

WAHLSTROM (*Nouvelles Archives d'Obstet. et de Gynec.*, September 20th, 1895), publishes another interesting example of this singular clinical phenomenon. On January 29th, 1892, the appendages of a woman, aged 27, were removed. It was then discovered that there was extensive tuberculous peritonitis, especially towards the pelvis. The patient regained her health after the operation. But empyema set in, and she was tapped on October 7th, 1893. She died on November 23rd. The pelvic viscera were found free and covered with a smooth shiny serous coat. Higher in the abdomen there were adhesions. The empyema communicated through the diaphragm with a fistulous opening in the abdominal cicatrix.

(330) Heredity of Twin Bearing.

VON SPRYER (*Mittheilungen aus kliniko und med. Institut der Schweiz*, 1st Series, Part 11, 1895) detected hereditary tendency in eight out of a series of twin bearers under his observation during the past ten years. In one patient it was found that four generations in her family had borne twins. In several the twins showed feeble vitality, and died almost simultaneously soon after birth. Twin bearing does not seem particularly related to the prime of the generative period, nor to its earlier or later stages. In some families already blessed with twins, triplets and quadruplets were borne. These rarer forms of multiple pregnancy are undoubtedly hereditary.

(331) Missed Labour.

STRAHL (*Der Frauenarzt*, October, 1895) relates a case in which he feels sure that labour was missed, and where he afterwards induced a kind of secondary "premature labour," as he terms it—or, in more usual terms, he delivered a fetus which the uterus refused to expel. The patient was intelligent. Her pelvis was contracted by prominence of the sacrum. Three labours had been normal, and only lasted some two hours each; a fourth had been more lingering, and a very big child was delivered at term. Labour pains, very distinct, set in at term in the fifth pregnancy. For three hours the uterine contractions were strong and regular; then the intervals grew longer and the pains weaker till they ceased. When 302 days had elapsed after the last period, Stahl found the patient inconvenienced by the great size of the abdomen, so he turned and delivered a very well-developed fetus, which was

alive at the beginning of the delivery. The prominent sacrum gave great trouble; the perineum was badly torn owing to the great size of the fetal head; ossification of the cranial bones had advanced very far, and made the parts incompressible. The fetus weighed 12 lbs. 8 oz., the placenta and membranes 2 lbs. The measurements of its head were: circumference, 16 in.; occipito-frontal diameter, 5.8 in.; bi-parietal, 5.2 in.; bi-temporal, 4.6 in. The perineum and the rent—nearly an inch long—in the rectum were sewn up at once, and the mother made a good recovery. No uterine disease nor rectal trouble ensued.

(332) Normal Range of Germ in the Genital Canal.

SDROGANOFF (*Centralbl. f. Gynäk.*, September 21st, 1895) has conducted a series of bacteriological experiments in the Clinical Institute, Helena Pavlovna Hospital, St. Petersburg. Specimens of mucus from the higher and lower parts of the vagina and uterus were removed, with every precaution, in test tubes, and carefully examined. He finds that not only is the canal of the cervix sterile as a rule in pregnant and non-pregnant subjects, but its mucus is actually fatal to bacteria. The os externum marks the limit between the germ inhabited and germ-free districts of the genital canal.

THERAPEUTICS.

(333) Diuretic Action of the Lithium Salts.

MENDELSON (*Deut. med. Woch.*, October 10th, 1895) observes that if a remedy is to act efficiently it must be administered in a form in which it can be absorbed. Lithium carbonate is in this respect almost an insoluble body. If it is used it should be given in carbonic acid water whereby it is converted into a soluble bicarbonate. When administered alone it is changed by the action of the hydrochloric acid in the stomach into a chloride which can only be absorbed to a limited extent; thus it is not the action of the carbonate but of the chloride which has to be reckoned with. Of all the lithium salts the chloride is least able to combine with uric acid, and to produce a soluble salt which may lead to the elimination of the uric acid. Thus the preference given to this lithium salt is not well-founded. It is admitted that the treatment which aims at bringing about a solution with elimination of the uric acid deposited in the tissues is not altogether satisfactory. It would appear that the increased diuresis has much to do with the benefit obtained in these cases. By a series of experiments on animals the author has established the diuretic action of the lithium salts. An acetate of lithium was mostly used in these experiments. Both when administered subcutaneously or by the mouth an increased diuresis was registered. In a few minutes after the administration of

the lithium salts their presence in the urine could be demonstrated. Of all the lithium the citrate has the most diuretic action. Investigations carried out upon healthy individuals as well as on those suffering from various manifestations of the uric acid diathesis showed that diuresis was also produced in man by the lithium salts. The citrate and acetate of lithium were the salts mostly used.

(334) Treatment of Epilepsy.

LUI (*Rev. spec. de Freniatr.*, vol. xxi., 1.23) has been trying the treatment of epilepsy advocated by Flechsig and Bechterew. Three cases were treated by Flechsig's method, which consists in a preliminary course of opium in gradually increasing doses up to 1.15 grain of the extract daily, followed by bromides, 7.5 to 8 grains daily. During the opium course two of the patients had a slight lessening in the fits, whilst in the third they became much more frequent and intense, so that instead of having two or three a week he had five or six. Severe opium intolerance set in in one case, so that the drug had to be discontinued for a week. With the commencement of the bromide the fits ceased at once, and in one case have not reappeared after four months; in the two other cases the fits reappeared after two months, but much reduced both in frequency and in severity. Bechterew's method—the simultaneous administration of bromide and adonis veratris and codeine—was tried in ten cases and with denaturation of the fits both in intensity and duration in each case. With this method there are none of the inconveniences that are liable to arise from opium intolerance, and on the whole the author is inclined to prefer Bechterew's method. He has little faith in the boric treatment of epilepsy. Gulicardi, in the same review, gives an account of more cases of epilepsy treated after Bechterew's plan. The author concludes that the good effects which follow are due to the bromide and not to the adonis or codeine. It appears to be better borne than simple bromide and does not produce any ill-effects moreover from the tonic effects on the vascular system due to the adonis. Bechterew's treatment may have an advantage over the ordinary treatment in cases in which there is cerebral debility.

(335) The Treatment of Chlorosis.

HAYEM's treatment (*Journal des Praticiens*, No. 17, 1895) consists of (1) rest in bed, which must be absolute in severe cases. This prevents the destruction of the red corpuscles, benefits the neurosthenia, does away with the nervous excitability, regulates the gastric functions, and removes the stasis, which are a frequent cause of dyspepsia. (2) Diet, which is of equal importance in view of the frequent gastric troubles (generally paralytic or atrophic gastritis). These must be relieved before prescribing iron. The diet must consist of milk and raw meat at first, later lightly boiled eggs, non-fatty fish, green vegetables as a salad, and stewed fruit. Bread is to be ab-

lowed only after four or five weeks. (3) Iron, which must be given only when the gastric functions are restored, and the author thus disagrees with v. Ziemssen on this point. The author prefers the proto-oxide, which he prescribes before meals, with dilute hydrochloric acid half an hour after.

(396) Treatment of Pediculosis Vestimentorum.

ALLAN JAMIESON (*Brit. Jour. Derm.*, August) says that in pediculosis corporis no remedy acts so promptly and efficaciously as petroleum, but there is an awkwardness in applying it to the general surface of the body. Incorporated in a soap such as Calvert's "petrolenic" soap, which contains carbolic acid as well as paraffin oil, it can be employed to wash the skin, the lather being allowed to dry on. In this way the eggs, which are sometimes attached to the downy hairs are killed. The insects themselves live in the body clothes, and deposit most of their ova there. Treatment must, therefore, be perseveringly directed against them. This can be accomplished by taking advantage of the property of sulphur of slowly subliming and becoming oxidised into sulphurous acid at the temperature of the body. A piece of roll sulphur, the size of a pigeon's or bantam's egg, is enclosed in a porous bag made of muslin or canvas, and worn next the skin day and night. The sulphurous fumes imperceptibly impregnate the clothes, and render them unsuitable for the existence of the parasites. Patients can thus be freed from a source of annoyance, or the accuracy of a suspicion can be tested without their being taken into the practitioner's confidence as to the cause of their trouble. The plan suggested has proved of service to the author in several instances.

(397) Treatment of Syphilitic Alopecia. To expedite the cure of syphilitic alopecia, Brocq (*Journ. de Med. et de Chir. Prat.*, September 10th, 1895) recommends the rubbing in every two days of the following: B Bichloride of mercury, 0.50 centigrammes; eau de cologne, 200 grammes. The following ointment should also be applied twice a week: B Yellow oxide of mercury, 1 gramme; pure vaseline, 25 grammes.

(398) Jaundice after Lactophenin.

STRAUSS (*Therapeut. Monatsh.*, September, 1895) deals farther with the effects of lactophenin. Cases have been reported in which troublesome sweating and also irregularity of the heart followed its use; in two cases rashes have been seen apparently due to lactophenin. He now reports three cases of catarrhal jaundice which seemed to be due to the same cause. In each case the drug was being administered for neuralgia, and a dose of 1 g. was being taken four times per diem; the length of time before the jaundice appeared varying from fourteen to twenty-one days from the commencement of the treatment. The jaundice appeared to be of the

ordinary catarrhal type, the stools being white and the urine bilious. Experiments on dogs showed intense congestion of the stomach and duodenum after administration of lactophenin, but no jaundice; similar congestion was observed by Lewin after the use of phenacetin, which has also been followed by bilious urine; it is suggested that these facts may point to catarrh of the duodenum as being the cause of the jaundice after lactophenin.

PATHOLOGY.

(399) The Action of Toluylenediamin and the Pathology of Jaundice.

HUNTER (*Journ. of Path. and Bacteriol.*, August, 1895) records the results of a number of experiments with respect to the action of toluylenediamin and the pathology of so-called non-obstructive jaundice. Previous researches by Stadelmann and others have shown that the jaundice produced by poisoning with toluylenediamin and phosphorus, and probably many forms of jaundice hitherto regarded as non-obstructive, are really obstructive in nature. According to Stadelmann, an increased destruction of blood occurs; this gives rise to an increased formation of bile pigment, and an alteration in the character and an increased concentration of the bile to which the obstruction is due. Hunter records a number of experiments on animals which show that toluylenediamin, injected subcutaneously, produces extensive catarrh of the bile ducts and duodenum, and that the bile is one of the channels through which toluylenediamin is excreted, though only in small quantities. The author believes that an irritative derivative of the poison is also excreted in the bile and induces catarrh in the bile passages and duodenum. The involvement of the duodenum is a mere adjunct to the catarrh of the bile ducts and occurs only in severe cases. Hunter concludes that the increase of catarrhal viscid mucus causes concentration of the bile, the flow of which finally becomes arrested for a time, and that the obstruction is produced primarily by catarrh of the bile ducts at their origin. In order to study the relation between jaundice and hæmoglobinæmia, the author produced the latter condition experimentally; but he found that mere excess of hæmoglobin in the blood, or increase of the bile pigments, apart from the operation of other causes, was not sufficient to give rise to jaundice. The author also records a number of observations on the mode of action of toluylenediamin and other agents which destroy the blood corpuscles. But he found that the blood changes produced were not so distinctive, either as regards their character or degree, as to explain the remarkably different action of these drugs in producing jaundice. The experiments show that neither hæmoglobinæmia, nor mere increase of the bile pigment, nor changes in the character of the hæmoglobin, can account for

the increased viscosity of the bile which occasions the jaundice in poisoning by toluylenediamin. Hunter concludes that the increased viscosity of the bile, which is the cause of the obstruction and therefore of the jaundice, is produced by catarrh of the bile ducts due to the excretion of the poison or its products.

(400) Morphology of Blastomycetes.

MAFFUCCI AND SIRLEO (*Il Pollicino*, June 1st, 1895) give an account of their experiments with a form of blastomycetes. The morphology of the parasite varies considerably, according to the time of culture and the nature of the nutritive medium, but the maximum changes were noted in the passage from cultures to animals. The particular form studied by the authors had a nucleus, and multiplied by a modified form of karyokinesis. The best temperature for cultivation was 20° C. to 37° C.; above 40° C. it could not be grown. Potato and preserved fruit were the most suitable media, and on these the parasite developed in chocolate-coloured colonies. In the moist state it resisted a temperature of 40° C. to 50° C. for one hour, and 60° C. for five minutes, after which it died. It also resisted desiccation for twelve days. Light weakened its vitality. Left to ferment with moisture it gave rise to CO₂ and alcohol. It could be developed anaerobically. Injected into animals (rabbit, guinea-pig, chicken, dog) it gave rise to non-inflammatory new formations resembling epithelial or endothelial growths. The authors never succeeded in obtaining pure cultures from malignant epithelial growths in man. They therefore withhold their opinion as to the exact relation between the blastomycetes and cancer.

(401) Vaccine Immunity.

BEUMER AND FEJER (*Berl. klin. Woch.*, August 26th, 1895) observe that the active agent in vaccine still remains undiscovered, and yet its microparasitic character is hardly contested. A protective action is induced by the inoculation. The duration of this protection varies according to different observers from six to seven up to ten years. Analogy with other diseases would suggest that protective bodies are developed in the protected individuals. The authors then refer to the recorded researches into this subject, where an attempt has been made to immunise animals by using the serum obtained from already vaccinated animals. The results have, however, been discordant. The authors have themselves made a series of experiments, chiefly on calves, in which they have used the blood serum or defibrinated blood of vaccinated calves, but with negative results. They conclude that in the blood of vaccinated calves no protective bodies are to be found which can confer immunity upon other calves, or that these bodies exist in such small quantities that any practical application appears to be excluded.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(402) Lumbar Puncture.

QUINCKE (*Berl. Klin. Woch.*, October 14th, 1895) mentions the fact that the cerebro-spinal fluid can distend the dural sac down to the sacral canal, and that some fluid may be drawn off even in the normal state by an exploring needle. No injury is done to the nerve roots by introducing the needle. In pathological states the condition of the fluid or the amount of the pressure is altered. This pressure should always be measured at the same as the puncture is made. This may be done by attaching india-rubber and glass tubing to the cannula, and noting the height to which the fluid rises about the level of the puncture when the glass tube is held in a vertical position. The normal cerebro-spinal fluid has a specific gravity of 1.007, and contains 0.2 to 0.5 pr. m. albumen and a little sugar. The author has used spinal puncture in 53 cases of various kinds, mostly when the pressure has been increased, as in cerebral tumour, hydrocephalus, and various forms of meningitis. The fluid is then mostly clear, more rarely turbid with leucocytes, etc., or discoloured with blood. The amount of albumen present is increased in acute inflammation up to 1 to 3 pr. m.; in chronic inflammatory conditions it exceeds the normal very slightly or not at all; and in cerebral tumour it may amount to 7 pr. m. Sugar is often absent in inflammation. In cerebral hæmorrhage rupturing into the ventricles, the fluid may contain blood. Cocci of various kinds may sometimes be found in the turbid fluid, or tubercle bacilli in the deposit or coagulum. Increased pressure is present in meningitis, but especially in tumour. Thus it would appear that moderately increased pressure with severe pressure symptoms points to an acute affection, whereas greatly increased pressure with slight pressure symptoms to a chronic one. The amount of fluid withdrawn in his cases varied from 3 to 60 c.cm., and gave an average of 20 c.cm. The diagnostic value of the puncture is very obvious from these facts. The local pain is slight, and anaesthesia is extremely rarely necessary. In a few cases pain or a spastic stretching in one leg was noticed, but this passed off at once, or at most in twenty-four hours. The effect upon a distended fontanelle was obvious. In some cases a remission of some of the symptoms was noted after or during the puncture. In chronic lesions this was much less marked than in the acute. Therapeutic results were noted in serous or seropurulent meningitis, and these will become more frequent when spinal puncture is adopted earlier, and more frequently in the various acute forms of meningitis. The author describes the apparatus

which he uses in spinal puncture. The technique is very simple. The needle is introduced in the middle line in children, and 5 to 10 mm. to the right in adults, the patient lying on the left side with the legs drawn up. If the needle impinges on bone it is slightly withdrawn and the direction altered. The author has never used aspiration like Fürbringer. In cases where the pressure rises more or less quickly after puncture the author has attempted to secure permanent drainage by incising the dura mater with a special scalpel. Here a few drops of fluid may escape at once, but more often the fluid drains away into the tissues, causing more or less oedema. He has never seen bad results follow this procedure.

(403) Stokes-Adams's Disease.

HUCHARD (*Arch. gén. de Méd.*, September, 1895) draws attention to certain incomplete forms of this disease, which consists in a permanent infrequency of the pulse with syncope or epileptiform attacks. In some cases the bradycardia is not permanent but paroxysmal in character, occurring only at the time of the attack. Thus two conditions may exist, namely, a paroxysmal bradycardia only, or a bradycardia paroxysmal at first but later in the disease becoming permanent. It is open to doubt, however, whether the latter does not always occur. The author gives four illustrative cases in detail. He also refers to other incomplete forms of the disease. In one case the pulse was permanently at 20, and the attacks consisted of slight insomnia, a little precordial anxiety, or a further infrequency of the pulse, which became irregular. Such cases of the incomplete disease are also of serious prognostic import. The author lays stress on the attacks revealing themselves only by pallor of the face and surface of the body; such attacks are frequently associated with infrequency or absence of the radial pulse. In all these cases there are other morbid manifestations, such as angina pectoris, symptoms of renal disease, etc. These do not strictly belong to the syndrome of Stokes-Adams's disease, but their frequency shows that this disease is not to be detached from the important chapter of arterio-sclerosis. There are four indications in treatment, namely, in respect to the arteries, heart, brain, and associated symptoms: (1) The iodides and vaso-dilator agents, such as trinitrine, nitrite of amyl, should be used. (2) Digitalis should be employed with the greatest caution. The author prefers sulphate of sparteine, caffeine. (3) The lachemia in the medulla oblongata must be counteracted. All remedies with a vaso-constrictor action, such as bromides, belladonna, ergot, etc., must be avoided. Trinitrine should be administered permanently along with the iodides and caffeine. In bad cases nitrite of amyl should be inhaled night and morning. Posture may be of value. The horizontal position may ward off the attacks. In bad cases with prolonged syncope total inversion of the body with the head downwards may be

practised. Death in Stokes-Adams's disease may be ward off by rest, avoiding overexertion, etc. (5) In the symptoms arising from the kidneys, etc., milk diet may be useful. The author concludes that (1) different maladies have been described under permanent infrequency of the pulse with syncope, epileptiform, or epileptiform attacks. (2) Stokes-Adams's disease is a cardio-bulbar arterio-sclerosis, and is very different from the infrequent pulse of nervous origin, as seen in compression of the upper part of the cord, cerebral or medullary tumours, compression of the pneumogastric nerve by tumours. (3) In Stokes-Adams's disease there are associated symptoms, renal or other, quite absent in the other similar affections. (4) The treatment is quite different. (5) There are incomplete forms often ending in sudden death. (6) There are associated forms; and (7) the disease is due to intermittent lachemia of the mitral orifice and heart, to which the treatment must be directed.

(404) The Red Blood Corpuscle in Legal Medicine.

M. C. WHITE (*Medico-Legal Journal*, vol. xii, No. 4), in a very careful paper on the measurements of red blood corpuscles in man and in the lower animals both in the fresh state and when recovered from a clot, concludes (1) that in favourable cases blood stains can be so treated that reliable measurements and credible diagnosis of their origin can be given. (2) That if error occurs on account of imperfect restoration of the form and diameter of the corpuscles obtained from a stain proved by the guaiacum test, the spectroscope, and the production of haemin crystals to be blood, the error, if any, will be to make human blood appear like that of one of the inferior animals, and never to mistake the blood of the ox, pig, horse, sheep, or goat for human blood. (3) That in general when a stain has been proved to be blood by the above tests, it may be decided certainly whether it is or is not mammalian blood. So also a stain from the blood of the ox, pig, horse, sheep, and goat may be distinguished from human blood, thus confirming the claim of an accused person in many cases that his clothes are not stained with human blood. Lastly, the expert can say when the average of a suitable number of corpuscles from a blood stain corresponds with the average of fresh human corpuscles, that the stain is certainly not from the blood of the ox, pig, sheep, or goat, and in other cases he can say with great certainty that a given stain is not human blood.

SURGERY.

(405) The Treatment of Wandering Spleen by Enterostomy.

KOWWIK (*Wien. Klin. Wochenschrift*, October 24th, 1895), after referring to Kugelberg's recent paper, quotes two cases of his own in which this operation was performed about four years ago.

The first was a widow, aged 42, who had been compelled by her illness to give up her occupation, that of a washer-woman. Her chief symptoms were abdominal pain and vomiting. A tumour was felt on the left side which, owing to splenic dulness being obtained in the right place, was supposed to be a floating kidney. A lumbar incision having been made for the performance of nephrotomy, the kidney was found in place, and the tumour having been pushed into the wound was discovered to be a slightly enlarged spleen. It was fixed in the incision with some little difficulty, the Paquelin cautery being required for the hemorrhage. The wound was plugged and allowed to granulate up. There were no complications; the patient was kept in bed seven weeks from the operation. Complete recovery and disappearance of the symptoms resulted, and the woman was well at the time of writing, in spite of the unanatomical position of the spleen. The other case was that of a married woman of 38, who was admitted soon after an abortion. There was complete prolapse of the uterus and vagina, and a well-marked cystocele. Behind the uterus was a firm but movable tumour, half as large again as a man's fist, which kept up the displacement. After the Thure-Brandt treatment had been tried in vain splenectomy was performed. Unfortunately, owing to the tympanites and vomiting, the plug had to be removed on the sixth day for fear of the intestine being caught in. The result was that the spleen came down again after a few months; this result was not unexpected owing to the great laxity of the peritoneal adhesions. The prolapse was operated on successfully, but reappeared after another pregnancy; it was not then too great, however, to be kept up by a pessary. The spleen remained deep in the iliac fossa, and could easily be reached *per vaginam*. Kouwer considers his operation simpler and much less dangerous than that of Rydygier.

(106) Pathogenesis of Myopia.

BIRROS (*Annales d'Oculistique*, October, 1895) has been investigating this subject. He finds that a sclerotic crescent or ring exists, not only in myopia but in almost all cases of ametropia, and may be bordered by a crescent or ring of pigment, but in hypermetropia it never entails any choroidal atrophy; astigmatism does not appear to influence the direction of the crescent but accelerates its evolution. There must be 5 dioptres or more of myopia before pigmentary changes occur in the macular region. In myopia the globe not only lengthens antero-posteriorly, but increases in size in all diameters. The choroid is not so elastic as the sclerotic, and hence cannot stretch so much, but becomes detached from the optic patella and thus exposes a crescentic portion of the sclerotic. The choroid has only a slight attachment to the papilla by fibres which traverse it in the lamina cribrosa; therefore, when the choroid ceases to stretch, it

is this attachment which first gives. If the myopia progresses, the separated choroidal border undergoes atrophy and macular changes occur. The crescent is usually external, because, the disc being taken as the *point d'appui*, there is a greater surface of choroid external to the disc exposed to the intraocular pressure. In somewhat rare cases the crescent may be above, below, or to the inner side of the disc—explainable on the supposition that the disc and the posterior pole of the eye are not in their usual relative position. He explains the increased intraocular pressure, before which the sclerotic and choroid stretch, as resulting from excessive near work, it being well known that the tension of the eye increases during accommodation. He thinks the sclerotic at the posterior pole of the eye participates in the inflammatory atrophy of the overlying choroid, and thus accounts for the posterior staphyloma. If this increases in size, the external sheath of the optic nerve becomes detached. Myopia is ordinarily arrested at 25 years of age, by which time the development of the organism has taken place. General ill-health and debility, by weakening the firmness of the sclerotic, predispose to myopia.

(107) Fatal Fat Embolism after Forebleb Straightening of both Knee-joints.

AHRENS (*Bruns' Beitr. z. klin. Chir.*, xiv., 1), reports this case. A woman, aged 53, had ankylosis of both knee-joints in a right angle position. This was to a great extent corrected by continuous extension. Afterwards, under ether, they were completely straightened, very little force being used. Two days later the patient became drowsy, and died the next day. *Post mortem* an extensive fat-embolism of the lungs was found. On the ends of the bones forming the joints, which were in a state of advanced osteoporosis, there were recent crushes and depressions. Two analogous cases have been reported from Halle and Marburg. It follows that this proceeding is not so devoid of danger as is usually supposed. It is suitable only for recent cases where but little force is necessary (these usually yield to extension), and is altogether contra-indicated in chronic cases where one must suspect fatty degeneration of the bones or muscles.

(108) The Surgical Treatment of Laryngeal Tuberculosis.

RÉTTEI (*Wien. klin. Woch.*, Oct 17th, 1895) holds that on this question statistics do not always form a reliable guide. He relates two cases indicating opposite sources of error. The first was that of a woman, aged 27, with extensive tuberculous disease of both lungs, tuberculous infiltration of the interarytenoid mucous membrane, ulcers on the posterior ends of the vocal cords, and almost complete aphonia. Réttei declined to operate, and symptomatic treatment only was adopted. The laryngeal condition cleared up to a large extent, and the patient recovered her voice almost completely. The improve-

ment persisted for some months; then a fresh laryngeal attack came on with oedema of the lungs, proving fatal in ten days. Had this case been operated upon, the temporary cure would no doubt have been put down to the treatment. The other case was that of a man, aged 34, with tuberculous infiltration at both apices. He had considerable infiltration of the interarytenoid mucous membrane, slight thickening of the right vocal cord, and affection of the epithelium of the right processus vocalis and the adjoining part of the right arytenoid cartilage. Curettage was practised for some days; a spreading ulcer resulted with no tendency to heal. Dysphagia came on with violent paroxysms of coughing, the lung troubles made rapid progress, and the patient died in six weeks from the commencement of the treatment. Here it is, of course, difficult to say what would have been the event if the patient had not been curetted, but Réttei believes that the fatal issue was hastened by the treatment. He considers that operative interference should only be undertaken when the lung process is either not advanced or has been stationary for months, and when the laryngeal affection is more or less localised; there must either be a prospect of benefiting the patient's condition, or danger in delay from threatening dyspnoea or dysphagia. Operation is contraindicated: in advanced or rapidly-advancing lung disease; if there is no imminent danger from the laryngeal condition; if there is high fever, or if the laryngeal disease has so far advanced as to have involved the deep as well as the superficial structures. The first case shows that amelioration may occur in the larynx even when the lung affection is very severe; the second that surgical interference may at times hasten the morbid process, not only in the larynx but in the lungs as well. The value of statistics is much discounted unless these indications are adhered to; thus some operators record successful results in two-thirds of their laryngeal operations, but include many cases in which curettage was unnecessary. Through such statistics it is easy to be led into operating on unsuitable cases to the danger alike of the patients and the method.

MIDWIFERY AND DISEASES OF WOMEN.

(109) Influenza and the Female Generative Organs.

MÜLLER (*Munch. med. Woch.*, October 8th, 1895) analyses from this point of view, 157 cases occurring in women. He first discusses the effects of influenza upon pregnancy illustrated by 21 cases. Of these 21, 2 were near the end of pregnancy, 1 in the eighth month, 1 in the sixth, and the remaining 17 in the first to fifth month. Of the 17, abortion occurred in 15. Of the remaining 4, the pregnancy was uninterrupted in 1, miscarriage was undoubtedly due to the influenza in another, but in the other 2

it was impossible to state positively the relation of the influenza to the delivery. In 1 of these cases the patient was seized with fever the day before delivery, and later the pains came on. The infant appeared premature, and its birth was not expected for a fortnight. In the other case birth occurred a week before the expected time, but the foetus appeared fully developed. In the case in which pregnancy was uninterrupted, abortion had occurred during an attack of the disease in a previous epidemic. In the other 15 cases, the author thinks that the abortion was due to the influenza. Thirteen of these patients he saw then for the first time, but the remaining 2 had previously been under his treatment (one for retroflexion and the other for cystitis). Both these last patients had endometritis, but they were looked upon as cured. There was no evidence of disease of the appendages in these 15 cases. It was very striking that at the same time as the onset of the influenza, or shortly after it, the pains or hæmorrhage appeared. Protracted blood-stained lochia were often observed, without there being any evidence of anything being left behind in the uterus. Among the 138 non-pregnant women, all with the exception of 3 had either menorrhagia or metrorrhagia, or an already existing local disease was made worse. The author says that, as in cholera, typhoid fever, measles, scarlet fever, etc., a hæmorrhagic endometritis may occur in influenza, causing bleeding or the interruption of pregnancy.

(410) Radical Hysterectomy for Cancer.

CLARK (*Bulletin of the Johns Hopkins Hospital*, July to August, 1895) believes that this operation has proved unsatisfactory because the broad ligaments are cut too close to the uterus, and the vaginal tissue adjacent to the cervix is not freely removed. The risk of injury to the ureters has been neutralised by Kelly's practice. He introduces bougies into the ureters in all operations where those ducts may be involved. The prethra is first anaesthetised with cocaine, and a urethral bougie is passed with the aid of a urethral speculum (about No. 8). Clark insists on another precaution. The ureter being made secure during the operation by the presence of a bougie in its canal, the layers of the broad ligament are opened up, and the uterine artery being found, it is dissected out up to its origin and tied. The course of the operation is as follows: (1) catheters are passed into ureters; (2) abdominal incision; (3) upper part of broad ligament is tied off so as to secure the ovarian artery; the vesico-uterine peritoneum is divided horizontally, and the bladder pushed down. Then the layers of the broad ligament are spread apart so as to expose the uterine arteries; (4) the uterine artery is dissected out and tied; (5) the ureter is dissected free in the base of the broad ligament; (6) the remainder of the broad ligament is tied close to the iliac vessels and cut away from its pelvic attachment; (7) the dissection is carried well down below the cancerous

area, even though the cervix alone seems to be involved; (8) the same manœuvres, 3 to 7, must be carried out on the opposite side; (9) the vagina is perforated with sharp-pointed scissors; firm traction is made on the uterus with a small volsella so as to pull up the vagina and make tense its walls; then the tissues are tied in small segments, about a third of an inch, each segment being cut as it is tied. (10) Iodoform gauze is inserted from above into the raw space left by the hysterectomy; the vesical and rectal peritoneum are united over the gauze by means of a continual fine silk suture. (11) The pelvic cavity is irrigated and the abdomen closed without drainage. This operation has twice been performed, both patients recovering; but the first is as recent as April 26th this year, and, unfortunately, a cancerous deposit developed two months later in the rectum. The proceeding allows, it is evident, of very free excision of the structures surrounding the uterus.

(411) Fatal Jaundice in Pregnancy.

DEMELIN (*Répertoire Univ. d'Obstét. et de Gynéc.*, September 25th, 1895), publishes three cases of marked jaundice during pregnancy, two ending fatally. In the first case jaundice appeared at the fifth month, the temperature was subnormal, no external hæmorrhages were seen, and there was no albuminuria. At the end of ten days nervous symptoms set in. Abortion was induced, but the patient died. In the second case icterus continued for several months, and repeated multiple hæmorrhages occurred. No albumen was found in the urine. Nerve symptoms set in, and death followed spontaneous delivery at the eighth month. The case which recovered was remarkable on account of the presence of albumen and also blood in the urine, a symptom not observed in the fatal cases. There was at first nervous disturbance, indicating the onset of eclampsia, as well as hæmorrhages. The jaundice lasted but a short time, and both mother and child recovered. No fits actually occurred, and all nerve symptoms were absent when the jaundice began to clear up. Demelin holds that the uterus should be emptied of its contents as quickly as possible before neuroses set in.

(412) Perforation of Uterus by a Degenerate Fibroid.

RICHELOT AND TOUCHER (*Bulletins et Mémoires de la Soc. Obstét. et Gynéc. de Paris*, No. 8, 1895) report this case. A woman, aged 43, not pregnant for seven years, had for the first time profuse menorrhagia in May, 1893. Large clots passed. In June the symptoms recurred. Early in July a tumour was discovered by a physician. After rest the free metrorrhagia ceased. Temperature was normal. A fluctuating mass filled the flanks and hypogastrium, reaching as high as the umbilicus. The uterus, on vaginal examination, seemed normal below, but was clearly connected with the tumour. The fornices were free. On opening the abdominal cavity, a soft reddish mass

was found firmly adherent to the parietes as low down as the true pelvic cavity. The fundus uteri was exposed, and a perforation about 2 inches in diameter discovered. The spongy mass protruded through the perforation, the edges of which constricted the mass. Internally another part of the mass was found lining the true uterine cavity. All the morbid growth was removed, the uterine cavity cleaned, and the edges of the perforation sutured to the abdominal wall. The cavity formed by the extraction of the uterine portion of the growth was drained. The growth was a degenerate uterine myoma. The cavity was dressed with iodoform.

THERAPEUTICS.

(413) The Serum Therapeutics of Tetanus.

NOCARD (*Bulletin de l'Acad. de Médecine*, October 22nd, 1895), points out that the difference in the value of this treatment as applied to diphtheria and tetanus depends upon the evanescence of the immunisation. In the former a local lesion precedes the general poisoning, and one can intervene before the intoxication has become general; in the latter the first symptoms of the disease are those of general intoxication, when it is already too late for treatment. The efficacy of antitoxic serum depends directly upon the speediness with which its injection follows the introduction of the pathogenic microbe or its products. If an animal is poisoned by strychnine, tetanic convulsions come on almost immediately; after the introduction of tetanus toxin no convulsions appear—even with a five-fold fatal dose—for twenty to thirty hours or more. In the meantime the poison has no doubt been exerting its specific action on the cells of the animal, so that the injection of tetanus antitoxin at the time of the appearance of convulsions is useless, even when accompanied by excision or amputation of the part into which the toxin has been introduced. Nocard, therefore, considers that we must, for the present at any rate, abandon the hope of curing an established case of tetanus, since the injection of antitetanic serum has but little influence on the course of the disease. If one could, however, foresee which wounds would be likely to give rise to tetanus, prophylactic inoculation would undoubtedly be of great service. It might be used, for instance, in countries where umbilical tetanus kills 20 to 40 per cent. of newborn children, or in the New Hebrides, where wounds by the arrows of the aborigines are speedily followed by tetanus. Even in France the preventive treatment is being used by many surgeons in the case of certain wounds—by firearms, machinery, rusted, or when fouled by cultivated earth—likely to cause tetanus. A still more promising field is that of veterinary surgery, where tetanus so often follows the minor operations of docking, castration, docking, etc. Nocard has, since December, 1894, distributed antitetanic

serum to 26 veterinary practitioners, who have employed it in 375 operations, no animal developing tetanus, while among unincubated animals no fewer than 55 cases of tetanus appeared. All the operators agree as to the great diminution of the disease resulting from the preventive treatment. Details and a table are given, and the author feels justified in concluding that if the curative treatment of tetanus is yet to seek the incidence of the disease can be greatly diminished by prophylactic methods.

(414) Camphorated salol.

JOHN T. BOWEN (*Boston Med. and Surg. Journ.*, September 19th) states that Eisenburg has used this preparation in various cutaneous affections for two years, and has found it of special value in furuncles and carbuncles. It is prepared by moistening 1 part of camphor with a few drops of alcohol, rubbing this in a porcelain mortar with 1.4 part of salol until a transparent liquid is obtained. A change takes place in from twelve to twenty-four hours; the pain diminishes, the redness and inflammation of the adjoining parts disappear, and the tumour becomes progressively smaller, without the formation of pus. As a rule the secretion obtained from the vesicle at the point of the furuncle yields a pure culture of the staphylococcus aureus on nutrient media, as do also bits of the infiltrated tissue. After camphorated salol has been used for twenty-four hours no such cultures can be obtained. When suppuration has already taken place in the furuncle, and after the slough has been removed, the pain and hyperemia may be much lessened by the application of the camphorated salol, and the suppuration diminished. The healing process then advances quickly, a slight discoloration and some infiltration being left only for a short time. The method of using the drug is to lay bare the point of the furuncle, or, in the case of carbuncle, to make several moderately deep incisions in order to facilitate penetration into the infiltration; afterwards the lesion and the surrounding hyperemic parts are covered with cotton compresses soaked in camphorated salol, and an impermeable covering is placed outside.

(415) Aïrol.

VEIEL (*Wien. klin. Rundschau*, October 20th, 1895) gives the results of his experience with this antiseptic in a paper read before the recent German Dermatological Congress. Aïrol is a compound containing bismuth, gallic acid, and iodine; it is a green powder, tasteless and odourless and insoluble in water, spirit, or glycerine. Veiel first used it in the treatment of ulcers of the leg; these rapidly became painless, and their secretion diminished to an extraordinary degree. The granulations became much firmer, and showed none of the tendency to overgrowth which is so common with iodoform; inflammation of the neighbouring skin, which is sometimes seen with iodoform and less

often with dermatol, was absent with aïrol. This latter is therefore strongly recommended in ulcers of the leg, particularly when complicated with eczema. Veiel has also found it most serviceable in the treatment of ingrowing toenail with dermatitis repens and of small wounds, both fresh and infected; in the latter its disinfecting power appears to be greater than that of iodoform. The obstinate fissures of the nostril accompanying syphilis of the upper lip, which so often lead to erysipelas, heal rapidly under the influence of aïrol ointment (10 per cent.). Lupus ulcers skin over very rapidly, but aïrol has no specific action on the disease any more than iodoform has. Other special uses are in the treatment of primary syphilitic sores and the ulcers of mercurial stomatitis. Veiel concludes that aïrol is in many cases superior to iodoform, in that it is inodorous, non-poisonous, and non-irritant, while at the same time it greatly diminishes the secretion.

(416) On the Use of Nitrite in Infective Diseases.

PETRONI (*Rif. Med.*, August 31st, 1895) found that rabbits inoculated subcutaneously with rabies lived as long again after hypodermic injections of sodium nitrite. The author has also tried the same treatment in 2 cases of syphilis, with good results. The first case was that of a man suffering from marked malarial cachexia and enlarged spleen, who contracted syphilis in December, 1893. During the early manifestations he took mercury and pot. iod., but as soon as the symptoms disappeared he ceased taking medicine. In March, 1894, he suffered from marked nocturnal osteocephalic pains, periostitis of the skull and tibia, and abundant papulo-pustular syphiloderma. Five to ten grains of sod. nitrite, rapidly increased to 50 gr., were injected daily in two doses. The nocturnal pains were relieved on the second day, and the rash and periostitis gradually disappeared, so that at the end of a month the patient was able to work and in much better health in every way. The second case was that of a woman, aged 22, suffering from hereditary syphilis, which had first developed ten years before, and been treated with pot. iod. and mercury. When admitted to hospital in April, 1895, she presented loss of bony substance over an area equal in size to a 5-franc piece on the right frontal bone and on the left parietal, confluent ulcerating gummata in the left dorsal region, gummata on the thigh, and very extensive ulceration of the left leg. The same treatment—50 gr. of sod. nitrite in two divided doses daily—was practised here, and the ulcers merely cleansed with boracic solution. After twenty-six days the sores were almost all healed. Treatment was then interrupted for a few days by an attack of acute bronchitis. On resuming the injections the patient was cured in another ten days and her general health much improved. No local troubles or general symptoms followed

the injections. The solutions should not be more concentrated than 2 or 3 per cent.

PATHOLOGY.

(417) Bacteria in the Urine in Typhoid Fever.

BAART DE LA FAÏLLER (*Bacteriurie bei Febristypheiden*; *Inaug. Dissert.*, Utrecht, 1895) investigated the question whether the possible recognition of typhoid bacilli in the urine could be used in the diagnosis of doubtful cases of typhoid fever. Since the *B. coli communis* is often present in the urine, the investigation necessarily included the differential diagnosis of these two bacilli. From a careful consideration of recorded cases the author believes he can draw the conclusion that the presence of *B. typhoides* in the urine is almost invariably associated with albuminuria, and frequently with acute nephritis. The author examined the urine of twenty-seven patients, during and after the disease. In the greater number of cases the diagnosis had been established clinically before the bacteriological examination was made; in some the diagnosis was made later in the course of the disease. The author was not fortunate enough to assert, bacteriologically, the existence of typhoid fever before it had been made clinically. The urine was obtained aseptically centrifugalised, and of the sediment gelatine and agar plate cultures were made. If colonies like those of *B. typhoides* or *B. coli communis* made their appearance, they were examined as to shape, motility, indol reaction in culture media, gas formation in media containing sugar, and coagulation of milk. In four of the twenty-seven cases bacteria were found which in no respect differed from the typhoid bacillus; in four other cases bacteria resembled the *B. coli communis*. In the remaining cases different other bacteria were found. The author is uncertain whether all the negative signs (absence of indol reaction, of gas formation, of power to coagulate milk) used to establish the existence of the *B. typhoides* may not possibly refer to a variety of the *B. coli communis* present before the disease commenced in the organism; if this be the case, then bacteriological examination of the urine in this disease would be useless as a diagnostic method. After examining varieties of *B. coli communis* from healthy and sick persons with great care, the author comes to the conclusion that in the four cases mentioned above he had to deal with true typhoid bacilli. Bacteriological examination of the urine suspected of typhoid fever may aid the diagnosis, though the probability of establishing it by this alone is small. No relationship was found to obtain between the numbers of bacteria and the amount of albumin. The author finds that a number of bacilli, including *B. lactis aerogenes* and *B. acidilactici*, are identical with or only varieties of *B. coli communis*.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(418) Subdiaphragmatic Abscess following Gastric Ulcer.

WITTHAUS (Therapeut. Monatsheft., October, 1896) discusses the treatment of subdiaphragmatic abscess following perforation of a gastric ulcer, where the diagnosis is difficult owing to the obscurity of the symptoms. He records two such cases: (1) A man, aged 47, subject to epigastric pain for several years, was able to follow his usual occupation till six days before coming under observation. He then complained of some pain in the epigastrium, and felt ill; slight dulness at bases of lungs with feeble breath sounds; abdomen distended, no tenderness; liver dulness normal; temperature normal. Cancer of stomach diagnosed. Three days later there was dyspnea; dulness at right base had increased; slight rise of temperature. These signs increased, and death ensued three days later. Necropsy showed perforated gastric ulcer, with subdiaphragmatic abscess and right pleural effusion. (2) A woman, aged 25, had suffered from epigastric pain several years. The day before she was first seen, she had suddenly been seized with pain in the abdomen while lifting a heavy weight. Next day no signs of collapse; temperature and pulse about normal; abdomen flaccid; slight tenderness over liver; lungs normal; complained of severe abdominal pain. Three days later slight rise of temperature, which subsequently persisted, though irregular; pulse became more rapid, and dulness developed at both bases. Exploration with needle in 11 places gave no result, except a little clear serum in pleural cavity. Fourteen days later stinking pus found in left pleura, but it was too late for operation, and patient died in a few hours. Necropsy showed perforated gastric ulcer with subdiaphragmatic abscess, communicating by a perforation in diaphragm with the left pleural cavity, which contained foul pus. In such obscure cases where there is a possibility of abscess beneath the diaphragm the free use of the exploring needle is advocated, and the importance of using a very long needle is insisted upon, the value of diagnosis outweighing any risk therefrom. Where, as in the second case recorded, there is reason to suspect perforation of a gastric ulcer, early laparotomy is recommended, even where peritonitis and collapse are not present to confirm the diagnosis.

(419) Association of Migraine with Neuroses.

KRAFFT-EHING (Neurol. Centralbl., Nov., 1896), points out the close connection between migraine and other neuroses. The cortical disturbance which produces migraine may extend, and so

produce other neuroses; thus hemianesthesia, functional motor paralysis, aphasia, or alenia may result. In two cases he has observed mental disturbance; in one hallucinations and loss of memory occurred immediately after an unusually severe attack of migraine, and were followed by a condition of stupor lasting thirty-six hours; gradual recovery took place. In the other, each attack was associated with manic symptoms lasting about a hour and a half, the patient having no remembrance of the attack when it was over. In both these cases there was typical migraine with teichopsia; both patients were males, and had suffered from migraine several years before the mental symptoms developed. Migraine is not to be regarded as a special form of epilepsy or of hysteria, but either of these may replace it.

(420) Gangrene after Enteric Fever.

QUERVAIN (Centralbl. f. inn. Med., August 17th, 1896) observes that gangrene is one of the rarest complications of enteric fever. The embolic character of the lesion has been proved in several cases in which clots have been found in the left heart. Spontaneous thrombosis arising from the condition of the blood has been maintained by some. It has also been shown that an arteritis occurring in enteric fever may be of bacterial origin. Typhoid bacilli have been found in cardiac vegetations. The author relates the following case in a man aged 25. At the beginning of defervescence the patient had severe pain in the leg. When he was seen by the author, the lower part of the leg was cold, almost entirely anesthetic, and the site of severe neuralgic pain. There was no pulsation in the popliteal artery. The region of the popliteal space was painful on pressure, and slightly cedematous, but there was no cedema over the foot. No movements were possible in the toes or foot. Seven days after the onset there were all the typical features of gangrene due to obstruction of the popliteal artery. Three days later slight cedema was noted in the other foot. Twelve days after the onset it was found necessary to amputate the leg just above the knee. The hemorrhage during the operation was uncommonly small, although no Esmarch's bandage was used. The patient made a good recovery, although a localized gangrene occurred in one of the flaps. A clot was found in the popliteal artery, and the popliteal vein was also thrombosed. Just above the level of the joint the sheath of the vessel was cedematous, the artery, vein, and nerve forming a thick cord embedded in an intramuscular abscess. Typhoid bacilli were found in the pus, but no strepto- or staphylococci. No changes were present in the vessel wall, and there was no trace of periarteritis or phlebitis but unfortunately the vessel was not examined in the region of the abscess. The clotting may have been due to (1) a deep phlegmon caused by the typhoid bacillus, and thence the damage to the arterial and venous walls;

(2) phlebitis caused by the typhoid bacillus, and then periarteritis with abscess and a secondary arteritis with clotting; or (3) a primary arteritis due to the typhoid bacillus, then arterial thrombosis and a secondary periarteritis, phlebitis, and abscess. It is impossible to say absolutely which was the cause, but the author inclines to the third supposition. The case is interesting inasmuch as it proves that typhoid bacilli were present in pure cultures in the neighbourhood of the thrombosis. Therefore the thrombosis here was not due to typhoid toxins nor to miasmata, but it owed a direct infective cause in a metastasis of the typhoid bacillus. It was combined with phlebitis of both lower extremities. Amputation was not contraindicated even in the embolized state of the patient. The condition of the vascular system must be taken into account in such cases, and Esmarch's bandage avoided.

SURGERY.

(421) Lung Surgery.

In opening a discussion on the Surgery of the Lung at the Ninth French Congress of Surgery, Reclus (Ann. Med., October 23rd, 1896) stated that at the present date the pulmonary affections indicating surgical intervention may be arranged in three groups: the first of hemorrhages, traumatic and pathological, capable of being arrested by ligature; the second of tumours, represented by cancerous growths; and the third of cavities, containing fluid or broken-down tissue, such as tuberculous vomice, bronchial dilatations, circumscribed gangrene, abscesses, and hydatid cysts. With regard to cases of traumatic hemorrhage, notwithstanding the bad results in the rare instances in which such treatment has been applied, and the intense shock likely to be thus caused, Reclus thinks that when the bleeding persists and threatens to bring on fatal syncope, or by the accumulation of blood in the pleura to arrest the movements of the heart or the injured lung, it might be advisable to make a large opening in the thoracic wall in order to expose the wound and to stop the flow of blood either by the application of a ligature or by plugging with gauze. Aspiratory puncture of the lungs in cases of pulmonary apoplexy has not afforded more than temporary relief. Pneumostomy for tuberculous, it is held, has been ineffectively condemned, as it can be practised with any chance of success only in cases which might prove amenable to medical treatment. Resection is opposed also to surgical intervention in cases of cancer. He grants that in cases which, however, are very exceptional - of malignant growths extending from the thoracic wall to the lung, extirpation of the invaded parenchymatous structure might be permissible, but, at the same time, he thinks that abstention from such treatment would in most instances be preferable. Extirpation of primary cancer of the lung should, he holds, be

positively abandoned. If the tumour be a single and small one it will probably reveal no sign of its existence; if it be large, diffused, and multiple, an operation would inevitably be fatal. Surgical treatment should, it is argued, be applied only to exceptional cases of tuberculous vomice and dilated bronchi. In either of these affections, when the patient has overcome the risks of an operation which is always formidable to the cachectic, and has begun to experience the benefits of drainage of the cavity, the primary malady is still progressive and pneumonotomy, if it has not hastened death, has only retarded it. On the other hand, when the pulmonary excavation constitutes the essential lesion, when the symptoms of putrid absorption predominate and excite much fever, and when the patient suffers much from cough and is exhausted by the abundant expectoration the surgeon, it is acknowledged, may have recourse to pneumonotomy, not in the vain hope of cure but simply to afford some relief. Reclus has been convinced by recent statistics that pneumonotomy is really very beneficial, and, indeed, the treatment of election in cases of hydatid cyst of the lung. This operation is also indicated in those cases of pulmonary gangrene in which the cavity, though distinctly circumscribed, is large, and when there are symptoms of poisoning by its retained putrid contents. In cases of abscess of the lung also the results of surgical intervention have been very favourable, Reclus having met with complete success in twenty out of twenty-three cases. The prognosis of pulmonary abscess, it is pointed out, depends on the primary affection. Pneumonia is the most frequent cause of the localised suppuration, and surgical treatment in purulent collections of this organ has been attended with a large proportion of good results. In the performance of pneumonotomy the incision of the skin and muscles, made in the shape of a U, an H or a T, according to the choice of the operator, should allow of free exposure of the ribs. The surgeon should give himself full access to the pulmonary cavity and lay it open to an extent permitting rapid and complete deteration. Moreover, free removal of the osseous wall of the thorax favours contraction of the cavity and apposition of its walls. In order to prevent serious hemorrhage Reclus uses in opening the cavity a thermo-cautery just heated to a dark red colour. The opening thus made can afterwards be enlarged by introducing the finger. Failure of an exploratory puncture need not contraindicate pneumonotomy. Even though the surgeon may fail after resection of one or more ribs to find pus the operation will not be less profitable. The cavity which has been missed will, as has been proved by abundant experience, ulcerate or break through the walls at this point of least resistance. The cavity when opened should be carefully and freely drained. Reclus is strongly opposed to the use of injections. In one reported case, he states, the injection of a solu-

tion of boric acid and thymol was followed by fatal inflammation of the air passages. At this meeting further valuable contributions to lung surgery were made by Péan, Bazy, Tuffier and other surgeons, abstracts of which will be given in future numbers of the EPITOME.

(422) A Novel Application of Tendon Grafting.

MILLIKEN (*Med. Record*, October 26th, 1895) describes a new operation for deformity following infantile paralysis, and reports a case in which a healthy muscle has been made to do the work of one which was completely paralysed, without in any way interfering with its own function. The patient was a boy 9 years of age, who for seven years had been lame, in consequence of "drooping" together with extreme valgus of the right foot. The author having made out that this condition was due solely to paralysis of the tibialis anticus, performed the following operation: An incision one inch and a half in length was made, extending from just below the annular ligament obliquely over the tendons of the extensor proprius pollicis and tibialis anticus. The sheath of each tendon was carefully opened for a distance of about an inch. The tendons were then split with a small fascia knife, and an inch flap partially detached from each. The flap from the tibialis anticus was left attached to the distal, whilst that from the extensor of the great toe was attached at its proximal or muscular, end. The cut surfaces of the flaps were adjusted and sutured with three fine kangaroo tendons. This operation proved successful as the patient, it is asserted, is now quite an expert on roller skates, walks without a limp, and can adduct the foot to almost the normal extent.

(423) A New Treatment of Keratitis with Hypopyon.

ZIRM (*Wien. klin. Woch.*, October 31st, 1895) refers to the intractable nature of infected corneal ulcers; he considers pus in the anterior chamber to be an invariable result of septic inflammation of the cornea. The ulceration usually begins quite superficially, and the hypopyon forms an index of the penetration of the micro-organisms into the deeper structures. It is well known that these organisms, particularly staphylococci, have great power of resistance to antiseptics, surviving even the application of 1 in 1,000 corrosive sublimate. Hence stronger measures, such as scraping, excision, and the actual cautery have been adopted for their destruction. Even these have met with but variable success, and where they have stopped the disease they have often been the cause of irreparable damage to the cornea. Zirm has often noticed that the good done in the effort to overcome the disease has been more than counterbalanced by the injury resulting from the means employed. He instances the secondary glaucoma resulting in many cases from Saemisch's method of para-

centesis, for which he himself has substituted the older operation of lancet puncture, except in the case of interlamellar abscesses. The new treatment for corneal ulcer with hypopyon is the use of a 1 per cent. solution of silver nitrate. Zirm discovered the value of this in an intractable case, which had only got worse under daily and nightly washing out with sublimate. He found that touching some warty granulations of the conjunctiva with the AgNO₃ solution resulted in great general improvement; continuance of the treatment led to rapid healing of the ulcer, the cornea being left in better condition than he had ever seen after a similar case. He gives notes of in all seven cases which he has treated by this method, all of which made speedy and complete recoveries, often after all other means had proved unavailing. Leber has shown that disturbance of the growth of pathogenic cocci in the conjunctival sac puts an end to their penetration into the deeper tissues. Zirm believes that his method inhibits their multiplication in the sac, and so leads to a natural healing of the ulcers without fresh loss of substance; and that all the hitherto adopted energetic operative and antiseptic measures will now be given up as dangerous. He claims the following advantages for his procedure: (1) No new disturbances are introduced; (2) further progress of the disease is at once cut short; (3) An ulcer allowed to heal naturally terminates favourably; (4) the method is extremely simple; and the course of the disease rendered shorter and much more favourable thereby.

MIDWIFERY AND DISEASES OF WOMEN.

(424) New Pulse in Childbed.

NEUMANN (*Monats. f. Geburtsh. u. Gynäk.*, October, 1895) has studied with great care this interesting phenomenon, and publishes full observation of the pulses of 500 women in childbed, with tracings. Amongst the theories on the subject, he remarks, are some which deserve consideration. According to Biot and others, bradycardia in the normal puerperium is due to increased arterial tension and blood pressure owing to the sudden diminution of the uterine circulation. Olshausen traced it to absorption of fat from the degenerate uterus. Löhlein believes in disturbed innervation owing to an altered constitution of the blood. Swiecicki traces this alleged disturbance to chemical irritation of the uterine nerves as part of the process of involution. This irritation in turn influences the vagus. Fritsch simply attributes the bradycardia to the mental and physical rest involved in normal labour. Schröder believes that, after the suppression of foetal circulation, the maternal heart, having less to do, contracts more slowly. Vejas refers the phenomenon in question to increased vital capacity of the lungs. Neumann concludes that puerperal bradycardia depends on stimulation of the cardiac

inhibitory fibres, and arises through irritation of the vagus centre during labour.

(403) The Female Pelvis in "Primitive" Races.

STRATZ (*Niederl. Tijdschr. van Verlosk. en Gynaecol.*, 6th year, Part I, 1895) has investigated a series of cases in Java, in order to test the accuracy of certain theories in respect to the relative characters of the pelvis in European and in barbarian or semi-civilised women. Zaayer, of Leyden, declared twenty years since that the Javanese pelvis was unusually round at the inlet. Stratz rightly reminds obstetricians that this theory was based on the examination of a few macerated pelvises. He therefore carefully measured a large number of pelvises of Javanese women living up country. Two races were included in his series, the more primitive being darker, more slender, and smaller. The measurements showed little or no difference more than could be explained by the small general proportions of one of the races. The same may be said of the difference between the average Javanese and European pelvis. As it happens, however, the theory of Zaayer seems substantially correct, the transverse measurement of the Javanese pelvis being, on an average, relatively small. The obstetric teacher should further bear in mind that Stratz found plenty of contracted pelvises amongst these "primitive" women, who, escaping the "evils" of civilisation, do not enjoy its benefits.

(404) Suprapubic Lithotomy in Pregnancy. ROSENFIELD (*Munch. med. Woch.*, No. 39, 1895) describes a fatal case of this kind. The patient was 27.5 months pregnant. There was acute cystitis, and much pus passed. The gravid uterus was high up and ante-flexed. A large calculus filled the bladder. Though the patient was very ill and feeble, lithotomy was held to be necessary at once as retention of urine gave great trouble, uræmia threatened, and pain was severe. The patient was placed in Trendelenburg's position. A solitary calculus was removed; it weighed 4½ ounces, and measured 2½ inches in its longest diameter. Abortion followed forty hours later; the fetus was nearly 8 inches long. The mother died on the third day of pneumonia. Hydronephrosis and pyelonephritis existed on both sides, and the right ureter was dilated. No glandular tissue remained in the left kidney; compensatory hypertrophy had occurred in the right.

(405) Abdominal Section for Puerperal Septicæmia.

BALDY (*Amer. Jour. Obstet.*, July, 1895) writes that 19 cases of hysterectomy during the puerperium have been reported by American operators, with 7 successes. Although some of the successful cases might, he thinks, have recovered without the operation, a careful study of the reports indicates, in his opinion, that quite the reverse is probable. The list does not include

hysterectomies, in which a distinctly circumscribed collection of pus existed in a sac. Baldy reports 4 cases, all fatal; distinct specification of the stage of pregnancy is not given in his paper. Six out of the remaining 15 were performed after abortion with only 1 recovery, whilst 9 were performed after normal delivery, with 6 recoveries. In 5 of these cases the uterus was suppurating when removed; in the sixth there was diphtheritic endometritis. Baldy holds that if any good is to be accomplished the earlier the hysterectomy is performed the better. In 2 of the 6 successful cases performed after delivery, however, the operation was not done till the end of the second week. In 2 more it was undertaken at the end of a month. In the remaining 3 the hysterectomy was carried out on the fifth day. In the 3 fatal cases the operation took place within the first week, on the fifteenth day, and at the end of a month respectively. This does not exactly support early operation, but further experience—should such experience be held justifiable—is needed.

(406) Triplet Labour: Acardiac Twin.

FREUDENBERG (*Der Frauenarzt*, August, 1895), in a statistical paper on midwifery in Cologne, records a case of delivery at the sixth month in a multipara. There was hydramnion, causing extreme abdominal distension. Pains set in, and over 10 pints of liquor amni escaped. Severe flooding ensued, and labour had to be hastened. By aid of the sharp hook a very oedematous male infant was extracted, though not without extreme difficulty. A round body lay in the way. Hemorrhage continued, so labour was again hastened, the hand being introduced into the uterus; a second bag of membranes was ruptured, and a living female infant extracted with perfect ease. The round body remained. The sharp hook was once more used, and the body, which was thus extracted, proved to be an oedematous, ill-developed fetus nourished by the placenta with which the oedematous male fetus was connected. The uterus being emptied, the hemorrhage ceased. The patient passed through a normal puerperium.

(407) Uncontrollable Vomiting of Pregnancy.

BRUNET (*Der Frauenarzt*, September, 1895), has successfully treated uncontrollable vomiting in pregnancy by faradisation of the vagi before or after meals.

THERAPEUTICS.

(408) Apolyrin.

DR NURCKI AND DR JAWORSKI (*Poznań Med.*, October 28th, 1895) have studied apolyrin chemically, physiologically, and clinically. (1) *Chemistry*: It is really monophenetidin being allied to phenacetin, as they both are derived from parphenetidin. The difference between them is that in phenacetin one atom of H in the amide group is replaced by the radical of acetic acid,

while in apolyrin the same atom of H is replaced by the radicle C of citric acid. It is a crystalline, yellowish-white powder of peculiar odour and taste, less acid than citric acid. Its melting point is 72° C. It is soluble in cold water (1 in 25), alcohol, and glycerine, and in concentrated sulphuric acid without change of colour. The solution in nitric acid turns a pale orange colour; in hydrochloric acid, concentrated to 1 decigramme for 1 c.c.m. of acid, warmed and mixed with 10 volumes of water, it turns the colour of Burgundy wine when a few crystals of chromic acid are added. The aqueous solution is not clouded by silver nitrate, nor the acid solution by sulphide of hydrogen. (2) *Physiology*: It is not toxic. To prove this, experiments were made of injecting watery solutions (1, 4, and 8 per cent.) into frogs. These were perfectly borne, and none died. An injection of 3.5 g. of a 10 per cent. solution into a rabbit weighing 1.345 g. was followed by no marked symptoms. By experimenting on themselves as well as on animals—the authors found that the drug is eliminated partly in the urine as paramidophenol and parphenetidin. It has remarkable antipyretic properties. Experimentally it reduced the temperature in rabbits suffering from diphtheria and streptococcus poisoning. (3) *Clinical study*: The authors have given the drug as an analgesic and antipyretic, or simply as the latter in a large number of febrile affections (pneumonia, influenza, scarlet fever, etc.) and painful cephalalgia, migraine, neuralgia, etc.). In all the febrile cases the temperature was lowered 1° to 2° C., and did not rise again for three or four hours. The pain in neuralgia, etc., ceased after several doses, and most of these latter cases had been treated unsuccessfully with other analgesics. The doses used were from 0.50 g. to 3 g. *pro die*. Owing to its chemical constitution and solubility it acts more promptly and regularly than other drugs of the same group, and has no bad effects. It is contra-indicated in the fasting state and in gastric hyperacidity.

(409) The Serum Treatment of Diphtheria.

HARNER (*Deut. med. Woch.*, October 17th, 1895) first refers to the diminished death-rate from diphtheria noted in Berlin and other large cities since the introduction of the serum treatment. Since February, 1895, he has treated 177 cases with a mortality of 10.2 per cent., making a total of 230 cases with a mortality of 11.4 per cent. treated by him since May, 1894. Among 174 cases of pure diphtheria 110 came under treatment within the first three days; of these only 6 died, making a mortality of 5.3 per cent., a figure very slightly higher than Behring's prediction. The mortality in 174 pure cases was 5.6 per cent., and in 45 complicated cases 21.7 per cent. Among the 174 cases there were 11 infants under 15 months with only 1 death. Six had laryngeal obstruction, and 2 were tracheotomized with 1 death. Al-

though the diphtheria has been less malignant within the past year, there have been two periods when the type was severe. During these periods 68 cases were admitted, 53 being severe, but the mortality was only 13 + per cent. The local action of the remedy in throwing off the membrane is very generally admitted. This is an important matter in connection with laryngeal and descending diphtheria. Of the 174 cases 52 had laryngeal obstruction; 19 of these were intubated with 3 deaths, and 4 tracheotomised with 1 death. In regard to the effect upon the fever opinions differ, but since the fever of itself brings no danger the point is rather of theoretical than of practical value. In 1 case in which there was chronic nephritis the serum had no injurious effect on the kidneys. There is no single instance recorded in which it can be strictly proved that the serum is otherwise than harmless. There will still be cases against which even the most efficient serum will be powerless. The involvement of the larynx, trachea, etc., is of considerably less fatal significance now than formerly. In relation to the frequency of death from cardiac paralysis, the author shows that the supposed increase is merely relative and not absolute. Such deaths are really due to the insufficient action of the serum in severe toxic cases. The author speaks favourably of immunising those coming in contact with the disease. Although the effect may last only a short time the inoculation may be repeated. As regards the dose of the curative serum, Heubner uses larger doses now than formerly. He never employs local treatment owing to the distress which it causes the child. The throat is cleansed by frequent water drinking, or in older children, by gargling. The author concludes that the probability of a truly specific action of the serum becomes with every month's additional experience nearer to being a certainty.

(432) Serum Treatment of Malignant Disease.

EMMERICH and ZIMMERMANN (*Deut. med. Woch.*, October 24th, 1895) relate 5 additional inoperable cases treated with erysipelas serum. Increasing doses from $\frac{1}{2}$ to 10 c.cm. are given for four or five days until a reaction is produced; then an interval of four to eight days is allowed and a new course begun. The authors have often seen a considerable diminution in size, and even total disappearance of the growth. When threatening symptoms are present due to pressure, etc., they have even inoculated virulent cultures of the erysipelas coccus with good results. Case 1: A woman, aged 52, after three rapid recurrences of mammary carcinoma, was treated with the serum. In three weeks' time the tumour had considerably diminished in size, and the axillary glands were two-thirds their original size. Two months and a-half later the tumours were still of the same size. Thus a rapidly growing and inoperable carcinoma can be brought to a standstill, and may even diminish in size. The

terrible pain may also thus be relieved. The good effects still persisted four months after the commencement of the tumour. (2) An ulcerating and very extensive inoperable carcinoma of the breast ceased to grow and showed a considerable diminution in size. (3) A man, aged 40, had extensive epithelioma of the tongue and neighbouring glands. A radical operation was pronounced to be impossible, and the ulcerated parts were cauterized. Six weeks later the serum treatment was begun. As the case was very severe a virulent culture of the erysipelas coccus was injected into the tongue after a preliminary serum treatment. A mild erysipelas, without fever, spread over the neck. The improvement in the patient's condition was remarkable (the illustrations taken from this patient before and after the treatment are certainly very striking). (4) A man, aged 28, had within a very short period three recurrences of a very malignant spindle-celled sarcoma of the thigh. Four very extensive operations were performed, but hardly had the wound healed after the last one than a further recurrence appeared. A very considerable improvement resulted from the serum treatment; the tumour ceased to grow, and parts of it were reabsorbed. (5) An inoperable and rapidly growing sarcoma of the right cheek was brought to a standstill, and a very slight diminution in its size was noted. The authors say that in a number of cases of carcinoma they have purposely injected serum containing virulent erysipelas cocci, and they have thus seen more rapid effects than from coccus-free serum. In such cases no serious symptoms arose. The simultaneous injection of serum and erysipelas cocci cuts short the erysipelas processes, and one may even say that it guarantees a favourable course of the erysipelas. Only in one of several hundred injections have the authors noted any unfavourable effects. In Case III marked cyanosis, dyspnoea, palpitation occurred once from the serum entering a vein. This can easily be avoided by discontinuing the injection when the serum disappears from the syringe too readily. These symptoms soon passed off.

(433) Treatment of Tapeworm.

PROSPERO (*Sperimentale*, Anno 49, No. 26) speaks strongly of the value of pelletterine (an alkaloid prepared from the pomegranate) in the treatment of the two larger varieties of tenia. He administers it in doses of 20 cgr. of the sulphate (Merck) with 25 cgr. of tannin in syrup, to be followed by an aperient next morning. Extract of male fern is unreliable in its effects, may be poisonous, and is not easy to get pure. For the ankylostoma thymol is the best vermifuge. In one of the author's cases proglottides of the tenia medio-canellata were voided through the mouth, and that without any severe vomiting. The tenia in this case presented an uncommon pathological appearance in that several of the pro-

glottides were fenestrated in a scalari-form fashion. This peculiarity has occasionally been observed before, and is supposed to be due to the action of the intestinal juices on parts of the worm where the external protective coating has been worn off. Pelletterine is costly, but therapeutically it gave the best results in the author's hands.

PATHOLOGY.

(434) Parasitic Forms in Malarial Blood.

DANILEWSKY (*Centralbl. f. Bakt. u. Parasit.*, September 19th, 1895) describes certain parasitic forms hitherto unnoticed which in the course of his studies of malarial blood he found in cases of protracted infection. (1) Pseudocytes in leucocytes: These occurred in a case of quotidian fever of several months' duration, and after the ordinary forms of the malarial parasite had disappeared. The pseudocyte, which was spherical with distinct contour, enclosed many fine grains, not melanin, in rapid molecular movement; it occupied about one-third to one-half of a large leucocyte. Methyl blue and gentian violet stained the organism, though faintly. Apparently it was the remains of a disintegrating leucocytozoon. Similar bodies Danilewsky has seen in the blood of birds and reptiles in company with the better known hæmatozoa. (2) Leucocytozoa (?): Round, greyish, faintly granular bodies, with sharp regular contour, containing (a) a granular, rough, and sharply-defined little body, suggesting a deformed and shrivelled nucleus, and (b) a sharply-outlined sphere. These bodies were found in the blood of a patient who had been suffering from continued fever for several weeks. (3) Unusually large malarial crescents, which might very well cause serious nervous trouble by plugging the vessels of the medulla: They were from 20 to 22 μ in length—two and a-half to three times the length of a blood corpuscle—and from 4 to 6 μ in breadth. These parasites were free, motionless, slightly bent, with one end narrower than the other, and they contained a wreath of melanin about the centre. The presence of pigment proved that the body had been formed originally in a red blood corpuscle like the ordinary malarial crescent. (4) Intracellular crescents (8 to 10 μ by 3 to 4 μ), one end stumpy and broader than the other, and the usual melanin clump at the middle. But, besides this crescent, the affected corpuscle contained a small, dark, round little body, free, but lying against the centre of the crescent. This form occurred in the same patient as the preceding. The crescent was of the usual malarial type, but the small free body is quite unusual and could not be explained. Other writers—Canalis, Celli, Guarnieri, and Manna-berg—depict similar bodies without advancing any satisfactory theory as to their origin and nature. They are not bodies thrown off by the crescent as some have conjectured.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(433) Diphtheria of the skin: Incubation Period.

MAX FLEISCH (*Berl. Min. Woch.*, October 28th, 1896) reports a case of diphtheria of the skin in which the period of incubation could be fixed with considerable approach to accuracy. A girl, aged 2½ years, was scalded on the right side of the face and over the front of the neck and trunk down to the umbilical level. The scald was more severe on the trunk than on the neck or face. The scalded surface was treated an hour and a-half after the accident with Lassar's salicyl vaseline (2 per cent.), and covered with cotton-wool fixed by a bandage. There was slight fever on the second and third days; but the child did well, and on the eighth day the scald of the face and neck was healed and the dressings were not reapplied there, whereupon the mother kissed the neck where it was covered with young and tender epidermis. This occurred at 11 A.M. on August 10th. The following morning the mother had a sore throat, and in the evening the diagnosis of diphtheria could be made with certainty. The mother's sister had diphtheria and her husband a sore throat on the following day. The child had not at any time sore throat, but on August 12th in the morning, there was a notable change in the appearance of the parts which had healed on the face and neck. A little above the right eye there was an area about 1½ in. in diameter which was white and swollen, and around it and extending on to the face the skin was cedematous. Cultivations from the white patch yielded typical colonies of the diphtheria bacillus. The child was given two injections of antitoxic serum, and on August 16th the white patch had disappeared, leaving in its place a small granulating surface. Fleisch considers that any other source of infection but the mother's kiss may be excluded. He comments also on the fact that the diphtheria infection did not extend to the granulating surface on the trunk, which was covered by serous effusion, but involved only the part of the original lesion which had become covered by epithelium. The diphtheria must have commenced in the child between 7 p.m. on August 12th and the morning of the following day—that is, between fifty-six to seventy-two hours after infection. The child had subsequently slight paralysis of the palate.

(434) Acroparæsthesia.

GEORGE HALLER (*Soc. Med.*, November 6th, 1896) describes a disease already noticed by several observers, and which Franz Schöner proposes to call acroparæsthesia. The etiology of the dis-

ease is obscure; it is oftenest seen in middle-aged women. The symptoms are numbness and a feeling of swelling or lightness which begins in the fingers (usually in the region supplied by the median nerve), and spreads to the forearm. The feet and legs are also attacked, and later the tongue and lips. The symptoms come on on lying down at night or during the first sleep, or else on waking in the morning. They occasionally persist through the day, causing the subject of them to become weak and clumsy, so that continuous work becomes difficult or impossible. The disease cannot be confounded with Raynaud's local asphyxia ner with the erythromelalgia of Weir Mitchell, for there is no circulatory or vasomotor disturbance, and no modification of temperature or colour in the affected part. Though rheumatic pains occur in some cases, there is no deforming arthritis nor reason to class it with chronic rheumatism. Sensibility of skin is slightly if at all affected; there may be hyperæsthesia or the reverse. Slight hypochondriasis or melancholia has been observed, probably in conjunction with loss of sleep or of habitual occupation. The affection cannot be classed with any known disease of the nervous system. It differs profoundly from the ordinary peripheral neuritis. There are no active pains, muscular atrophy, or paralysis. The affection lasts for years and gets well spontaneously. Drugs affect it very little; phosphorus, bromides, ergotin, quinine, phenacetin, antipyrin have been tried, and also sulphur douches and local inunctions with a preparation of tannin, all without any definite good effect.

(435) The Prognosis of Exophthalmic Goitre.

PRIBRAM (*Wien. klin. Rundschau*, November 3rd, 1896) insists on the importance of an exact knowledge of the mortality of this disease in relation to the advisability of the new treatment by operation. There is great discrepancy between the mortality statistics in unoperated cases published by different observers, as also in the proportion improved or cured. Hospital records are untrustworthy in that the patients are not sufficiently long under observation. Pribram bases his arguments solely on those cases which he has been able to follow during a long period outside the hospital. In his hospital experience he has seen three cases and fatally, but cannot exclude the possibility of others having died after their discharge; in the whole of his private practice, however, he has only seen one fatal case, carried off by intercurrent diabetes mellitus, while in the great majority of the others there was a lasting retrogression of the cardinal symptoms. The cases referred to are only those in which all the signs of the disease were present and well marked; in illustration he gives details of a number of instances. The advocates of operative interference consider disordered functions of the thyroid to play the principal part in the causation

of the disease; they have yet to reconcile the contradictory results of the favourable influence of leading with and extirpation of the gland. Furthermore, the toxic basis of the exophthalmic goitre is not established in cases where one or other of the symptoms is unilateral, or where the signs suddenly supervene upon a mental or physical shock. Pribram admits that when the percentage of cures by operative and other means has been reckoned up and compared, there remain a certain number of cases in which surgical interference has been observed to determine a rapid change for the better. It should not, however, be undertaken in cases where the thyroid enlargement is absent or slight, where there is a strong hereditary neuropathic taint, where there is marked cardiac affection with signs of secondary insufficiency, or where circumstances permit of a careful and prolonged hygienic treatment. This latter class is the one in which the severest cases often end in the most marked and complete recovery. Within the limits strictly laid down, symptomatic treatment, and especially insistence upon the most absolute mental and physical rest, will often ensure a satisfactory termination to the most alarming of cases.

SURGERY.

(436) Lung Surgery.

PIBAN (*Presse Med.*, October 23rd), in concluding a lengthy address on the Surgery of the Lung, gave the following results of his personal experience and of his study of the numerous published reports on this subject: (1) The surgery of the lung, like that of other viscera, has of late made much progress, thanks to the precision of our knowledge relating to the topographical anatomy of this organ, and to the perfecting of operative procedures of means of arresting hæmorrhage and of antiseptic and aseptic measures. (2) Equally favourable conditions for surgical intervention do not occur in all situations of the lungs; (a) Wounds caused by contusing bodies, by stabbing and cutting instruments, and by guns or projectiles of small and medium calibre usually heal well and without causing suppuration or troublesome reaction. (4) The danger which results from such injuries is due, not to the injury of the lung structure itself when the lung is traversed, but rather to the mortality and extent of the wounds, to their extent, and to the lesion of important neighbouring parts (brachial plexus, large vessels, pericardium, heart, spinal cord). (5) The surgeon should not intervene too hastily in these injuries, either by making a simple exploration, or by attempting to extract a projectile which can be seen near the surface. (6) Large projectiles, such as fragments of shot, give rise, especially on the field of battle, to disorders which in a large majority of instances are recoverable. It is imperative for the surgeon to make out, before even by entering with the

resources of modern surgery the visceral and parietal layers of the pleura. (7) A certain number of spontaneous affections of the lung may be successfully dealt with if the surgeon be careful to make a methodical study of the symptoms and indications, and a careful selection of his operative measures. (8) Simple and gangrenous abscesses, when they are of limited extent, show no tendency to cure, and threaten life, are amenable to surgical treatment. (9) In such case the results are almost always favourable. (10) It is advisable to open, scrape, drain, and even cauterise tuberculous abscesses of the lung when these cause severe pain, or have resulted in fistula or contracted extensive adhesions with the pleura. (11) It is often useful in such cases to associate with this treatment partial resection of ribs. (12) No benefit is likely to result from excision of the fragments of lung surrounding the tuberculous cavities, as the tubercle bacillus has already spread beyond the apparent limits of the disease. (13) It is advisable to open hydatid cysts of the lung, the surgeon taking advantage of adhesions when they exist, and establishing still further adhesions if those existing are not of sufficient extent, in order to be able to wash out the cavity with antiseptic solutions. (14) Solid tumours of the lung, the same precautions being taken, should be extirpated when superficial; the occasions, however, for this treatment must be rare, as such growths are almost always secondary.

(439) **Antipyrin in Tannic Acid Solution as a Styptic.**

ROSWELL PARK (Philadelphia Med. News, November 16th) has for years used a 5 per cent. solution of antipyrin in the form of a spray (sterilising the water before making the solution) in surgical practice. He sprays this on any surface, peritoneal, cerebral, or other, from which parenchymatous oozing may be taking place to an extent complicating the operation or jeopardising the success of an ideal dressing. He uses it also in the urethra and in the bladder in cases of hæmaturia. Even in the eye it may be used without fear, its application being preceded by that of a weak solution of cocaine; in this situation, however, the solution need not be so strong. On the other hand, it may be used in much larger percentage when the 5 per cent. solution fails; even when small vessels spurt, compression for a few moments with iodoform or acetanilid gauze soaked in the solution will be effective. There are cases of bleeding, however—for instance, from the nasal cavities or from divided bone—in which even stronger solutions of antipyrin will be inoperative. Roswell Park now calls attention to a combination of antipyrin and tannic acid in solution, by which there is precipitated an intensely agglutinative and cohesive substance of which he does not know the chemical composition, but which seems to him to be an ideal styptic. He hit upon the combination by accident in an emer-

gency (intractable bleeding after removal of adenoid growths), when he added antipyrin in powder to an alcoholic solution of tannin, with the result that there was at once formed a gummy mass of surprising adhesiveness. The application to the post-nasal space of a small sponge dipped in this material at once stopped the bleeding. The author has since experimented with these substances and finds that they may be mixed in almost any proportion. It is possible by pouring the powder of one into the solution of the other, to precipitate so much of the agglutinative composition as to make a gum that may be placed about the margin of the bleeding bone—for instance, in operations upon the cranium; or a small piece of sponge or cotton soaked in this material may be forced into a tooth socket, or in various other ways its use may be advantageous. There is but one attendant difficulty—that it is so remarkably cohesive that when the time comes for detachment or separation of the tampon it is difficult to remove it. It may even be necessary to wait a sufficient time for the formation of granulations and separation by natural processes.

(440) **Operative Treatment of Traumatic Rupture of the Diaphragm.**

SCHLATTER (*Korrespondenzblatt für Schweizer Aerzte*, No. 12, 1895) reports an instance of successful operation for a penetrating wound of the chest, which extended through the diaphragm into the abdominal cavity. The patient had received several wounds by stabbing in the left side of the chest. Through one of these, which was situated in the ninth intercostal space, there was a protrusion of omentum, on the reduction of which a penetrating wound could be felt in the diaphragm. After the protruded omentum had been replaced in the abdominal cavity, and the wound in the thoracic wall enlarged, the slit in the diaphragm was closed by sutures. Healing occurred by first intention, and the patient made a good recovery.

(441) **A New Operation for Varicocele.**

BRAULT (*Lyon Méd.*, October, 1895) describes a new operation for severe cases of varicocele, which he has frequently practised on the cadaver and applied with success to two living subjects. This method consists in removing a large elliptical portion of skin from the external and posterior surfaces of the affected side of the scrotum. After this flap, the extremities of which are directed upwards and downwards, has been dissected away, the enlarged veins are exposed, and resected separately between two ligatures. The large and gaping wound is finally closed by bringing the lower to the upper angle of the ellipse, and by stitching together the apposed margins of skin. This operation may be performed rapidly, and without much hemorrhage, and is in many respects superior to that in which a portion of the scrotum is removed by a transverse wound.

MIDWIFERY AND DISEASES OF WOMEN.

(442) **Rapid Dilatation of the Os during Labour.**

DEMELIN (*Rev. Obstét. Inter.*, November 11th, 1895) has found this proceeding necessary in many cases. In the interests of the mother he has dilated the os for eclampsia in 2 cases; faulty insertion of placenta, 5 cases; cardiac asphyxia, 1 case; and apoplexy, 1 case. In order to save the child, he has dilated the os for lingering labour in 5 cases; rigidity of the cervix, 3 cases; shoulder presentation, 3 cases; face presentation, 1 case; compression of the funis in vertex presentation, 4 cases; prolapse of the funis in 3 cases; and amniotic infection in 2 cases. In this last class, the infection of the waters, especially when the membranes have ruptured early, is serious for the mother, but especially grave for the child. In order to save it from pneumonia or infectious enteritis which come on soon after birth, it must be removed as quickly as possible from its poisonous surroundings. In eclampsia rapid dilatation is indicated, and it speedily terminates a perilous delivery without in itself increasing the number of convulsions. Demelin maintains that rapid delivery is quite the order of the day, the old prejudice having passed away. In the circumstances given in detail above it is dangerous to wait for complete spontaneous dilatation. On the other hand Demelin admits that the practice is likely to be abused.

(443) **Congenital Sacral Tumour Impeding Labour.**

HEINRICH (*Centralbl. f. Gynäk.*, No. 46, 1895) attended a woman who had borne one child, the labour being complicated by rupture of the perineum. On this occasion the fetus lay in the first position; the pelvis seemed normal. The mother had albuminuria and oedema of the feet. When labour came on it proved lingering without evident cause, the pains being strong. The forceps was applied and the head delivered, two incisions being previously made in the vagina with the view of preserving the perineum, already in danger. The body followed the head and projected from the vulva as far as the lower angle of the scapula, but could not be drawn out any further. The child breathed well and cried out loudly. On exploration the cord and the fetal abdomen were found normal, as well as the external parts. A tense fluctuating tumour could be felt in the sacral region. It was as big as a man's head. Heinrich made the midwife draw down the head of the child, and then took a Nägele's perforator in his right hand, guiding the point up to the tumour by aid of the left forefinger. With a smart thrust the tumour was perforated and a quantity of serous fluid escaped. As the perforator was being retracted the rest of the child with the tumour was delivered. The perineum, completely torn, was sewn up at once. The child

died in half an hour. It was a well-developed male; the tumour was clearly a teratoma and contained a square piece of bone and numerous small cysts. There was no spina bifida.

(442) Septic during Pregnancy.

BAR and RENON (*Répert. Universel d'Obstet. et de Gynec.*, September 25th, 1895) read at the recent congress at Bordeaux a clinical report of a case of "streptococcism" in pregnancy. A woman was admitted into hospital suffering from high fever. She was about eight months pregnant, and occasional pains set in. Some cervical secretion was removed for examination before any obstetrical manipulations. Cultivations proved that the secretion contained streptococcus. As the patient was very ill labour was hastened. Specimens of placental maternal blood were cultivated, and colonies of pure streptococci were obtained. The child died before birth; samples of its blood from the placenta, liver, and heart, and fragments of the liver and lungs were cultivated. The cultures remained sterile. The mother died fifty-three hours after delivery, and pus was found in the parametrium. Bar and Renon maintain that the "streptococcal" provoked labour. Though the fetus succumbed, there is no evidence that the germs invaded the fetal organism through the placenta.

(443) The Uterus in Ectopic Gestation.

PILLIET (*Ann. de Gynec. et d'Obstet.*, October, 1895) has studied the histology of the modifications which the uterus undergoes in tubal gestation. He finds that the development of a decidua in its empty cavity during ectopic pregnancy is more than a pathological phenomenon; it is a distinct clinical complication. As long as the decidua remains in place the uterus is practically in a condition of subinvolution; hence both hemorrhages and membranous dysmenorrhoea may occur. When the decidua has been shed there is danger of diffusion of metritis to the whole uterine muscle. Pilliet adds rather significantly that the etiology and pathology of endometritis are both obscure, and that probably ectopic gestation, overlooked in its early stages, may account for many peculiarities in cases of endometritis hitherto hard to explain.

(444) Ruptured Interstitial Pregnancy.

DUNNING (*American Gynecol. and Obstet. Journ.*, November, 1895) operated last April on a patient who had been seized the day before with violent pain and collapse. She believed herself to be two months pregnant. She was almost moribund before the beginning of the operation. During the preparations, 8 ounces of saline solution were transfused into the cellular tissue of the patient in the inframammary region. Strychnine and whisky were given hypodermically and also nitroglycerine. A large amount of blood was found in the peritoneal cavity. The tubes seemed to be normal, but the uterus was enlarged and there was a rent on its

upper aspect posteriorly, from which a portion of placenta protruded. A small artery in the raw surface of the lacerated uterine wall was bleeding freely. It was tied, and then the patient seems to have died suddenly. Death apparently could not be attributed to the anaesthetic—ether. On further examination the canal of the uterine end of the right Fallopian tube was seen to be dilated and continuous with the gestation cavity within the uterine cornu. The walls of the cavity were uterine; they were very thin around the rupture. Dunning believes that hysterectomy involves too much shock in cases of ruptured tubo-uterine sacs. He thinks that drainage after closure of the rent by sutures, or sewing the sac to the lower angle of the wound, with drainage from above and through the uterine cavity, would be better if practicable.

THERAPEUTICS.

(445) Pituitary Extract in Acromegaly.

MARINESCO (*Sem. Méd.*, November 13th), reports three cases of acromegaly in which he gave pituitary gland substance. In two of the cases the patients, a woman aged 58, and a man of 54, were examples of the massive type of the disease; the third, a woman aged about 30, was an example of the giant type. Under the treatment the headache which, in the "massive" cases was extremely violent, diminished considerably in intensity, but the remedy had no effect on the neuralgic pains in the limbs. The general condition was improved, but Marinesco could not detect the slightest diminution in the size of the affected extremities. The most definite objective effect of the treatment was increased diuresis. Without denying that suggestion may have had some part in the matter, Marinesco believes that the treatment had some action either on the pituitary tumour or on the encephalic circulation. Marinesco stated that both Marie and he believed that acromegaly depends on perverted function of the pituitary gland, but they reject the hypothesis of Tamburini and Massalongo that the hypertrophy of acromegaly is a result of pituitary hypersecretion. In certain cases *post-mortem* examination has shown that the pituitary body had undergone a heterogeneous transformation, the gland cells having been replaced by elements of a different kind, incapable of supplying the normal secretion of the gland.

(446) Subcutaneous Injection of Fat.

LEURS (*Verhand. des Congresses der Inn. Med.*, Twelfth Congress, p. 418) was led, by observing the harmlessness of the hypodermic injection of even large quantities of olive oil (used as a menstruum for camphor) to make some experiments on dogs to ascertain whether fats injected under the skin would be absorbed and assimilated. He found that this was the case. Thus a dog, which on a diet of fat-free horse-flesh was brought to a constant weight of about 10.8 kilograms, was, while kept on

the same diet, given in daily injections under the skin in all, during a period of two months, 3,480 g. of butter, rendered fluid by warming to the body temperature. It increased in weight to 13.175 kilograms, a gain of 2,335 g. Another dog, weighing 5.850 kilograms, received about 1,400 g. of butter by daily injections under the skin in the course of forty-five days, and during the same period increased in weight to 8,300 kilograms. Chemical examination afforded evidence that the fat accumulated about the viscera and in the mesentery was approximately of the same composition as that of a dog fed in the ordinary way—that is, that the butter fat had not merely accumulated in the body, but had been truly assimilated. Much butter, however, remained unchanged under the skin. Leurs believes that these observations have a practical therapeutic importance.

(447) Transfusion in Chronic Anemia.

EWALD (*Berl. klin. Woch.*, November 11th, 1895) speaks of the life-saving effect of transfusion in the severest forms of chronic anemia, and relates an illustrative case. A patient, aged 32, the subject of this primary anemia, was so collapsed that it was necessary to use camphor injections hourly. The blood showed very slight poikilocytosis and no leucocytosis, but it was extraordinarily watery and thin. The liver was somewhat enlarged and tender. The urine contained no albumen or sugar. Transfusion was adopted as a last resource; 85 ccm. debarbated blood, obtained from the patient's wife, was injected with all the usual precautions. The author always employs this arm-to-arm transfusion as being the simplest and the best method. Improvement was noted from this time. The man gained 3 kilos in weight. The number of red blood cells increased as well as the haemoglobin. The slight poikilocytosis still persisted. In the occasional attacks of diarrhea the stools were very offensive and frothy; no animal parasites or their eggs were present, but abundant micro-organisms. Once an erythema bullosum appeared in the month, for which balsam of Peru and occlusion applications before meals were employed. In less than a month the patient was able to travel to Baden-Baden. Although greatly improved, he still remained anemic. The author then discusses auto-intoxication as a cause of pernicious anemia, and he suggests that the injected blood might have such an antitoxic action as to neutralise poisons which increase at times to a maximum, and then call forth such accidents as were seen in the above recorded case. The supplementary treatment consisted in arsenic, antifermentative remedies (resorcin, etc.), and light vegetable in preference to animal diet, including prepared foods.

(448) Paraneoplastic Injections of Arsenic in Cancer.

F. HETZ, of Rosen (*Sem. Méd.*, November 9th) has tried injections of arsenic in inoperable cancerous tumours. For

this purpose he first used a 1 in 1,000 solution of arsenious acid; now he employs the following: B Arsenious acid, 0.30 centig.; hydrochlorate of cocaine, 1 g.; boiled distilled water, 100 g. One or two Pravaz syringefuls of this liquid are injected into the substance of the tumour at intervals varying from two to eight days. In a case of epithelioma of the cheek, which had recurred after operation and was accompanied by swelling of the neighbouring glands, Huf claims to have effected a complete cure by daily injections during several months of 1 in 1,000 solution of arsenious acid. During the treatment, however, the patient had two attacks of erysipelas, and this may have had a curative influence on the tumour. A woman with cancer of the breast, under Planel of Beaumont-le-Roger, is also said to have been cured by the same treatment. The method has been tried in several other cases of recurrence of cancer; in some the progress of the disease has been distinctly retarded, in others the treatment had no effect.

(431) Quinine as a Prophylactic against Influenza.

GRABER (*Wien. klin. Rundschau*, November 10th, 1895) was led to try the effects of quinine in the prevention of influenza by the similarity shown by the onset and course of this disease to those of malaria. During the influenza epidemic he administered quinine to some of the employees of various establishments but not to others, and found that the former acquired a considerable amount of protection. Thus, for instance, in one out of five squadrons encamped at Bonn, 0.5 g. quinine hydrochlorate was administered daily to each man in his schnapps for twenty-two days. During this treatment only 7 men in the squadron contracted influenza, of whom 3 fell ill on the first day of the experiment; in the other four squadrons there were respectively 23, 19, 33, and 42 cases. After the sixth day of treatment there were no further cases in the squadron, while the disease continued to progress in the other detachments. Graber therefore considers it proved that quinine is not only a specific against influenza, but if given at the right time and in sufficient doses, can also prevent the outbreak of the disease. Mossé has more recently confirmed these views by experiments on rabbits.

(432) Thyroid Treatment in Goitre.

MARIE (*Sem. Méd.*, November 13th) recently reported to the Paris Société Médicale des Hôpitaux the case of a girl aged 19, belonging to La Orense, in whom a goitre had begun to develop at the age of 14. When she came under observation it was of the size of half an average orange, and hard in consistence, but elastic. On September 14th, she began to take two tablets of sheep's thyroid every day. On the 19th the neck was distinctly smaller, and on the 26th it was found by measurement that the swelling had diminished in the transverse diameter (at the level of the

clavicles) from 80 to 45 millimetres, and in the vertical from 55 to 40 millimetres. The goitre was also much softer. At this time slight symptoms of thyroidism (weakness, trembling of limbs, headache, pains in the limbs, nausea) showed themselves. The patient had to go home, and has not been heard of since. This case, together with similar ones reported by Séné and Bruns, appears to Marie to warrant the conclusion that in a certain number of cases of simple goitre, thyroid treatment is useful. Bruns treated 60 cases in this way with the following results: 14 cures, 20 very marked improvements, 9 distinct improvements. The indications for the treatment, according to Bruns, are that the tumour shall be of moderate size, of recent origin, and the patient young. Marie's patient lost 3 pounds in weight during the treatment.

(433) Ichthylol in the Treatment of Burns.

LEO LEISTIKOW (*Monatsh. f. prakt. Derm.*, November 1st) has during the last six years used ichthylol in the treatment of burns of the first and second degree with the best results. The application of this substance at once eases pain and the anodyne effect is lasting. Even in extensive burns of the second degree the oedema quickly subsides, the hyperemia disappears, and as soon as the destroyed tissue has been shed the regeneration of epithelium begins. The remedy can be applied in many different ways—in powder, in wet compress, in colloid, in salve or plaster mulls, varnishes, ointments, or pastes. Leistikow mostly uses it in powder, in paste, or in salve mull. The latter is best used in the form of zinc-ichthylol salve mull. (Beiersdorf) and is most serviceable in circumscribed burns of the first and second degree, particularly on the face and extremities. The dressing should be changed once every twenty-four hours. The powder is most useful in extensive burns of the first degree on the trunk, and it must be sprinkled thickly and frequently on the part. The paste is used in extensive burns of the second degree, and when there is much inflammation it is advantageously combined with the powder treatment. The formula of the powder is: R Zinc. oxydat., 30.0; magn. carbonic, 10.0; ichthylol, 1.0 to 2.0. That of the paste is: B Calcar. carbonic, 10.0; zinc. oxydat., 5.0; amyli, 10.0; ol. zinc., 10.0; aq. calois, 10.0; ichthylol, 1.0 to 3.0.

PATHOLOGY.

(434) Parasites in Variola.

V. SICHENKIN (*Münch. med. Woch.*, August 20th, 1895) first refers to the researches of Guarnieri and L. Pfeiffer into this subject. The author has inoculated the conjunctiva of the rabbit with lymph taken from the vaccine pustule on a child's arm. Inflammatory manifestations were but very slightly marked. In twenty-four hours the site of the inoculation looked dull. A few grey miliary points could be discovered with

a lens in the neighbourhood. An ulcer of the cornea subsequently developed. The further progress was obscured by the increased exudation of leucocytes. A hypopyon at times appeared. The eye was excised, placed in 3 per cent. nitric acid for half an hour, then hardened in alcohol of increasing strengths, and embedded in paraffin. A proliferation of epithelium was seen in the neighbourhood of the inoculation. In nearly every epithelial cell there was besides the nucleus a rounded well stained body surrounded by a clear space, and similar to the organism described by Pfeiffer. Sometimes two such bodies would be found in the same cell at the different poles. As a rule the superficial and flattened cells were not involved. Not only the pre-existing cells were affected, but also newly developed cells in active proliferation. Very slow amoeboid movements have been observed in these parasites by Pfeiffer and Guarnieri. The author concludes that here, after the inoculation of lymph from a child's arm, a localised infection ensued which was caused by the animal parasites (cytocytes) described by Pfeiffer and Guarnieri. The affected cell retains its life for a long time, and the organism grows at the expense of the general protoplasm of the cell, the nucleus being spared.

(435) Transmission of Tuberculosis through the Placenta.

BAR AND RÉNON (*Ann. de Gynéc. et d'Obstét.*, September, 1895), in 5 cases in which the parturient mothers were tuberculous, at the moment of division of the umbilical cord, injected blood from the placenta under the skin of the abdomen in guinea-pigs. In 3 cases the results were negative; in 2 positive. In the first of these the mother was in the third stage of phthisis, with bacilli in the sputa but no obvious lesion in the placenta. At the seat of injection an ulcerated tuberculous sore formed in the guinea-pig, and two months later it died from tuberculosis of the liver and spleen, and tubercle bacilli were found in the spleen and in the caseous masses at the wound. The fetus had died shortly before birth; no tubercle was detected in its organs; but of 3 guinea-pigs injected with pulp from the viscera, 2 succumbed and showed evidence of tuberculous infection. In the second case the mother had cavities in the lungs, and the dead dead of bronchopneumonia on the first day. At birth 2 guinea-pigs were injected with blood from the placenta; 1 of these died and presented extensive tuberculous lesions, and the pulp taken from the spleen and injected into other guinea-pigs caused generalised tuberculosis, which the presence of bacilli in microscopic preparations verified. The 2 mothers referred to died soon after confinement so that there seemed to be some relation between the obtaining of positive inoculation results and the gravity of the condition of those from whom the inoculations were made.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(454) **Primary Pulmonary Actinomycosis.** ASCHOFF, of A. Fraenkel's clinic (*Berl. klin. Woch.*, 1895, Nos. 34 to 36), first refers to the three stages described by Israel as follows: (1) Limitation of the disease to the lungs; (2) extension by contiguity or by metastasis; and (3) rupture upon the surface. The recognition of the disease in the first stage from tuberculosis may be very difficult. Actinomycosis spares the apices, and there is no marked hemoptysis, although the sputum may be blood-stained. The presence of the fungus in the sputum is the most important fact. In the second stage a partial shrinking of the lung occurs, with exudative pleurisy. When the chest wall begins to soften an empyema may be simulated. More recently some of these points advanced by Israel have been controverted. Actinomycosis has been known to affect the apex of the lung, and the shrinking is not so constant as was thought. It has been maintained that not suppuration but tumour formation is the characteristic of this mycosis. The fungus may not be found in the sputum or even in the pus. It has been maintained that not only the teeth and tonsils may be the original source of the lung infection, but that the fungus may be directly inhaled. In the case reported by the author there was on admission a right-sided pleural effusion with flattening of the upper part of the chest. A systolic murmur was heard over the base of the heart. Later there was a moderate hemoptysis lasting four days. Clear fluid was drawn off by the exploring needle. No tubercle bacilli, tumour elements, elastic fibrils, or fungi were found in the sputum though repeatedly looked for. Later a local bulging below the right breast was noted, and eventually pus containing the actinomycetes was obtained from this. A day or two later about 150 c.c.m. of pus containing the fungus was spat up. An incision was made into the chest at the site of the bulging, and stinking pus containing the actinomycetes was let out. Peritoneal symptoms eventually appeared, and the patient died. The author draws attention to the following points in the case: (1) The infection was derived from a carious tooth; (2) the disease lasted over two years; (3) the diagnosis lay between tuberculosis, echinococcus, and possibly malignant tumour; (4) the pus has a characteristic smell, and may in all probability be caused by the actinomycetes alone; (5) the sputum is often flesh-coloured or like blackberry jelly, and may simulate that of tumour of the lung; (6) an appreciable glandular swelling was not present; (7) the extension occurred by contiguity; and

(8) the urine showed the diazo reaction. He adds that in an early stage it might be possible after resection of ribs to scrape away the disease.

(455) *Syringomyelia.*

MÖLLER AND MEDER (*Ztschr. f. klin. Med.*, Bd. xxviii, H. 1 and 2) relate a case in a man aged 43. The disease had lasted over ten years, and the patient died of phthisis. The clinical picture of the disease was fairly characteristic. It is worthy of note that, after sensory symptoms in the arms and legs, a complete paralysis occurred in the limbs which after some months disappeared entirely from the legs, but only incompletely from the arms. A year and three-quarters before death symptoms very like those of tabes supervened in the legs, but they disappeared in a few weeks, and no corresponding lesion could be found to account for them. A kyphosis developed as the result, and not as the cause, of the disease owing to the weakness of the extensor muscles of the neck. The anatomical changes were different from those usually found. Thus overgrowth of the glia was but slightly marked, and the disintegration of the substance of the grey matter was the cause of the cavity formation. In larger or smaller areas of irregular outline there was a diminution of the nerve elements, with shrunken ganglion cells without nuclei, and varicose and broken up nerve fibrils. These disintegrating changes were almost limited to the grey matter, and were obviously in connection with disease of vessels. In the lower dorsal region Goll's column was degenerate, apparently in consequence of vascular obstruction, but higher up it was intact. A defect was present in the medulla, and the ascending roots of the trigeminal and glossopharyngeal nerves as well as a portion of the restiform body were absent. In discussing the characters of the cavities in the medulla, it is mentioned that the bulbar symptoms develop intermittently in this disease so that ischemic processes would seem to be the cause. The case shows that vascular disease may play a greater part in syringomyelia than has hitherto been expected. Syphilis does not appear to play so important a part in producing syringomyelia as might have been anticipated. The authors point out (1) that in spite of considerable meningitis with obvious pressure on the posterior roots there was no degeneration of the corresponding root zone and no lesion resembling that found in locomotor ataxia, and (2) that where no gross lesion, such as softening, glia overgrowth, etc., was present, the ganglion cells were at times seen to be diminished in numbers, shrunken, and pigmented.

(456) *The Value of Gastro-diaphanoscopy.*

MEINERT (*Centralbl. f. inn. Med.*, November 2nd, 1896) first refers to Martin and Meitzner's investigations into this subject. Kelling has examined 11 cases in the author's clinic by the diaphanoscope and also volumetrically by induction with air after the author had determined the condition of the stomach by

the usual CO₂ method. In one case the lower boundary of the stomach was found by the author to have been raised after the distension to three fingers' breadth above the umbilicus. Kelling obtained a similar result a few days later by the volumetric method. A few days afterwards 1 of a litre of water was put into the stomach and the gastro-diaphanoscope used. The limits of the figures obtained were marked out on the abdominal wall. In varying positions of the lamp different pictures were obtained. In cases of gastroptosis a correct representation may be got of the lower margin of the stomach, but no information can be obtained in regard to the upper margin. The diaphanoscope can only occasionally be of use. It may facilitate the detection of tumours in the neighbourhood of the spleen, also the topographical determination of palpable tumours of the stomach and parts in the neighbourhood. Any attempt to determine the position, size, and shape of the stomach by this means is not only unsuccessful but may mislead.

SURGERY.

(457) *The Operative Treatment of Simple Fractures.*

Is a discussion at the recent Congress of French surgeons, Berger (*Med. Moderne*, November 2nd, 1896) pointed out that in simple fractures in the shafts of long bones primary operation has not been seriously proposed except in cases of broken clavicle and leg. In fracture of the clavicle, except when this injury is complicated by vascular or nerve lesions, surgical intervention, it is held, is unjustifiable. The results obtained by ordinary treatment are very satisfactory with regard to function, and the swelling caused by the formation of callus cannot be prevented by operation, and, after such treatment, is associated with a scar which is more objectionable than the deformity caused by the injury. In fractures of the leg, especially the oblique and so-called helicoid forms, an apparatus which will ensure consolidation without shortening of the limb has yet to be found. The cause of the partial irreducibility consists in the obliquity of the corresponding surfaces of the fragments, and in the action of the strong muscles at the back of the limb. Osseous anastomosis, Berger urges, would fail altogether to overcome these difficulties, and would add fresh risks and troubles. Callus obtained by osseous anastomosis is always more abundant and more sensitive than callus that is spontaneously developed. The presence in the interior of bones of metallic bodies may, moreover, be the cause of serious and persistent cysts. Even the most elaborate forms of fracture of the leg may be treated successfully by careful management, and by refraining from the immediate application of a rigid apparatus such as a plaster-of-paris splint. Reduction should be effected gradually and progressively, and not until it has been rendered as complete as possible ought

any immovable apparatus to be applied. Langer thinks that no surgeon is justified in exposing the seat of fracture in a leg with the view of placing the fragments in good position and of uniting them by wire suture, except in the very exceptional instances of persistent irreducibility due to the interposition of isolated pieces of bone, and of bands of ligament, periosteum, or muscle. With regard to articular fractures it is thought that only those of the elbow and knee, on account of the bad functional results so frequently observed after such injuries, should be subjected to primary intervention. Fractures of the elbow often cause persistent osseous deformity and restriction of movement in the forearm, but it is very doubtful whether such unfortunate results can be modified by osseous suture of the fragments. In condyloid fractures of the knee in which the fragments are more superficial and offer better opportunity for the application of retentive agents, the use of pegs or metallic sutures is more frequently indicated. But, it is pointed out, as the danger of operative infection of the knee is so great, surgical intervention ought not to be advised except in cases of exceptionally extreme displacement which has resisted very energetic attempts at reduction. Berger excludes from this consideration fractures of the olecranon and patella.

(1400) Skin Grafting from the Lower Animals.

MILES (*Edinburgh Hosp. Reports*, iii) has used skin grafts taken from the lower animals in 10 cases, 8 of which were burns or scalds—1 a varicose ulcer of the leg and 1 a wound made by excision of the breast. In 7 instances the skin was taken from kittens varying in age from 2 to 7 days; that of 4-day rabbits was twice used, of puppies twice, and of an old frog once. Thus in two cases the patient was at different periods grafted with skin from animals of varying species. The ulcers having been rendered healthy it was found that the grafts took equally well whether applied on top of the granulations or after the superficial layer of granulations had been scraped away. The animals were killed by pithing, chloroform, or a blow on the nape of the neck, the skin of the abdomen and flanks shaved, purified with 1 in 40 carbolic, and then dissected off from the subcutaneous fat, and floated on to warm boracic lotion. After being cut into pieces of suitable size and shape it was applied, deep surface down, to the ulcers. Firm pressure was made by a moist pad of gauze, over which were narrow strips of oil silk protective. A pad of moist gauze formed the deep dressing, which was covered in by absorbent antiseptic wool and a bandage, with, if necessary, a splint to prevent movement. The grafts were left undisturbed for at least forty-eight hours (longer, if possible), and subsequent manipulations were extremely gentle, so as not to disturb the feeble adhesions at first formed. No wiping was allowed, any *débris* being removed

by a very feeble stream of lotion. The process was occasionally complicated by sloughing, pustulation, and redundancy of granulations. In 4 cases out of the 10 the results of the grafting were perfectly successful (one of these unfortunately died of erysipelas when the ulcer was practically well); in 4 more the success was only partial, though Miles believes that the animal grafts were most useful in stimulating the margins of the sores. In the other 2 cases, one a callous ulcer of long standing in an old man, the other a burn in a rickety girl, for which Thiersch, Reverdin, and flap operations had been equally unsuccessful, no benefit resulted from the grafts. The scars in the successful cases were exceptionally strong and firm.

(1411) Conjunctivitis due to Larvæ.

BAQUIS, of Leghorn (*Annali di Ottalmologia*, fascic., 4, 1895) relates a case of acute conjunctivitis due to the larvæ of one of the tachinidæ (class diptera) being deposited in the conjunctival sac. The patient, a mechanic in the naval dock-yards, was at his work in the morning when an insect flew into his eye and then off again. The eye became irritable, and on this increasing a comrade examined it and saw some grains of what he took to be sawdust. The eye was washed out, and this afforded some relief for the time; but by the evening the pain was again very great, the lids swollen, and the conjunctiva very injected. On everting the lids Baquis found a great number of whitish little bodies, the size of a fly's egg, which moved about rapidly; when he attempted to remove them he found it impossible to do so, as they fixed themselves to the conjunctiva. On instilling cocaine, the movements of the larvæ became quieter, and they allowed themselves to be removed. The eye was then irrigated with perchloride of mercury 1 in 4,000, and $\frac{1}{2}$ per cent. sodium chloride, and was quite well on the third day. Microscopical examination of one of the larvæ showed it to be elliptical in form, and made up of twelve metameres; each metamere was provided with lateral setæ, of which there was also a median ventral series. Its movements were vermicular. A diagram of the larva is appended. Nearly all the members of the family of tachinidæ deposit their eggs on other creatures, principally caterpillars, where they develop into larvæ. Baquis had heard of two other cases similar to his own.

MIDWIFERY AND DISEASES OF WOMEN.

(142) Digital Exploration in Midwifery.

CROUZAT (*Rev. Obstét. Internat.*, October 21st, 1895) does not agree with certain German obstetricians who would discard digital exploration in normal labour, relying on abdominal palpation. The diagnosis of normality may demand the introduction of the finger into the vagina. Crouzat's principles simplify digital exploration and guard

against its dangers. Vaginal examination, he thinks, should be made as seldom as possible. One exploration at the beginning of labour and another immediately after the rupture of the membranes are usually sufficient. His practice is to make the external parts antiseptic; then the hands and forearms are washed and brushed thoroughly. The nails must be specially attended to. The washings afterwards repeated in a 1 in 1,000 solution of sublimate. Great care in the introduction of the forefinger is strongly advocated. It should be dipped in sublimated vaseline and guarded by the thumb and the other fingers whilst the hand is passed under the clothes and near the patient's thighs. On reaching the perineum the labia are parted by the thumb and middle finger. The forefinger is lastly introduced into the vagina without having touched any part of the patient or her clothes since the instant it was made aseptic.

(143) Dermoid Ovarian Cyst of Unusual Size.

ULLMANN (*Wiener med. Presse* September 22nd, 1895) states that a married woman, aged 53, recently came under Professor Hofmökler's care for a large ovarian tumour. She said that it had only been growing for a year. The abdominal swelling was marked, the skin shiny, the subcutaneous veins dilated. The uterus was drawn up high, and measured $2\frac{1}{2}$ inches. Part of the tumour lay in Douglas's pouch. When the cyst was exposed and tapped 13 pints of a greasy fluid escaped. Great care was taken to keep the fluid from escaping into the peritoneum. There was a soft parietal adhesion, easily separated. The pedicle was very broad. Three interlocking ligatures were applied, and it was divided by a thermocautery. A drainage tube was applied, and left in for five days. The patient made a very good recovery. The tumour weighed over 35 lbs. It consisted chiefly of one large cavity, which had contained the greasy fluid, and still held masses of fat and hair. The remainder of the tumour, as is usual in dermoids developing late in life, was multilocular and glandular as in the commoner form of cyst.

(144) Oedema and Prolapse of Cervix in Pregnancy and Labour.

SWIFT (*Australasian Med. Soc.*, September 20th, 1895), in reference to Geyl's recent memoir (*Epidemiol.*, July 23rd, No. 55), believes that Geyl is in error in asserting that the above condition is so very rare. More probably many cases have not been reported. Swift has seen three cases during the last four years. The first was in the third month of pregnancy; there was much bearing down. An oedematous cervix protruded from the vulva. It was easily replaced and the patient was kept at rest. A three months' foetus came away on the night after reduction of the cervix. On the same evening Swift was called to another and similar case. The patient was five months pregnant, and

thought that the womb had fallen. The cervix was extremely elongated and edematous, protruding through the vulva. It was reduced without difficulty; the patient remained in bed for two days. She was delivered easily at term. The third case was six months pregnant. The womb was said to be down, and there was troublesome amnion. Swift found the cervix outside the vulva very edematous and excoriated in several places from chafing. Reduction and pessaries proved of no permanent benefit. A T-bandage and a pad were applied and the patient kept at rest till term. The os dilated easily, and labour was in no way impeded.

(645) Acute Yellow Atrophy following
Twisted Pedicle and Ovariectomy.

Brookman (*Centralbl. f. Gynäk.*, No. 45, 1895) observed a tumour in a woman, aged 25, shortly after delivery. It was chiefly in the right side of the abdomen, and lay separate from the uterus. Suddenly violent pain set in, and torsion of an ovarian pedicle was suspected. Ovariectomy was performed; a large cyst with a pedicle twisted four times was removed. The tumour, which had developed in the right ovary, was livid, and full of recent clot. There were no adhesions. Some bloody serum lay in Douglas's pouch. On the second day the patient became restless, then sleepy, and next day she was comatose. Urine was secreted sparingly, and contained much albumen. The conjunctivae at length became distinctly yellow. The abdomen never felt tense to the last, the patient dying on the fourth day. The liver was found to be very small, flaccid and intensely yellow; there were minute ecchymoses sparingly spread over its surface. The urine contained leucin and tyrosin crystals. There was no trace of peritonitis, and the pedicle was healthy. Stocker believes that the liver disease began before the ovariectomy, and was due to the torsion of the pedicle, necrosed products being absorbed into the circulation.

(646) Myoma of the Uterus.

Hacken (*Virchow's Archiv.*, vol. cxlii, Part 2, November, 1895) has made researches in order to throw light on the true origin of uterine fibroid. He does not support the opinion of Kleinwächter and others that the muscle cells in a myoma were originally discarded, so to speak, from arterioles subsequently blocked. There is strong reason to believe that myoma has usually an embryonic origin. In certain cases very distinct epithelial relics are found in myoma. These seem to represent remains of the primitive epithelium of Müllerian duct. Relics of the Wolffian duct are decidedly to be found in the uterine wall; in fact, Ricker seems as certain as Coblentz as to the persistence of this duct and its relation to new growths. Abnormal ingrowths of muscle cells around the duct are represented in Ricker's drawings. Hence it is probable that every myoma originally

arises from some abnormal growth of muscle around the Wolffian duct in the uterine wall, or around epithelial relics from the Müllerian duct, relics which may even be distinct diverticula not entirely effaced after the fusion of that duct with its fellow to form the uterus. Ricker notes that, on a priori reasoning, cancerous changes in a myoma ought not to be rare, since epithelial elements originally form an essential part of that new growth. Yet he admits that not a single authentic case of cancerous degeneration of a myoma has ever been recorded. Sarcomatous changes have been detected by good authorities, but so rarely that a "fibroid" is practically as innocent as a true fibroma developed in any part of the body.

THERAPEUTICS.

(647) The Antithermic Analgesics.

J. SCHMITT (*Rev. Méd. de l'Est*, October 15th), reviews, chiefly clinically, these remedies. They may be classed as follows: (1) Phenol group, with phenic acid as its chief. The chief action of these is antiseptic. Their analgesic powers are feeble. The objections are, that they are protoplasmic poisons, they paralyse or destroy the blood corpuscles, and depress or paralyse the nervous system. Their antithermic action is energetic but transitory. More permanent reduction of temperature can be obtained only at the risk of dangerously toxic doses, or at that of inducing cachexia and profound anemia by frequently repeated small doses. (2) The aromatic acid group, chief of which is salicylic acid. The chief characteristics are a still predominant antiseptic action, less toxicity than group 1 owing to the substitution of COOH for OH. Apart from rheumatism their analgesic power is weak. The large doses required to lower temperature, cause digestive troubles, buzzings in the ears, and even cardiac enfeeblement and renal irritation. But with undamaged kidneys they increase diuresis and depurate the blood of extraneous and nutritive residue. (3) The anilide group. Its antiseptic properties, though strong, are less than those of phenol and salicylic acid. The fall of temperature caused is rapid but transitory, with abundant sweats, shiverings, cyanosis, and often hæmoglobinuria. (4) The phenylhydrazin group which are even less satisfactory than the anilides. Like the latter, they are eliminated as amidophenol derivatives. (5) The Chinoline group possess considerable antifebrile and antiseptic properties, but are liable to disorder the digestive tract, and to give rise to severe nervous symptoms. Their antithermic power is fugacious, attended by profuse sweating, collapse, etc., and attended by too severe corpuscular destruction. Hence, as a group, they are not satisfactory. (6) Pyrrol group, the most important and almost the sole representative of which is antipyrin. Endued with a real antifermentative and microbicidal action, almost ineffective as

regards the blood if pure, possesses antifebrile and analgesic properties second to none. A few derivatives of antipyrin must be mentioned: salopyrin, tolipyrrin, tolysal—which do not present any special advantages.

(648) Apolysin and Citrophén.

HILDEBRANDT (*Centralbl. f. inn. Med.*, November 9th, 1895) first discusses the chemical composition of these bodies, which are combinations of phenetidin with citric acid. The phenetidin molecule is more loosely combined in citrophén than in apolysin. In experiments made on mice citrophén acted very much like phenetidin chloride. The latter is recognized as a blood poison. When citrophén was given to dogs an intense indol reaction could be demonstrated in the urine, and there was methemoglobinæmia with irritation symptoms from the side of the kidneys. It is to be observed that citrophén contains 40 per cent. phenetidin and as much as 75 per cent. phenacetin. The author warns against the unrestricted use of citrophén. Apolysin has been recommended as a quicker and more reliable antipyretic and analgesic than phenacetin. Its toxic properties are far less marked. In his experiments the author shows that in weak HCl solutions apolysin is more easily split up than phenacetin (lactophénin occupying a middle place), whereas in alkaline solution phenetidin splits up more readily than apolysin. These experiments explain the hæmoglobinæmia of apolysin when injected subcutaneously into the albino mouse. The readiness with which apolysin splits up in acid solutions is a disadvantage when it has to be given by the mouth; in marked hyperacidity a large quantity of phenetidin may thus be disengaged. This phenetidin can produce irritation symptoms in the stomach and duodenum, and even jaundice. Recently some unpleasant effects of lactophénin have been reported; lactophénin would be more easily split up in acid gastric juice than phenacetin. Von Nencki and Jaworsky (*Erkrank.*, November 30th, 1895 par. 423) have used apolysin as an antipretic and analgesic, and have found the indol reaction in the urine. Here the drug was administered by the mouth. It would be interesting to know whether the same result would arise if it were given subcutaneously.

(649) Treatment of Eczema.

A. RÖNN (*Bull. de Thé.*, October 30th), says that in herpes zoster the treatment has to be directed to the eruption, to the neuralgia which precedes and accompanies it, and to the pain which persists after the disappearance of the skin lesions. Treatment should always be begun by the administration of a saline purge, preferably sulphate of soda. In dealing with the eruption the affected part must be kept absolutely dry. The painful region should be covered with a layer of cotton wool sprinkled with the following powder: Bismuth powder, 60 g., oxide of zinc, 15 to 20 g., powdered cam-

phor, 1 to 3 g., crude opium powdered, 1 g. In old people special care should be taken to prevent ulceration. For the neuralgia the following pills are given by Robin: B extract of stramonium, extract of hyoscyamus, aa 0.01 g., extract of belladonna, 0.005 g. To make one pill. Four of these to be taken daily. If these pills do not relieve the pain, antipyrin must be given internally. This drug should be given hypodermically for the pain which persists after the disappearance of the eruption. Subcutaneous injections of glycerophosphate of soda may also be tried.

(476) Amyl Nitrite in Pneumonia.

HAYEM (*Sem. Méd.*, October 11th, 1895) describes the treatment of 77 cases of pneumonia by inhalations of amyl nitrite. It is generally agreed that this drug should be used with great caution, 4 or 8 minims having hitherto been considered as a large dose. Hayem's experiences show that a much larger quantity may safely be used. For a single inhalation he gives 60, 80, or even 100 minims. These are administered 15 minims at a time on a compress held 2 or 3 centimetres from the patient's mouth; the whole inhalation lasting from three to five minutes. In ordinary cases one inhalation a day suffices; in severe cases two, given morning and evening, are better. No accident ascribable to this treatment has followed. The inhalations are continued throughout the illness and for one or two days after the crisis has occurred. The drug does not seem to influence the duration of the disease or the temperature; the effect produced is purely local, consisting of a diminution, more or less marked in the dyspnoea, in a modification of the sputum, which becomes less viscous, and in a diminution of the stethoscopic sounds. It does not seem to affect the virulence of the pneumococci; its action seems to be exercised entirely on the pulmonary circulation, which is probably subject to a sudden flushing with blood, analogous to that occurring in the skin, which hastens the return of the blood by the pulmonary channels and promotes the absorption of the exudation. In eighteen months 77 patients were treated in this way, the deaths numbering 16. A large number of these were bad subjects, being drinkers or confirmed drunkards. Neuritic subjects bear the treatment badly owing to the fears they entertain. It is highly important that during the inhalation the patient should be in the recumbent position.

PATHOLOGY.

(477) A Toxic Substance extracted from the suprarenal Capsules.

GOURFEIN (*Rev. Méd. de la Suisse Rom.*, October 20th, 1895) gives the results of his researches. The method at first used to isolate the substance was to precipitate a glycerine extract of the capsules by alcohol. Later, as the

glycerine itself proved to some extent toxic, he devised the following method: Cut up and triturate the suprarenal capsules of oxen, calves, or sheep in a mortar with a little water; pour several volumes of warm water over them, and leave in a water bath for a quarter of an hour; filter and add to the filtrate the liquid obtained by pressure from the residue on the filter; evaporate in a water bath to a syrupy consistence, and add four times its volume of alcohol; leave the mixture for twenty-four hours in a cool place and filter. The precipitate by alcohol (chiefly albuminoids), when redissolved in water and injected into animals subcutaneously is quite inactive, but the residue obtained after evaporating the alcoholic liquid is very toxic. This substance, which is not destroyed by heat, injected hypodermically into animals produces a series of constant symptoms. (1) Green frogs, after an injection of a quarter of a Pravaz syringe, become motionless immediately, but are not paralysed, as mechanical irritation of the foot causes reflex action. This weakness increases; if placed on the back the animals cannot turn over again. Respiration is first slowed, then accelerated and weakened, and finally stops. The heart is affected later; in 20 experiments the auricles continued beating twenty to thirty minutes after death. The spinal cord and motor nerves do not lose their electric excitability for three or four hours after death, which ensues a quarter to three hours after the injection. In those frogs where the glycerine extract was used tetanic convulsions also set in. These proved to be due to the glycerine, as in control experiments where glycerine and water (1 to 4) was injected the same convulsions occurred without being fatal. (2) Mammals. The first symptom, after injecting from $\frac{1}{4}$ to 1 Pravaz syringe of the extract subcutaneously in white rats, mice, guinea pigs, and rabbits, is dyspnoea, which progresses till death takes place. Inspiration is prolonged, expiration is short and forcible. Extreme weakness, caused by depression of the central nervous system, is present, but no paralysis. General sensation and the sensorium are intact. Electric excitability of motor nerves lasts fifteen to eighteen minutes *post mortem*, but the vagi are paralysed. If artificial respiration is used in rabbits they die later through paralysis of the heart. Animals which are able vomit repeatedly soon after the injection, this being preceded by copious salivation. The toxic substance, however, is not excreted in the saliva as when precipitated by alcohol; evaporated and injected into mice hypodermically it produces no symptoms. No diarrhoea or intestinal symptoms were observed. In all the experiments on mammals paralysis of the respiratory centre was the principal cause of death. Convulsions were frequently present, but were asphyxial. *Post mortem* the lungs are found congested, the heart flaccid in diastole, the stomach and intestines sometimes hyperemic. Twenty control experi-

ments where hypodermic injections of extracts of spleen and muscles of the same animals, and prepared in the same way as the suprarenal extract were given to cold and warm-blooded animals, proved that these produce at most a slight *malaise*. The proportion of the active substance present in a given quantity of capsules is very variable, the length of time the animals survive the injection being proportional to this toxicity. Cold-blooded animals are less sensitive to the extract than warm, probably owing to their cutaneous respiration. The author's results differ from some of those obtained by Gluzinski (*Wien. klin. Woch.*, No. 14, 1895), who observed immediately after the intravenous injection of a glycerine extract paraplegia with anaesthesia of the posterior limbs and slight convulsions or even opisthotonos in the anterior half of the body, while hypodermic injection caused only a slight illness with rigors. Vomiting is not mentioned by him.

(478) The Blood Changes in Gastric Disorders.

BLINDERMAN (*Wien. med. Blatt.*, October 31st, 1895) has investigated the blood of 18 patients in Wassiljeff's clinic. Eight of these had chronic gastritis, 2 acute gastritis, 4 gastric ulcer, 4 carcinoma of the digestive tract. In acute gastritis the blood was found to be normal, in chronic gastritis the red corpuscles were normal in number or slightly diminished, the white corpuscles unaffected. In gastric ulcer the leucocytes were normal, the red corpuscles diminished except in one case where hæmatemesis was absent; in the others the diminution was exactly proportional to the amount of hæmatemesis, chlorosis, and melæna. In the cases of malignant disease, however (3 of which affected the stomach and 1 the rectum) there was great diminution in the number of red corpuscles, with (except in 1 case) increased leucocytosis. The percentage of hæmoglobin was much more reduced than in gastric ulcer. Blindermann concludes that: (1) Examination of the blood always affords a means of diagnosis between cancer of the stomach and other gastric disorders, particularly chronic catarrh and dilatation; (2) with rare exceptions the differential diagnosis between cancer and ulcer of the stomach is much simplified by microscopical examination of the blood; (3) in malignant disease of the stomach the diminution in hæmoglobin progresses steadily, whereas in gastric ulcer there is a sudden great drop after hæmatemesis, followed in a few days by return to normal. The only exception to the latter rule is in the rare cases in which pernicious anæmia supervenes; this may be recognised by the constant diminution of hæmoglobin, the number of the red corpuscles, and the presence of poikilocytes, microcytes, and macrocytes; (4) chronic gastric catarrh with marked dilatation causes no definite changes in the constitution of the blood.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(4123) Gastroscopy.

ROSENHEIM (*Dent. med. Week.*, November 14th, 1896) first discusses the position of the cardia and the course of the lowest part of the esophagus. He concludes that the usual position of the cardia in the adult is opposite the twelfth, rarely the eleventh, dorsal vertebra. The anatomical relations are important in respect to the gastroscope. He maintains that where it is impossible to pass a stiff tube into the stomach with the patient in the dorsal position, the difficulty is due to muscular cramp or to the physiological bend at the esophageal foramen in the diaphragm. By introducing the rigid tube from the right side of the mouth, and pressing the point to the left, the lowest part of the esophagus can be most readily passed. A certain gentle pressure may be necessary, and a change in the patient's position from the back to the right side may facilitate it. In a minority of cases with disease involving the cardia the parts may not be distinctly seen by the gastroscope without an anesthetic. The author then refers chiefly to Mikulicz's investigations into gastroscopy. This authority used a curved tube in order to overcome the difficulty of passing through the lowest part of the esophagus; he thought that it was impossible to accomplish this with a straight tube. This curve introduces difficulties in respect to the optical arrangements. The author maintains that the optical apparatus should be in the straight line. His observations lead him to say that in nearly 70 per cent. of the cases examined by him a straight gastroscope can be passed into the stomach. Under certain conditions, such as an abnormal curving of the esophagus due to pathological causes, it may be impossible. A local spraying with cocaine by means of a special apparatus has been tried by the author to overcome the cramping, but with indifferent success. He concludes that with few exceptions it is possible with a straight or slightly curved instrument to get deep enough into the stomach for purposes of purposes without an anesthetic and without doing any injury. One gastroscope will not suit all cases, but a straight instrument suffices in by far the majority of cases. The author gives details of his gastroscope, which is made by Hirs Kamm, of Berlin.

(4124) Gonorrhoeal Pleurisy.

FAHRETT (*Arch. clin. de Med.*, October, 1896) first refers to the cases reported previously in 1878 when Telson denied the existence of any conclusive example of this disease. He then mentions the case of Cornil and Klippel, in which a

young woman with gonorrhoea had a pleural effusion. At the necropsy, besides the effusion there was pus in the Fallopian tubes, but no micro-organisms were demonstrated in it. The connection between the two diseases was open to some doubt in this case. In Baisle's case there was gonorrhoeal rheumatism as well as evidence of a pericarditis and a dry pleurisy. In Ducroy's case a young man was seized with fever a few days after acquiring a gonorrhoea. First a right then a left pleurisy developed, later the knee and thumb joints were involved, and eventually the peritoneum was implicated. The effusion rapidly disappeared. In MacDonnell's case a young man had an acute gonorrhoea some four months previously. He had a further attack four weeks before his present illness. After exposure to cold he had pains in the knees, thumb, etc., and a double friction sound was heard over the base of the heart. Later he had an effusion into both pleural cavities. The patient made a good recovery. MacDonnell believes this to be an example of a gonorrhoeal affection of the serous membranes, because (1) there had been no previous rheumatic manifestations; (2) the temperature was only raised at the onset of the cardiac and pleuritic symptoms; (3) the articulations were but slightly affected, and (4) there was no sweating. The case of Mazza is more convincing. A girl, aged 11, had been raped by a man suffering from gonorrhoea. A few days later she had a polyarthritides and a double pleurisy. It is said that there was also evidence of an endo-pericarditis. Mazza found the gonococcus, both morphologically and by culture, in the pleuritic fluid. The author lastly discusses how the gonococcus could get to the pleura. It must be assumed that it is carried by the blood, as its presence there has now been demonstrated by several reliable observers. The investigations are too few to determine whether the effusion is always due to the gonococcus itself or to secondary infections, or whether even the gonococcus toxins play any part in producing the complications.

(4125) A New Method of Estimating Albumen in Urine.

RIEGLER (*Wien. med. Blätter*, November 28th, 1896) brings forward a new and rapid method of estimating albumen by means of the refractometer. It depends upon the power of his new reagent, aspirin, to precipitate all albuminous substances in acid solution; the precipitate is soluble in weak caustic soda or potash, and the refractive index of the solution bears a direct relation to the amount of albumen present. In practice the aspirin (10 per cent) is made up with 10 per cent. concentrated hydrochloric acid. Exactly 25 c.cm. of decinormal potash solution are used, and added to the precipitate resulting from the mixture of 5 c.cm. of urine with 5 c.cm. of urine. The refractive indices of the resulting fluid (after filtration) and of the potash solution are determined by Füllrich's re-

fractometer, and their difference multiplied by 270 gives the exact percentage of albumen present. The coefficient 270 was determined by Riegler as the result of experiments on measured quantities of albumen.

SURGERY.

(4126) Intubation in Diphtheria.

BOKAI (*Dent. med. Week.*, November 14th, 1896) discusses the question of how long the tube must remain *in situ*, his observations being based on 743 cases of intubation. Of the 763 cases, 286 recovered. Ninety cases, with 45 recoveries, have occurred since the introduction of the serum treatment. Out of the 673 before the serum treatment, 225 recovered, and only in 8 cases was a secondary tracheotomy necessary. The duration of the intubation was from a quarter of an hour up to 240 hours, except in 7 cases, where it exceeded 10 days. In 62.77 per cent. the tube was in under 72 hours, and in 82.35 per cent. under 120 hours. The author gives details of cases in which the duration was under 24 hours, and also of 2 cases in which it was 340 and 360 hours respectively, the latter being the longest time. The mean average duration was 79 hours in the 215 cases. It is the author's custom to withdraw the tube after 48 hours; in the 27 cases where the tube was out before this time, it was due to the child expectorating it or pulling it out by the string, and to the further introduction being deemed unnecessary. In the 45 intubated cases of recovery under the serum treatment, a secondary tracheotomy was only once necessary. The minimum duration of intubation was 2 hours, the maximum 168 hours. It 77.26 per cent. of these cases the tube was left out within 72 hours. The author gives tables which show that under the serum treatment the number of cases in which the tube can be left out within the first and second 24 hours is greatly increased. He compares these figures with those obtained from observations on withdrawing the cannula in tracheotomy, where the results are very different. Although the tube remained in over 5 days in 10.2 per cent. of the author's intubated cases, yet there was no case of severe decubitus (proton) in the larynx. Thus secondary tracheotomy can be avoided. If the above numbers are added to those of Bleyer and Barr, it is found that out of a grand total of 470 intubated cases the tube remained in longer than 5 days in 12.2 per cent. The author then discusses the relation of this length of time to the question of decubitus. Finally he draws the following conclusions: (1) That the time for withdrawing the tube varies within very wide limits; (2) that the average time was 79 hours before and 61 hours after the introduction of the serum treatment; and (3) that he cannot share the opinion of some writers who maintain that a secondary tracheotomy must be done if the tube cannot be left within 5 days. No definite fixed time can be laid down. The unquarantined

presence of severe decubitus in the larynx is an undoubted indication for a secondary tracheotomy, but the mere fear of such arising should not be taken as an indication.

(477) Iodoform Ointment Injections in Suppurating Abscess.

J. R. HAYDEN (*Amer. Journ. Med. Sci.*, November, 1895), treats suppurating abscesses by a modification of Fontan's method (see Espleux, *Thèse de Montpellier*, April, 1889). The following are the details: (1) The field of operation is shaved and rendered surgically clean in the usual manner. (2) A few drops of a 4 per cent. solution of cocaine are injected beneath the skin where the puncture is to be made. (3) A straight sharp pointed bistoury is then thrust well into the most prominent part of the swelling until pus flows. (4) All the pus is forced out through this opening by firm but gentle pressure. (5) The abscess cavity is irrigated with pure peroxide of hydrogen until it returns perfectly clear. (6) It is then irrigated with 1 in 5,000 bichloride of mercury solution, all of which is carefully squeezed out. (7) The now thoroughly cleansed cavity is completely filled, but not painfully distended, with 10 per cent. iodoform ointment, by means of an ordinary conical glass syringe, previously warmed in hot water. (8) A cold wet bichloride dressing is applied with a fairly firm spica bandage, the cold congealing the ointment at the wound, and thus preventing its escape into the dressing. The patient should be kept very quiet for the first twenty-four to forty eight hours, rest in bed being preferable, though not absolutely necessary. The dressing is removed at the end of the third or fourth day and the parts examined; if pus has reaccumulated or the ointment escaped into the dressing a second injection may be made. If all looks well, however, the first dressing is replaced by a gauze pad and spica bandage, and the patient is told to report himself in two or three days for examination. In fifteen cases treated in this way by the author, suppurative action and pain ceased after one injection of the iodoform ointment in all but two; in those the injection had to be repeated on account of a slight reaccumulation of pus. In order to get the best results from the method, it should be employed only when the glands are thoroughly broken down, so that the iodoform may come into direct contact with all the infected tissues.

(478) Bier's Treatment of Articular Tuberculosis.

Riess (*Berliner Klinik*, November, 1895) discusses the advantages of his method of treating tuberculous diseases of joints, which consists in establishing a chronic congestion of the affected structures by firm and prolonged constriction of the limb on the proximal side. In this lecture instructions are laid down for the application of this method to different parts of the body, and tables are added showing the results of the treatment in 52 cases of disease of the knee and wrist. A long ex-

perience of his method of dealing with tuberculosis in joints has convinced Bier that it is one of the most effectual means of dealing with this disease, and merits more attention than it has hitherto received. It is capable, he states, of restoring in the course of a few days the function of a painful and crippled joint, and is preferable to other conservative measures, such as rest and the local use of iodoform, with which, however, it may be associated. At the same time, he acknowledges that this is not a universal cure in cases of tuberculosis, and that it has its drawbacks and failures. Much stress is laid on the necessity, during this treatment, of an early recognition and a strict antiseptic treatment of cold abscesses. Congestion of the lungs, it is well known, not only affords a high degree of immunity against pulmonary phthisis, but may also, when developed in the course of this disease, effect a cure. It might be anticipated, then, that tuberculous disease of a joint would be similarly influenced when submitted to the action of a much more energetic hyperemia than would under any circumstances occur in the lung.

(479) Mustard as an Antiseptic.

ROSWELL PARK (*Med. News*, November 16th) some time ago (*Ibid.*, December, 1894) called attention to the remarkably efficient properties possessed by mustard as an antiseptic or sterilising agent for the surgeon's hands and for the skin of the parts to be operated upon. His custom is to scrub his hands thoroughly with a mixture of green or other soap, corn meal, and mustard flour, using this for about five minutes. After rubbing it thoroughly into all the crevices and creases of the hands and nails by aid of a nail brush, one may be absolutely certain that his hands are sterilised, no matter what he may have been doing previously. Roswell Park has no hesitation in proceeding from a necropsy to the operating room if he thus protects his hands. Used as indicated the mustard leaves no unpleasant sensation; and one may feel that by the time it produces unpleasant tingling or rubefaction of the skin its essential oil has done its desired work as an antiseptic. He has discarded all other means of preparing the hands, and in several years' use of mustard in this way has never been disappointed, nor had the slightest reason to question its effectiveness. He adds that mustard is an admirable deodorising agent, and will take away from the hands all offensive odour of dead or dying tissues, all redolence of iodoform, etc.

MIDWIFERY AND DISEASES OF WOMEN.

(480) Total Abdominal Hysterectomy.

RICHELOT (*Presse Méd.*, November 2nd, 1895) advocates complete abdominal hysterectomy for uterine fibroids, as operations in which a pedicle or stump is left have many disadvantages—for example, hæmorrhage from or

suppuration round the stump. He operates as follows: After the uterus has been pulled out through the abdominal wound, the next procedure depends on the number and position of the fibroids. If they are numerous or contained in the lower segment of the uterus, it would be folly to attempt to place forceps on the distorted broad ligaments. In such atypical cases he practises a preliminary removal of every fibroid which is in the way. Those with a pedicle are cut off with scissors, the interstitial ones enucleated, and lastly, the large fibroids in the lower segment are enucleated or removed piecemeal through a median incision. The uterus then becomes flaccid, and can be raised out of the true pelvis, while the broad ligaments can be depressed at will. The hysterectomy proper then begins. Standing at the woman's left side, he opens the anterior *cul-de-sac*, guiding the incision by the finger of the right hand in the vagina. There is no danger of infection if antiseptic precautions are taken. The advantages of opening the anterior *cul-de-sac* alone are (a) the tumour need not be pulled forward; (b) there is no dissection of or bleeding from the posterior edge of the vagina; (c) a saving of time. Next, large curved pressure forceps, such as are used in vaginal hysterectomy, are applied to the broad ligaments by the following method, which is said to be very easily carried out. Standing at the woman's right side he makes a narrow opening with blunt-pointed scissors in the base of the broad ligaments, close to the cervix, and just above the vaginal insertion. This is well above the ureter. The forceps are then introduced *per vaginam*, and their posterior blade is made to pass through the opening made in the broad ligament. They can then be passed upwards and made completely to grasp the ligament with the uterine artery, which are never too high to reach if the inferior segment is free or if a preliminary enucleation has been practised. This done on each side the uterus is detached by cutting through the posterior insertion of the vagina. This usually causes considerable hæmorrhage, which the author completely stops by pressure forceps introduced *per vaginam*. As regards dressing he introduces plugs of iodoform gauze through a speculum, which accurately fill out the vaginal wound. The abdominal wound is then sutured, and the operation is finished, the result being exactly the same as in a vaginal hysterectomy. The small openings made in the broad ligaments and the method of placing the forceps on the broad ligaments distinguish this operation from all others.

(481) Cholera and Pregnancy.

KOVALSKY (*Répert. Univ. d'Obstét. et de Gynéc.*, October 25th, 1895) after considering the experience gained in Russia on this question, concludes that pregnancy does not appear to predispose to cholera, though the small percentage of cholera cases amongst pregnant women is explained by the small

number of such women relatively to the general population. The prognosis is extremely grave for the fetus, and the mortality of 81 per cent. is, perhaps, lower than might be expected. As for the mother, the danger does not seem much greater than in a non-pregnant subject; 57.8 per cent. is the proportion, according to experience, in Russia. Between 20 and 40 seems the most susceptible age. This represents the greater part of sexual life. It is not clear why younger pregnant women should be less subject to cholera. Most probably the truth is explained by the number of married women over 20 being relatively larger. Kovalsky frankly admits that no ratios of any kind of scientific value can be established between the presence of cholera and the period of pregnancy, the previous sexual history of the mother or any other essential obstetric factor—even the possibility of abortion.

(1407) Ovariotomy in a Child aged 6.

REIN (*Repert. univ. d'Obstet. et de Gynéc.*, October 25th, 1895) operated successfully, at Kieff, on a girl aged 6. The tumour was a multilocular cyst of the left ovary. On the third day the patient's period ("règles") appeared. It is noted in the report that puberty was premature in this case, Rein believing that the abnormal phenomenon was the cause of the development of the cyst. The author, however, does not state that any symptom of precocious maturity was noted before the operation. Recovery in this instance was rapid. Childhood and infancy, Rein remarks, are favourable to laparotomy. Fenomenoff has successfully performed abdominal section on a newborn child.

THERAPEUTICS.

(1408) A Case of Pancreas Administration.

BORMANN (*Wien. med. Blatt.*, October 17th, 1895) points out that the treatment of diabetes with pancreatic extract has hitherto been productive of no very striking results. According to Brown-Séquard the pancreas has two functions—that of producing a glycolytic ferment—pancreatin—and that of providing the body with a specific and indispensable internal secretion. If the perverted function of the pancreas is simply a diminished production of pancreatin, it is easy to supply by substitution therapeutics the deficient pancreatin to the organism. If, on the other hand, the affection is atrophy of the gland parenchyma, it is very probable that the administration of preparations of pancreas will fail, since there is no means of ascertaining whether they contain the specific secretion. Bormann records a case in which a definite result was obtained by pancreas therapeutics. The patient was a man of 30, who had for many years suffered from general symptoms, with cough and furunculosis. Physical examination showed the condition to be one of diabetes mellitus,

with chronic bronchitis and visual complications. About 3,600 c.c.m. of urine, having a specific gravity of 1025-1018, and containing 80 g. of sugar, were passed daily. For twenty-four days he was treated first by dieting alone, then with the addition of apomorphine, salicylate of bismuth, and opium. These reduced the quantity and specific gravity somewhat; the amount of sugar fell to from 30 to 110 g. daily, but the patient lost weight. He was then put on one ox's pancreas (roasted) a day; after a week he stated that he could not go on eating it, so the juice was expressed and half a gland given daily *per victum*. Ten days later 1½ c.c.m. of pancreas extract subcutaneously was substituted for this. When he left the clinic after five weeks' pancreas treatment the sugar was below 30 g. daily, the minimum being 14.6. The patient was much better in himself, his bodily strength had considerably increased, he had gained 8½ lbs. in weight, and the thirst, together with the daily excretion of urine, had greatly diminished. Bormann thinks that if the literature of pancreas therapeutics could be brought into line with that of the thyroid treatment, and the method thus placed on a physiological basis, an effective and constant preparation might be obtained and employed.

(1409) Iron as Food and Drug.

STOCKMAN has made some fresh estimations of the amount of iron in various ordinary diets (*Jour. of Phys.*, November 16th, 1895). He found that the quantity of iron in the ordinary daily diet of healthy persons with good appetite averaged from 8 to 10 or 11 mg. a day (about ½ gr.). The convalescent diet of the Edinburgh Royal Infirmary, a sufficient maintenance for persons leading a somewhat inactive life, contained 6 mg. a day. In the diet of a young lady living in the ordinary way and taking an average amount of food, 8 mg. was found in the daily diet, while in that of two chlorotic girls who ate very little, the quantity of iron averaged 2.6 mg. a day (four estimations). From a consideration of the amount of iron in ordinary diets, Stockman is led to observe that the iron metabolism of the body must be small. Very little can be excreted, and the great bulk must be retained in the body and used over and over again. The total excreted daily by all channels is, he concludes, less than 6 mg. a day. When the red blood corpuscles break down, although their pigment is to a large extent excreted in the urine and bile, a large part of their iron must be retained in the liver and spleen, where it is gradually used for the formation of new red corpuscles—Quinke observed at the last German Medical Congress (*Verhandlungen*, 16th Congress, p. 167) that the amount of iron in the preparations in ordinary use was often forgotten, and he gives a table showing the percentage of iron in a large number of German official and unofficial preparations. Thus the citrate of iron and ammonia contains 1 gr. of

iron in 6 gr. of the salt. The *Liquor ferri perchloridi* of the *British Pharmacopœia* contains 1 gr. in 32. When it is desired to promote the absorption of iron, Quinke considers it important that the iron preparation chosen should be in a very dilute solution when it comes into contact with the gastric mucous membrane; this end may be attained either by giving the drug with food or freely diluted. He recommended the administration of iron by subcutaneous injection in cases of anæmia in which gastralgia or other gastric or intestinal disturbance placed obstacles in the way of the administration of most iron preparations by the mouth. He uses a 5 per cent. solution of citrate of iron; it produces very little local reaction and is quickly absorbed. He gives in this way from ½ to 1½ gr. daily (℥ xv to xxx). *Liquor ferri perchloridi* (Denayer) is also very little irritating when injected hypodermically, and is of about the same strength in iron as the 5 per cent. solution of the citrate. The ammonium citrate should not be used as it is very much more irritating than the citrate.

(1410) Bromhydrate of Arecolin.

MOUQUET (*Nouvelles Remèdes*, November 24th) states that bromhydrate of arecolin, an alkaloid extracted from areca nut, has a powerful sedative and diaphoretic action, and markedly stimulates intestinal peristalsis in horses and other animals. It has the same properties as eserine and pilocarpin, but in a higher degree, and the indications for its use are the same. Given hypodermically in doses of 2 centigrammes to 15 milligrammes it is found useful in animals, especially in the treatment of intestinal indigestion. Areca nut, though largely employed in veterinary practice, is little used in human medicine. The editor of the *Nouvelles Remèdes* suggests that arecolin might be worth trying on the human subject, but it would be prudent to begin with very small doses, such as 2 to 4 milligrammes. Areca nut is said to be a powerful anesthetic, the administration of which does not require to be preceded by a purge. It can be taken in milk or in soup without any unpleasant taste being perceived.

(1411) Amydophosphite.

SZÉVE, of v. Noorden's clinic (*Centralbl. f. inn. Med.*, November 16th, 1895) describes the therapeutic action of this paramide-phosphite derivative. It is a greyish-white powder, which dissolves with difficulty in water. (1) As an antirheumatic. It was tried in 20 cases. In 7 out of 11 acute cases a distinct remission of pain and diminution of muscular swelling were noted on the second day, and in almost all cases had disappeared in four to six days. Delirium occurred by hypæmia. The recovery was permanent, a relapse being noted in only 1 case. In 1 of the 4 remaining cases it was found less efficacious than usual; 5 g. produced slight vertigo on the second day; the remedy was continued in smaller doses, and im-

provement steadily progressed. In another case recovery was still more interrupted. A good effect was noted in a severe case of aortic disease with intercurrent rheumatism. Amygdophenin was entirely without effect in only 1 case. The remaining 9 cases were without fever; in 5 of these considerable improvement was noted, and recovery occurred in a few days. In 1 case other measures had to be employed in addition to the use of the drug. In 2 cases without objective joint signs the pains rapidly disappeared. In another similar case there was no improvement. (2) As an antipyretic. Amygdophenin in the doses employed by the author had no very distinct antipyretic effect. (3) As an antineuralgic. It was employed in many cases of headache, etc., with good results. In cases where the pains were due to central nervous disease, amygdophenin proved to be of service. It was used in doses of 1 g. once or more in the day up to a maximum daily amount of 8 g.; 4 g. per diem continued for some time produced no bad result. One woman had slight vertigo after 3 g. in the day. In 1 case tinnitus occurred after 8 g. in the day; it disappeared when the dose was lessened. No skin eruptions were noted, and no digestive or renal disturbances. Sweating occurred in three patients, and only after the larger doses. The author has used the remedy during the past six months in a number of rheumatism, and it was hardly ever necessary to have recourse to any other treatment.

(457) The Antitoxin Treatment of Diphtheria.

FORTUN Y ANDRÉ (*Rev. de Ciencias Médicas de Habana*, November 5th) reports the results of the serum treatment of diphtheria in Havana so far as he has been able to collect the statistics. The cases amount to 88, of which 12 died, a mortality of about 14 per cent. Of the fatal cases, however, 6 died within less than twenty-four hours after the serum was used; deducting these cases, the mortality under the treatment is reduced to a trifle over 7 per cent. All the fatal cases with one exception were cases of croup; in only 1 of these was tracheotomy performed. Of the cases that recovered, only 9 were cases of "true croup"; of these 2 were tracheotomized. In point of intensity the 88 cases are classified as follows: severe, 35; moderate, 34; slight, 20. In 74 of the cases the diagnosis was established bacteriologically; in 6 of the cases Loë's bacillus was associated with streptococci and staphylococci. The effects of the serum were the same as those observed elsewhere. As regards unfavourable consequences, albuminuria was noted as following the injection only in 2; in 4 of the cases in which it was present before treatment was begun, it diminished after the injection and in 1 it altogether disappeared. In 4 cases the phenomena of reaction (rise of temperature and constitutional disturbance) were somewhat alarming; eruptions of various types were seen in 20 cases; symptoms of

enteritis in 4; joint pain in 2. Serum from three different sources—Roux's in 15 cases, with 1 death; Behring's in 35, with 6 deaths; and serum prepared in Havana by Drs. Davalos and Acosta, and having a strength double that of Roux's, in 27 cases with 3 deaths. The author is unable to give exact statistics of the death-rate from diphtheria in Havana before the introduction of the serum method, but he says there is no doubt that it has diminished since the employment of antitoxin. He gives details of all the cases, with the names of the practitioners in whose care the patients were.

PATHOLOGY.

(458) The Conditions Regulating the Production of Poison in Diphtheritic Cultivations.

SPRONCK (*Annales de l'Institut Pasteur*, October 25th, 1905) has investigated the causes of the well-known differences in the amounts of toxin produced by diphtheria bacilli grown under apparently precisely the same conditions. Owing to want of space he was not able to grow the bacilli in thin layers of bouillon, but was compelled to use cylindrical vessels with straight necks plugged with wadding. The layer of bouillon was 4 inches deep; it was prepared from veal or beef, alkalinized with sodium carbonate, and peptonized with 2 per cent of Witte's peptone. In the series of experiments all the conditions were identical except for the differences in the bouillon which will be mentioned. The course of development of the culture can be classified under three types: (1) Acidity soon appeared, persisting for weeks or months. The liquid became clear, the bacilli dying and sinking to the bottom. When this had occurred the toxicity became and remained extremely feeble. (2) The bouillon never became acid, but remained turbid, with a thick deposit at the bottom and a whitish scum on the surface. After a while the alkalinity gradually increased, and the toxicity at the end of two or three weeks was extremely powerful. (3) After a few days the bouillon became acid and clearer; in a short time more the alkalinity and turbidity returned, and toxic properties developed to a considerable extent, though not so great as in (2). These differences depend upon the freshness of the meat from which the bouillon is prepared; the toxicity varies inversely with the amount of glucose present and directly with the length of time which the meat has been kept before cooking. Thus perfectly fresh beef (veal being still less good, and horse-flesh, according to Smirnow, yielding almost no toxin under any circumstances) approaches the first type, while meat which has been kept till the inception of decomposition is of the second, the third being intermediate. This has been confirmed by using different portions of the same joint, which by alterations in the time of keeping

could be made to furnish varying amounts of toxin. Furthermore, addition of glucose was found to inhibit the toxicity of the products of diphtheritic growth even in bouillon made from quite stale meat. Spronck therefore suggests that the most convenient method of obtaining strong toxin is to eliminate the glucose in the meat by keeping it till decomposition commences before making it into bouillon. He further considers that it is not yet certain that the antitoxin neutralization method of Roux and Yersin is in all cases necessary, or indeed advisable, when a material of powerfully toxic properties is required.

(459) Persistent Thymus in Exophthalmic Goitre.

HERTON (*Internat. Med. Mag.*, September, 1905) first briefly reviews the various theories put forward to account for this disease. He then reports a case in a girl, aged 20, where death was due to uncontrollable vomiting. The disease of which the symptoms were mostly characteristic only lasted three years. The tissues over the anterior aspect of the lower third of the leg are described as having been swollen elastic like myxodema, and a little tender on pressure. No coarse lesion was found in the central nervous system. There was no definite minute lesion in the medulla, cervical sympathetic, or in the tenth nerve. The hypophysis was healthy. The thyroid body weighed 100 g., and the microscope showed that the glands had increased in greater proportion to the glandular element. The thyroid cells were altered in shape and rather granular-looking, and some tubules had atrophied. The kidneys presented slight morbid changes, and all cellular structure had disappeared from the mucous coat of the stomach, but the author thinks this a post-mortem change. The thymus measured 6 mm. in its greatest thickness, 9 cm. in the vertical, and 6 cm. in the horizontal diameter. The microscopic appearances were such as are seen in an active thymus of a very young person. Not a single concentric Hassall's body could be found. There were no inflammatory changes in the connective tissue. How far the kidneys were responsible for the uncontrollable vomiting, if at all, remains a matter of conjecture. The author then refers to the various changes which have been found in the thyroid in Graves's disease. Here there were hyperplastic changes in both interstitial and glandular tissues, the former predominating. Proliferation of the epithelial lining of the follicles was marked, colloid material scanty, and the vesicles were slightly dilated. The author also quotes the various writers who have found a persistent thyroid in Graves's disease. Most of them do not attempt to explain it, but Marie holds that the thymus may undergo vicarious hyperplasia in diseases of the thyroid and hypophysis. The author thinks that this persistent thymus has been noted too often in Graves's disease to be merely an accidental occurrence.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(189) Myocarditis in Alcoholism.

AUFRECHT (*Therapeut. Monatsheft.*, November, 1895) discusses the symptoms and treatment of alcoholic myocarditis. The history, together with shortness of breath, increased cardiac dulness, irregularity of pulse, and perhaps a soft systolic *bruit*, are the characteristic features of the condition; enlargement of the liver and albuminuria may aid the diagnosis. General oedema and ascites may be present, and it is particularly to be noted that the prognosis is not necessarily made worse thereby; even in cases where repeated paracentesis abdominalis is necessary, the prognosis is by no means so unfavourable as is often asserted. Absolute abstinence from alcoholic drinks is the first essential in treatment, and no evil results from the sudden abstinence even in the most inveterate drinkers; indeed, the best results have followed in severe cases from immediate abstinence. Residence at a spa may be advantageously combined with this; and in some cases rest in bed may be necessary for irregularity of the heart. The sovereign remedy in all cases of heart failure from alcoholism is digitalis. In some cases diuretin is valuable in reducing oedema, and with this may be combined the use of warm baths. Complete recovery may be looked for where only the early heart symptoms are present, and, indeed, even where there is enlargement of heart and liver with albuminuria, if only of short standing; in cases where there is hypertrophy of the heart with interstitial hepatitis and chronic albuminuria, improvement may be considerable and the patient may live for years.

(191) Bronzed Diabetes.

This affection, described for the first time in 1882 by Hanot and Chausard, is the subject of a more extended study by Dutournier (*Journ. de Méd.*, October 10th, 1895). At the beginning this form of diabetes does not seem to present any special feature. Thirst, polyuria, glycosuria, and great appetite are present in variable intensity. In some cases pulmonary symptoms, such as intense bronchitis, are present from an early date. But at a period somewhat difficult to accurately determine the chief sign of the affection appears—pigmentation of the skin. When this is established, the principal features of the case are, besides pigmentation, diabetes, cirrhosis of the liver apparently hypertrophic in character, and very rapid cachexia. Later on a more or less marked ascites occurs, which may call for drainage of the abdominal cavity. Dryness of the mouth, inflammation of the gums, etc., are even more marked than in the ordinary form of diabetes.

The pigmentation of the skin, which forms the salient feature, is described as a uniform lead colour or a dark grey, not unlike that seen in argyria. It is uniform in distribution, and rarely are there any points of hyperpigmentation, although there may be a somewhat deeper coloration of the back of the hands and forearms. Pigmentation of the mucous surfaces seems to be very exceptional, only one instance being on record. The writer draws special attention to the constant and rapid cachexia observed in these cases, characterized by rapid wasting, extreme weakness, and inability to do anything. This weakness appears at the same time as the pigmentation of the skin, and differs from that usually seen in diabetes by its earlier appearance, its greater intensity, and its rapid fatality. The duration of bronzed diabetes is never long, rarely exceeding eight or ten months, two years being quite exceptional. At the same time it may remit to a slight degree, remission being always followed by more rapid symptoms. Death seems to take place by coma or profound cachexia. The nature of these cases and their relation to the ordinary form of diabetes, is quite uncertain. *Post mortem* marked cirrhosis of liver, accompanied by great accumulation of pigment, pigment granules, sclerosis and pigmentation of the spleen, pancreas, lymphatic glands and lungs have been found. The kidneys appear relatively healthy. The pigment seems to be of hematic origin, and is intravascular, intracellular, and interstitial. The author suggests that in these cases there is a decomposition of hemoglobin brought about by some as yet unknown cause.

(192) Infantile Progressive Paralysis.

BRESLER (*Neurol. Centralbl.*, December, 1895) reports a case of general paralysis in a girl, aged 13½. Strong family history of insanity; child backward in bodily development; went to school at 6 years old, and made fair progress, but after four years expelled as unruly and unteachable. Illness began fourteen months before patient came under observation with chorea. When first seen dull and passionate; markedly restless and nervous when watched; articulation normal; special senses normal; no paralysis; knee-jerks exaggerated; occasionally had refused food, and had been dirty in habits; reading and sewing, learnt at school, had been lost for last three years. After three months the child had become more dull, taking no interest in surroundings, nutrition steadily falling. At the end of four months weakness had become so marked that the patient was confined to bed; slight facial paresis; bed sores formed. Restlessness more marked, some loss of consciousness, and rise of temperature. Two convulsions then occurred, and death followed a week later. At the necropsy: thickening of dura mater; wasting of convolutions; surface of brain pale grey, substance hard cutting like liver; superficial layer could be stripped off like the skin

of a roasted apple. The writer points out that the recorded cases are mostly in girls—that in one other case the disease began with choreiform movements. In the present case the absence of bulbar symptoms, that is, of difficulty in articulation, and of ideas of grandeur is interesting. As to cause, syphilis, the probable important factor in many of the recorded cases could not be excluded here, and there were some appearances in the liver *post mortem* which seemed to point to it.

SURGERY.

(193) The Plurality of Osteomyelitis.

LANNELONGUE, who was the first to teach the microbic and clinical plurality of osteomyelitis, has recently communicated to the French Congress of Surgeons (*Séminaire Médical*, October 2nd, 1895) a report of the relative frequency of the different forms of this affection as shown in 60 cases under his care. *Staphylococcus* forms were found in 69 cases, the orange-coloured microbe being five times more abundant than the white. The streptococcus pyogenes was found in 10, and Eberth's bacillus in 4 cases. The streptococcus and pneumococcus, it is stated, have a decided predilection for young subjects. Each microbic form, the author has found, is accompanied by special symptoms. The streptococcus prefer the lymphatic vessels, and excite angio-leucitis and adenitis, whilst the staphylococci set up special disturbances in the venous circulation around the centre of infection. These latter lesions are indicated on the surface of the skin by a network of dilated veins, which seems to be a paralytic phenomenon probably due to a reflex act set up by the influence of the elaborated toxins on the extremities of the nerves supplying the affected region. Cases in which two or more different forms of microbes were associated proved especially serious, and the 3 cases in which this association was found terminated in death. Some curious points were noted in this series of cases. In one of osteomyelitis of the tibia occurring on the twenty-first day of an attack of enteric fever the staphylococcus was found, and not Eberth's bacillus. In a case of osteomyelitis of the femur with arthritis following enteric fever, the streptococcus was found in association with the white staphylococcus. In 2 cases of osteomyelitis complicated with inflammation of the thyroid and vesicular parotid, the golden staphylococcus was found in both these regions.

(194) The Intraoperative Treatment of Abdominal Hydatids.

RYAN (*Australian Med. Gaz.*, No. 10, 1895) reports 4 cases of hydatid cyst of the liver successfully treated by Russell's method. Russell recommends the method of entering the adventitious sac to the external wound. He holds that there is absolutely no reason for touching the sac thus, as for all practical purposes it is only the capsule neces-

sarily formed around a foreign body' and so may be disregarded as soon as the foreign body which has excited its formation has been removed. He is also opposed to the method adopted by Bond and others of suturing the opening made in the sac, and allows the fluid secreted by its inner surface to escape into the peritoneal cavity where, as has been proved by experience, it is readily absorbed. The cases reported by Ryan are important, from their relation to the question as to what will occur in cases of hydatid cyst of the liver, should bile escape from a bile duct into the sac which has been thus treated. In three cases the patients recovered rapidly, without any bad symptoms having been presented: in one some disturbance was evident at the wound on the eighth day after the operation, and, on the removal of two stitches, there was a flow of bile. This persisted for three weeks, and then ceased. The patient was discharged as quite cured after an interval of seven weeks from the date of operation.

(492) Murphy's Button in Resection of the Bowel.

Brunner (*Wien. klin. Woch.*, October 31st and November 7th, 1895) records his experiences with the button, the value of which he does not consider to be fully appreciated in Germany. Before its introduction he had performed 17 typical resections, of which 12 recovered and 5 died, only 1 through failure of the sutures. Of 8 intestinal anastomoses, 3 died within the first two weeks after the operation; the cause of death was not insufficiency of the stitches, but exhaustion from the length of the operation. On the other hand, out of 7 gangrenous hernia in which the conclusion of the patient did not warrant resection of the intestine, and in which an artificial anus was therefore made, 6 died within a week; the other recovered but was not cured until the gut had been resected. Latterly the author has used the button in 7 operations; 6 patients recovered, 1 died, from acute peritonitis entirely unconnected with the apparatus. Three of the cases had gangrenous hernia; in these the button was passed on the sixteenth, fourteenth, and eighth day respectively. Once lateral anastomosis was effected between the ileum and the ascending colon after resection of the stenosed ileum and caecum; the button was passed on the seventh day. Once the ileum was attached to the transverse colon after removal of the ascending colon and caecum for carcinoma; button passed on eleventh day. Once the two ends of the transverse colon, resected for carcinoma, were united; the button did not come away for two months. In the remaining case, the only fatal one, the duodenum was affixed to the posterior wall of the stomach after resection of the carcinomatous pylorus. The use of the button was always supplemented by a row of Lambert's sutures. No ill result ever followed its employment except a temporary obstruction in 1 case, easily overcome by gentle massage. Brunner con-

siders that this method is superior to any other procedure for resection of the gut, and is specially indicated as a substitute for the production of an artificial anus in gangrenous hernia.

(493) Radical Cure of Hernia.

MARCY (Reprint from the *Trans. New York State Med. Assoc.*) describes his method of treating reducible inguinal hernia, the objects of which are reinforcement and reconstruction of the posterior wall of the canal. He claims priority in using buried animal sutures for the cure of hernia by a restoration of the structures to their normal anatomical standard and relationship. It is stated that reinforcement of the structures posterior to the canal is ample if the inner border of the conjoined tendon and Poupart's ligament are joined to the relaxed, but strongly developed, transversalis fascia. This operation, the author holds, may be performed with good prospects of success in children and aged subjects, as well as in adults. It is exceptionally difficult, he states, to secure the proper wearing of a truss in children, and at the best, the cure of hernia by a retention apparatus in such patients is tedious, painful, and unsatisfactory. With regard to those who are of advanced age, he states that, assuming the ruptured subject is free from organic disease, age *per se* weighs far less seriously as an adverse consideration in aseptic surgery than has hitherto been supposed. Primary repair of the tissues is almost certain to ensue with remarkably little constitutional disturbance. The author has operated upon a considerable number of patients between 70 and 80, under the most unpromising conditions, and even upon several between 80 and 85, and in each instance with seeming easy cure.—Kummer (*Rev. Méd. de la Suisse Rom.*, No. 9, 1895) publishes a table of 49 cases of different forms of hernia treated for radical cure, and in his review of this subject holds that in a large majority of instances hernia may be definitively cured by surgical treatment, and that such treatment if properly practised is attended with no risk to life. According to this author closing of the external ring is useless, and the essential conditions for an effectual attempt at radical should be complete reduction of all the prolapsed viscera, and definite closure both of the peritoneal opening and of the hernial passage.

(494) Amputation at the Hip for Tumour in Callus after Fracture.

FINOTTI (*Wien. med. Woch.*, November 30th, 1895) records what he believes to be the first case of complete and permanent recovery after amputation at the hip for malignant disease of the femur. The patient was 53 years old, and had been healthy till five years and a-half before, when he fractured his right thigh about the middle. Treatment by a circular gypsum bandage lasted eighty-seven days. For three years and a-half he had perfect use in the limb; callus was profuse, but gave

no trouble. Two years before admission the limb began to get weaker, so that he had at first to use two sticks, then two canes. For the last year and a-half a painful rapidly-growing tumour had been present at the seat of fracture. Examination showed that the patient was much emaciated: the right thigh was the seat of a hard, smooth, deep tumour extending from a hand's breadth above the patella to the trochanter, and occupying the front and outer sides of the limb. When lying on his back the patient could not lift his right leg owing to a solution of continuity of the femur at the lower part of the tumour. Disarticulation at the hip was performed by Nicolsoni, the circumstances of the case necessitating some modification of the usual operation. Some suppuration occurred, but the patient was able to leave his bed in about six weeks, and twenty-eight months later was perfectly well in himself, with no trace of recurrence either in the scar or in the internal organs. He was able to walk with a stick. The tumour was found to occupy about the middle half of the femur, to be spindle-shaped, and encapsuled. Microscopically it presented the appearance of a round-celled very vascular sarcoma, in which were numerous lamellae and splinters of bone, not newly deposited, but derived from breaking down of the femur. As Nasse has shown that in such cases the fear of recurrence vanishes after two years, the patient may be considered cured, a result largely due to the thickness and integrity of the tumour capsule.

MIDWIFERY AND DISEASES OF WOMEN.

(495) Placenta Praevia.

DEMELIN (*Archives de Tocol. et de Gynéc.*, November, 1895) divides hæmorrhage from faulty attachment of the placenta into three varieties. In the first labour has not begun. Here, if the flooding has been slight and has ceased, a skilled nurse should be constantly at hand ready with the tampon. When no assistance of this kind is available, the uterus should at once be emptied if the patient be strong with a good pulse. If she be weak from the hæmorrhage, and therefore unable to bear so active a measure, the tampon should be introduced, and maintained till the patient is stronger. In about six or eight hours, as a rule, forcible delivery will be safe to perform. In the second class of cases labour has set in, but the cervix is but incompletely dilated. Then in lateral or marginal insertion of the placenta the membranes should simply be well opened if the vertex present, and be well engaged. This manœuvre is dangerous if the pelvis be contracted. In breech presentation, well engaged, one foot must be drawn down through the rent in the membranes. In any other presentation, or when the vertex or breech is prevented from coming well down, the dilating bag should be employed after rupture of the mem-

branes, as the presenting part cannot in such a case press strongly enough on the bleeding surface. The tampon may also be needed. In complete placenta prævia, when the cervix is not fully dilated, the placenta should be perforated and the cervix dilated with the bags, the fetus being rapidly delivered if the patient be still strong. When she is weak, the pulse falling, the tampon must be applied till she has regained strength. If suddenly the child and the tampon are delivered together, so much the better. There remains the third class of cases. Here labour has set in, and the cervix is completely dilated. To turn and deliver at once, or to deliver with the forceps if the head be well engaged, is the right course unless the patient be very weak from hæmorrhage. In such a case as before dilatation or labour the tampon should be used. The head must be lowered, the extremities bandaged, warmth applied, etc. Rapid delivery must be effected, under ether, directly the patient has regained sufficient strength.

(430) Puerperal Fever.

RABIN (*Revue Médicale de la Suisse Romande*, October 20th, 1895) denies that there is such a thing as puerperal fever without local lesions. Practically the disease begins as septic endometritis. The acute so-called "unlocalised" form is always rapidly fatal, so that no clear naked-eye changes can be detected in the infected endometrium. In a few slower cases definite pyæmic changes are observed; the disease is then rather acute septicæmia or pyæmia than fever. The chronic "unlocalised" form of puerperal fever is much milder; most cases of recovery belong to this type. The endometrium is always inflamed and septic, but the inflammatory process is locally mild, passing off before general symptoms are observed. The fever is due to intoxication, not infection. Toxins develop in the inflamed mucosa and pass into the blood. Microbes, Rabin insists, may enter the blood, but they are destroyed by phagocytosis or by the bactericidal action of the blood, in this form of fever. Thus chronic puerperal fever, "without localisation," is really chronic septic puerperal endometritis, the general rapidly replacing the local symptoms. The importance of the early use of the curette becomes evident.

(431) Delirium after Gynecological Operations.

Dist. Dr. N. Vassiliou (*Archives d'Obstet. et de Gynec.*, October 25th, 1895) has prepared an instructive memoir on the appearance of acute more or less maniacal delirium after "minor" gynecological operations and plastic surgical proceedings. In one case no operation was performed, but the patient worried continually about surgical relief, till a maniacal attack came on. Two fatal cases occurred in Doléris's experience. In both the patient was vicious, plethoric, alcoholic, and syphilitic. One was very rich and luxurious; she took great

quantities of ether. After an operation from the uterine side for the cure of suppurating tubes, violent delirium set in with icterus and no fever. Death occurred on the sixth day; complete asepsis was proved at the necropsy. The second patient was servant at a beer-shop. Very large sclerosed ovaries were removed. Fatal delirium ensued; neither vomiting nor fever were observed. In six instances the patient recovered. The curette and dilator, etc., were used in one for diseased appendages, after Doléris's principles. There was delirium for a few days. The same phenomenon was seen in a patient on whom he operated for prolapse and cystic cervicitis, and on a third also treated for these affections; this case was alcoholic. In a case of puerperia, the patient being 52 years old, symptoms of melancholia had been seen before a plastic operation for puerperia. Afterwards she was troubled for a time with acute delirium and ideas of persecution, etc. A nervous young Syrian woman had fits of violent fear after an operation on the cervix. Lastly, a stout phlegmatic woman had acute delirium and insomnia after an operation for prolapse. No other neuroses of the kind have been noted by Doléris in the course of about 2,000 similar operations.

THERAPEUTICS.

(432) Treatment of Alopecia Areata.

Brocq (*Jour. Cut. et Gen. Urin. Diseases*, September) describes the treatment of alopecia areata used by Sabouraud. He begins by applying upon the diseased patch a layer of vesicating fluid, and the following day, after having removed the blister, he applies upon the denuded corium a 15 per cent. solution of nitrate of silver, with or without previous cocaine anaesthesia. If necessary, he renews these applications after 10 or 15 days. He thinks he can thus arrest the evolution of an alopecia at its onset, and that the results obtained are much better than those of other procedures. Brocq himself has for some time experimented on an extensive scale with Gautier at his polyclinic of La Rochefoucauld, with cupric electrolysis. After numerous trials they have come to the conclusion that the method does not give appreciable results which permit of its being advocated. The passage of the current and the decomposition of the tissue are painful; there remain small wounds which leave deep cicatrices, depressed at the points where the needles have been applied. The hairs do not seem to grow in any noteworthy manner about the points of operation, and the progress of the disease has not been arrested in a sufficient number of cases for one to conclude as to the real efficacy of this treatment. They intend to try electricity in another form—Leistikow (*Monatsh. f. prakt. Derm.*, Lii. xviii) for the last four years has successfully treated alopecia areata almost exclusively with chrysarobin. Formerly he employed it in the form of an oint-

ment of 5 to 10 per cent. Now he uses it in "sticks" as follows: B Chrysarobin, 30 g.; colophony resin, 5 g.; yellow wax, 35 g.; olive oil, 30 g. This is rubbed like cosmetic on the scalp, care being taken as far as possible not to touch the hair. The head is then covered with a skull-cap, and the next morning the chrysarobin is removed with olive oil. After some days irritation of the scalp comes on, manifested generally by a characteristic redness due to the chrysarobin, very seldom by bullæ and pustules. When this occurs the frictions with chrysarobin are replaced by applications of oxide of zinc ointment, which is also in due course removed with olive oil. As soon as the irritation has subsided chrysarobin is again used. The result is satisfactory in proportion to the regularity and perseverance with which the treatment is carried out. This treatment has been very successful in Leistikow's hands in 23 cases. Some cases have been cured in four weeks, but often the treatment has to be continued for several months.

(433) Serum Treatment of Cancer.

At a recent meeting of the Académie des Sciences (*Arch. gén. de Méd.*, December), Richet and Héricourt presented a further report on the treatment of cancer by serum. Since their first communication on the subject (see ERRORS, June 1st, 1895, par. 435) they had been able to study the effects of the treatment in a much larger number of cases. Their own observations, together with those communicated to them by Bédou, Pinard, Terrier, Faure, Hallopeau, Tuffier, and others, amounting altogether to about 50 cases, led them to the following conclusions: (1) A very marked diminution of pain follows the injections; this effect had not been expected. (2) Cancerous ulcers become clean and assume the aspect of granulating sores, and may even heal over a fairly large extent of surface. (3) Marked shrinking takes place not only in the neighbouring tissues and related glands, but in the growth itself. In some cases the development of the disease is checked and the general condition is distinctly improved. To sum up: In four-fifths of the cases a real improvement is beyond question but a complete cure is not brought about. After a month or two new cancerous foci appear, and the disease goes on and ends in death. Is the serum specific or not? The authors find it difficult to give a definite answer to this question. The results seen in two cases, however, make them incline to the belief that the serum of immunised animals is much more active than that of healthy ones. In two cases also the serum seemed to have some effect in preventing recurrence, and they suggest to surgeons a trial of a combination of this treatment with the usual operative measures.

(434) External Use of Guaiacol.

LARRA Y CUBERO (*Rev. de Méd. y Cir. Pract.*, October 25th) has used external applications of guaiacol in a variety of conditions, including some of high tem-

perature (typhoid fever, "fever of growth"). The effect has been to reduce the temperature by two to three degrees Centigrade within half an hour or so. In one case (typhoid) the rapid reduction of temperature was followed by alarming symptoms of collapse. In this case 1½ grammes of the medicament had been painted on the skin of the popliteal space and the front of the knee. The experience of Larra y Cerezo has led him to the following conclusions: Guaiacol suspended in tincture of iodine may be applied externally to the thorax as a revulsive in chronic broncho-pneumonia, and as a means of promoting the absorption of pleuritic effusions; for this purpose he uses it in the proportion of 3 grammes to 20 grammes of tincture of iodine and the same quantity of glycerine, this being painted on every day. In anasarca from anuria due to scarlatinal nephritis the same mixture may be painted on the lumbar region. As a local anæsthetic guaiacol is less dangerous than cocaine; for this purpose it should be used dissolved in water in the proportion of 20 per cent., or suspended in sterilised olive oil (1 in 10, or 1 in 20); 5 to 10 centigrammes of either of these preparations may be injected under the skin or mucous membrane, the anæsthetic effect being produced in eight to ten minutes. Applied as an embrocation (1½ to 2 grammes of pure guaiacol) to the skin the drug is a useful antipyretic in tuberculosis, typhoid fever, etc. Collapse must, however, be guarded against, and the method is contraindicated in cases of cardiac weakness and in certain cases of idiosyncrasy.

(594) Pilocarpin in Influenzal Pneumonia.

POULET of Flancher-les-Mines (*Nouveau Remède*, November 24th) has used hydrochlorate of pilocarpin in influenzal pneumonia with very good results. During an epidemic which prevailed in that neighbourhood in February, 1895, and which attacked more than 1,000 out of a population of from 3,000 to 4,000, he treated 108 cases in which pneumonia and broncho-pneumonia were formidable complications with pilocarpin, with only 4 deaths. He gave the drug in daily doses of 5 centigrammes, except in the case of children, to whom a proportionally smaller amount was given. The treatment generally lasted two days, only in a few cases three days. The treatment was successful in several cases of old people over 70 years of age. It is to be noted that pilocarpin was by no means equally effective in pneumonia complicating whooping cough in children.

(595) Oxycyanide of Mercury as an Antiseptic.

O. MONOD AND MAGAIGNE (*Progrès Méd.*, October 28th) state that oxycyanide of mercury in 5 per 1,000 solution displays in laboratory experiments an antiseptic potency always equal to, and often greater than, that of 1 in 1,000 sublimate solution. It has no disadvantages other than those possessed by

corrosive sublimate, and it has the special advantage of not affecting either the hands or the instruments of the surgeon. It may therefore replace sublimate in surgical practice. This conclusion is based on an experience of the use of the oxycyanide in hospital and in private practice of more than four years, and on laboratory experiments in which the power of the oxycyanide to prevent the growth of cultures, to kill a developed culture, and to sterilise contaminated substances has been tested and compared with that of sublimate. The experiments were made not on pure cultures of streptococci and staphylococci destitute of spores, but on dust from hospital wards containing bacillus pyocyaneus, bacterium coli, streptococci, and especially a bacillus resembling that of anthrax, with spores which resist a temperature of 100° C. No serious toxic effect was ever observed. The authors, however, recommend that the oxycyanide should not be used for washing out cavities, especially where there is a danger of any of the fluid being left behind. Monod and Magaigne mention that oxycyanide of mercury was first recommended as an antiseptic by Chibret.

PATHOLOGY.

(596) Congenital Cystic Kidney.

MUTACH (*Virchow's Archiv*, October, 1895) discusses the causation of congenital cystic kidney; basing his views on two cases studied by a consecutive series of microscopic sections. The retention theory is the one most generally accepted, but the cause of the obstruction, which is generally localised to the papilla of the pyramids, is in dispute. While Virchow holds the atresia of the tubules to be due to interstitial inflammation, others hold that it is due to congenital malformation; the frequent association of congenital defects in other parts of the body supporting the latter view. In one of the cases under consideration, there was atresia of the ureters with dilated ureter and pelvis, and cystic kidney on both sides; in the other there was atresia of both ureters with cystic kidneys. The cysts were found to be dilatations of the capsules of the glomeruli just beneath the capsule of the kidney. The epithelium of the tubules was very slightly altered; there was marked increase of interstitial connective tissue, but it was particularly observed that this was not of the closely packed inflammatory type, but of the loose embryonic type; moreover the tubules were pervious throughout their course, from the glomeruli to the pelvis. In the development of the kidney the glomeruli appear first just under the capsule, being covered in turn by another row which appears superficial to them: so that the deeper layers of glomeruli are fully formed, while the superficial ones are still imperfectly developed. It is obvious that no urinary pressure can arise until some of the glomeruli are completed, and so secretion established; thus the deeper

glomeruli will at no time be subject to backward pressure till they are fully developed, whereas the superficial ones will be exposed to such pressure while they are still in process of development. It is suggested that although the obstructive conditions giving rise to hydronephrosis never cause dilatation of the tubules in the fully developed kidney, they may do so in the still developing kidney.

(597) Cultivation of the Diphtheria Bacillus.

TOCHTERMANN, of Unverricht's clinic (*Centralbl. f. allg. Med.*, October 5th, 1895) describes a new serum cultivation medium, and discusses the importance of the early diagnosis of diphtheria. Blood serum is looked upon as the most favourable medium for this bacillus. In Löffler's serum the streptococcus which grows well on agar does not thrive; other cocci, however, flourish, and the naked-eye appearance of the colonies is but slightly distinctive. Hueppe's method with agar and serum constituted an advance, but the difficulties of sterilising the serum remained; for this reason agar often takes the place of serum, but the colonies take longer to develop on it, and do not exceed a certain limit. It is possible that other constituents of the serum, apart from the albumen, may be responsible for its value in this relation. With this view the author has heated serum along with agar, and filtered off the precipitate. He has tested the value of the nutrient medium thus prepared. After making various comparative experiments, he recommends the following method. A 2 per cent. watery solution of agar is treated in the usual way with peptone (1 per cent.), common salt (½ per cent.), and then 0.3 to 0.5 per cent. of grape sugar is added, and the whole filtered. The filtrate is heated from a quarter to half an hour with serum from sheep's blood in equal parts, or 3 of serum to 2 of the agar solution. The filtrate is then put into tubes and sterilised in the usual way. The blood itself need not be previously sterilised, and the serum can be poured off after twenty-four hours' standing. As much agar as possible must be got into solution, and this is effected by prolonged soaking and warming. The ordinary sterilisation is practised without any ill-effect to this nutrient medium, and even a stay of one hour to an hour and a half on successive days in the steam steriliser does not impair its value. It is well, however, in preparing the agar, not to let it filter in the steam steriliser for hours together. The suspended material is well distributed over the surface with the platinum needle. Round colonies, white in colour with a darkened centre, and presenting a granular aspect, appear in twenty-four, often in twelve, and sometimes in eight hours if the diphtheria bacillus is present. It remains to be seen whether other micro-organisms partial to serum media will grow equally well on the above-described A.
